Treatment.—In a mild sprain apply at once a silicate or plaster of Paris dressing. The first indication after the infliction of a severe sprain is to arrest hemorrhage and limit inflammation. For the first few hours apply pressure and an ice-bag. Wrap the joint in absorbent cotton wet with iced water, apply a wet gauze bandage, and put on an ice-bag. After some hours place the extremity upon a splint and to the joint apply flannel kept wet with lead-water and laudanum, iced water, tincture of arnica, alcohol and water, or a solution of chlorid of ammonium. These evaporating lotions produce cold. Instead of them, an ice-bag may be used for a day or two. Leeches around the joint do good. Constitutionally, employ the remedies for inflammation. Morphin or Dover's powder is given for the pain. Judicious bandaging limits the swelling.

After a day or two, if the symptoms continue or if they grow worse, use hot fomentations, the hot water bag, plunge the extremity frequently in very hot water, or apply heat by Lister's tubes. When the acute symptoms begin to subside, rub stimulating liniments upon the joint once or twice a day and employ firm compression by means of a bandage of flannel or rubber. Frictions should be made from the periphery toward the body. Many cases do well at this stage under the local use of ichthylol and lanolin (50 per cent.), tincture of iodine, or blue ointment. Later in the case use hot and cold douches, massage, frictions, passive motion, and the bandage. Passive motion is begun a day or so after swelling ceases. If massage causes the swelling to return, abandon it for several days and then try it again. Blisters are used when tender spots persist and stiffness is manifest. If stiffness becomes marked, move the joint forcibly. Give iodid of potassium and tonics internally, and insist on open air exercise. If the person is gouty or rheumatic, use appropriate remedies. Van Arsdale treats sprains by massage almost from the start. Gibney treats them by strapping with adhesive plaster. Gibney's dressing is

of great service in a sprain of the ankle (Fig. 344). Many sprains may be put up in an immovable dressing the first day or two after the accident. If the joint contains much blood, aspiration should be practised before the dressing is applied.

The hot-air oven is a very valuable method for treating recent sprains, and the swelling, pain, and stiffness which follow sprains, of the extremities. The sprained extremity is placed in an oven, and the part is subjected to heat for an hour. The next day the treatment is repeated, and on as many subsequent days as may be necessary. In an acute sprain the pain often disappears during the first application of heat. In the intervals between the use of the oven the extremity should be at rest upon a splint.

Sprain of the Sacro-iliac Articulation.—A fall, lifting a heavy weight, a blow, or a twist may injure this articulation. Normally there is slight motion, rupture or stretching of ligaments may lead to increased motion and any considerable range of motion at the synchondrosis means lack of solidity and want of support. A sprain of this articulation may be caused by parturition, and also, as shown by Dunlop, it may develop during anesthesia because of obliteration of the normal lumbar curve by lying on a flat table without a support under the lumbar region ("N. Y. Med. Jour.," July 10, 1909). Dunlop thus explains, and I think truly, the severe backache which is so common after anesthesia.

A sprain causes severe pain, greatly aggravated by standing, by rising up from recumbency, by movements of the ilia which jar the joint, and often by direct pressure upon the synchondrosis. There is often lateral spinal curvature due to spasm, and the concavity is toward the injured side.

There is pain in the injured articulation, but there may be a general backache, and, just as in sacro-iliac tuberculosis (page 632), there may be pain in the sciatic nerve, in the groin, and in the hip-joint.

When the ligaments become distinctly relaxed we get the chronic condition described by John Dunlop ("N. Y. Med. Jour.," July 10, 1909) and which he calls *sacro-iliac relaxation*. When this exists the individual may injure the articulation again and again because of its unsteadiness, he may now and then have trouble, he may be in a constant condition of helplessness, with backache, groinache, pain in the hip and over the ischial tuberosity, lumbar rigidity producing lateral curvature, etc. I believe with Dunlop in the reality of the condition.

Treatment. A recent sprain is treated by rest in bed and adhesive plaster strapping, reinforced by a canvas roller around the pelvis. In a chronic case (sacro-iliac relaxation), insist on rest and apply a spica bandage of plaster of Paris.

Rupture of the Crucial Ligaments of the Knee.—This is a rare injury. Rupture of both ligaments is very unusual except in very grave injury, such as complete dislocation, and then other ligaments are also torn or destroyed.

The anterior crucial ligament instead of rupturing from force may cause avulsion of the tibial spine (page 618). When this portion of bone is not torn off, the ligament itself tears off from the femur rather than from the tibia. The posterior ligament, too, tends to tear off from femur rather than tibia. Pagenstecher ("Deutsch. Med. Wochenschrift," Bd. xxix) believes that the

anterior ligament may be ruptured by forced flexion of the knee and by blows applied to the posterior part of the head of the tibia when the knee is flexed. The same surgeon maintains that the anterior ligament may be ruptured by blows applied to the front of the head of the tibia when the knee is flexed. Pringle ("Annals of Surgery," August, 1907) maintains that the anterior ligament may be ruptured by "flexion, abduction, and internal rotation of the leg at the knee." If the ligaments are ruptured there will probably be abnormal freedom of anteroposterior movement between the femur and tibia.

Pringle ("Annals of Surg.," 1907) states that if, after an injury, the knee joint becomes distended with blood, the inference should be that one or other crucial ligament has been injured or that the tibial spine has been torn off, unless some other lesion is obviously present; that if internal rotation of the extended leg is possible at the knee, or if the head of the tibia can be brought forward on the femur, or if there is unnatural abduction, the indications are that the anterior crucial ligament has been injured or the tibial spine torn off; that injury of the posterior crucial is suggested by the possibility of pushing the head of the tibia backward during flexion of the knee-joint.

In most cases exploratory incision is required to make the diagnosis.

The treatment is to open the joint and suture the torn ligament.

Ankylosis. When a joint-inflammation eventuates in the formation of new tissue in and about the joint, contraction of this tissue limits or destroys joint-mobility, producing the condition known as "ankylosis." Ankylosis may be complete (bony) or incomplete (fibrous); it may arise from contractures in the joint (*true or intra articular ankylosis*) or from contractures in the structures external to the joint (*false or extra articular ankylosis*).

There are qualifying terms to indicate the extent of stiffness—viz., false, serious true, bony, ligamentous, partial, complete, or incomplete ankylosis. The significance of the above terms will be better appreciated if ankylosis is considered as meaning a stiff joint. It may be stiff without being rigid. Fibrous adhesions produce stiff joints and they become rigid only when bony union takes place between the bones forming a joint.

Spondylitis deformans is bony ankylosis of vertebræ.

Arthritis ossificans is a progressive bony ankylosis in which numerous joints are involved and are finally completely obliterated. It is an ossifying arthritis.

Etiology.—There are various causes—viz., traumatism and eruptive fevers resulting in acute or suppurative synovitis or arthritis, gonorrheal arthritis, tuberculous arthritis, syphilitic affections of joints, bony fixation when a fracture is near or extends into a joint, and osteitis deformans.

Pathology.—In complete—i. e. bony—ankylosis the bones forming a joint become united by callus in much the same manner as bone fragments are united after a fracture, or osseous bridging takes place at one or more places around the joint. Osseous ankylosis is preceded by a more or less prolonged stage of fibrous or partial ankylosis. In fibrous ankylosis, bands of fibrous connective tissue unite the bones forming a joint, thereby limiting the motion. In cases of joint stiffness produced by extra-articular fibrous, tendinous, or contractile contracture, the joint proper remains free from adhesions for years, provided it is not and has not been involved in inflammatory action.

Diagnosis of bony ankylosis is usually made without difficulty except where

there are several joints near together, as the carpus, tarsus, and the spine. When there are several joints near together the limitation of motion in one joint is generally compensated for by the excess in mobility of another, thereby rendering the associated parts capable of closely approaching normal function. Fibrous ankylosis is more difficult to recognize, especially if pain accompanies manipulative measures. It is most apt to be confused with fibrous, ligamentous, or cicatricial contractures of soft parts outside of a joint, but having more or less direct functional relations therewith.

Extra-articular thickening may usually be detected by the existence of resistance to free joint motion in one direction only, *i. e.*, that produced by the fibrous contracture while the joint moves freely in other directions. Muscular contracture, whether voluntary or involuntary, is but temporary, and is easily detected by the preternatural rigidity of surrounding parts. In bony ankylosis no voluntary muscular action can be detected, inasmuch as in the process of the formation of the callus uniting the bones the muscles have become atrophied from disuse. Conversely, voluntary muscle action about a joint always indicates that joint mobility is not entirely destroyed.

As muscular rigidity is one of the most important and reliable symptoms of joint inflammation and tuberculous invasion, it is a serious error to anesthetize a patient for examination of a joint until the full significance of the muscular action has been carefully studied.

Anesthesia removes the pain and abolishes muscle fixation and thus leaves the unguarded joint free for manipulative movements, which are generally prejudicial and rarely beneficial. Where no muscle fixation is present, much may be learned by the careful study of a joint while the patient is anesthetized. We thus determine the character of the adhesions, whether they are extra-articular or interarticular, whether they are fibrous, cicatricial or osseous, and if bony union exists, whether it involves the entire joint or only a portion of it.

Skiagraphs are invaluable helps in making an accurate diagnosis, especially when stereoscopic plates are made. Definite information can thus be obtained as to the character of the uniting material, its extent, and definite location. Positive information will be given as to the relationship of the bones composing the joint, whether there is luxation, subluxation, flexion, or other abnormal position that may influence decision as to the therapeutic measures to be adopted. It is important to remember that a joint very rarely becomes ankylosed in the position of extension. The almost invariable rule is that flexion is the posture of such joints, and the tendency is toward increase of the flexion until bony ankylosis occurs. In the steady progress of the flexion, subluxation is apt to be induced.

Treatment of Intra-articular Ankylosis. It is most important to prevent the occurrence of ankylosis, or in the event of its becoming inevitable, to avoid postures that will render the parts unfit for future usefulness when ankylosed.

The most useful position for a stiff joint is a matter of individual opinion; no definite rules have been accepted. In ankylosis of the elbow, the flexed position is more useful in certain occupations than the fully extended arm. In other occupations the extended arm is most useful. In walking when the knee is ankylosed and does not tend toward flexion the extended leg is more useful than the flexed leg, but it is more difficult to manage when sitting.

The hip, when ankylosed at various angles, is made useful by the increased latitude of motion of the other hip and by the compensatory motion of the lumbar spine. To such an extent is the lower spine reciprocal when one or both hips are abnormal that it has been termed the third hip-joint. For general usefulness the best position for an ankylosed hip is 20 degrees of flexion, 20 degrees of abduction, and 5 degrees of external rotation. In this position, when supplemented by reciprocal action of the other hip and by the lower spine, a very closely approaching normal carriage has been obtained in walking, and the sitting posture has been possible.

Each individual joint has its own peculiar requirement and must become a subject for careful study in determining the most useful posture if ankylosis is to be permanent. The trend of modern surgery is to greatly reduce the time of fixation of a fractured bone in order to avoid joint stiffness and prevent muscular wasting. Early passive motion when judiciously employed does not interfere with the efficient treatment of a fracture, but does prevent the joint stiffness that is often a serious and painful sequel.

Brisement forcé is a term applied to the use of such manipulative force as the surgeon can judiciously employ in freeing a joint from fibrous adhesions. It is important to keep constantly in mind the danger of breaking the shaft of a bone or of separating the epiphysis when unguarded leverage of the entire shaft of the bone is used. It is of paramount importance to avoid *brisement forcé* in all cases where the ankylosis has resulted from tuberculosis.

In applying manipulative force it is not always advantageous to have the patient profoundly anesthetized. If he is profoundly anesthetized we may be tempted to apply too great force. Great lacerations of fibrous adhesions produce painful joints which necessitates fixation or rest for several days to permit the reunion of the torn structures. A little gain, care being taken to maintain the motion gained, mobility being gradually increased by short progressive steps, is always better than attempts to do a great deal at once. Of course the patient's cooperation is necessary.

When pain is great, much can be accomplished during primary ether anesthesia or while the patient is under the influence of nitrous oxid. Bromid of ethyl and chlorid of ethyl are used by many because of their rapid action and brief effect. As stated elsewhere (page 1205), I seldom use either of these drugs.

Fixation appliances of any kind are contra-indicated during corrective manipulations, as increased freedom of motion is essential rather than fixation. Voluntary efforts are needed to maintain the joint's motion already secured as well as to increase the muscle function controlling the affected joint.

The operative procedures applicable to intra-articular ankylosis are excision to obtain a false joint (pseudo arthrosis), excision to obtain a better position for the usefulness of the limb, breaking the bone after partially cutting it with an osteotome (osteotomy), and breaking the bone without any excision (osteoclasis). These several procedures have special advantages in different joints.

Leaver ("Zeit. f. Chir. Med. Orth.," Oct., 1908, p. 479), after resecting a knee joint ankylosed at a right angle, transplanted the entire knee-joint apparatus from a freshly amputated limb. Complete union resulted. Muscle training was subsequently practised to improve the weak muscular control.

Wegrowski ("Zeit. f. Chir.," April 27, 1907) resorted to cartilage transplantation in a case of ankylosis of the elbow. After freeing and re-forming the

ends of the three bones, two plates of cartilage (one-half thickness of rib cartilage) with perichondrium were taken from the sixth and seventh ribs and placed between the newly formed joint surfaces, the perichondrial surface being turned toward the humeral epiphysis. No special fixation was used. No drainage was employed. Active and passive motion was begun on the tenth day. In a month the patient had 60 degrees of free flexion and extension and full pronation and supination. Death from pleuropneumonia of three days' duration occurred in five weeks. Postmortem showed that the perichondrial surface of the cartilage was united to the humerus, while the opposite side was smooth, even shining, the cartilage was enlarging and passed without definite margin into the surface of the humerus.

Microscopic examination showed newly formed blood-vessels between the cartilage and bone; the cartilage was well preserved in its entire extent, the cells and nuclei staining well.

Hugier and Murphy advocate a novel plan ("Traitement des Ankyloses par la Résection Orthopédique et L'interposition Musculaire," par Le Dr. Alphonse Hugier).

J. B. Murphy ("Journal American Medical Association," May 20 27 June 3, 1905) reviews the literature of the attempt to produce new joints and says: "In our work we have been able, by the interposition of fascia and muscle, covered with a layer of adipose tissue, to produce normal movable joints with capsules and collagen intra-articular fluid." In cases of synovitis with adhesions he resects the capsule and replaces it by aponeurosis or muscle and it is desirable, when possible, that the replacing piece contains fat, which under pressure, will form a hygroma or artificial synovial cavity. In long ankylosis he operates, separates the bones, removes adjacent bony prominences or processes, frees the soft parts, prevents the bones coming again in contact, and interposes between them tissue which will remain fibrous or will form a hygroma or artificial synovial surface. After wound healing has taken place, passive motion, active motion, and forcible extension are required.

W. S. Baer ("Am. Jour. Orth. Surg.," 1907, p. 234) advocates the use of sterilized olive oil injected into joints to prevent the formation of adhesions and thus increase the arc of motion. It may also be poured into a joint after arthrotomy. After using oil in the manner described, Baer summarizes as follows: "That injection of oil into joints under proper precautions is a harmless procedure, that the joint will apparently tolerate as much as it will hold.

"It is most useful in cases where adhesions have followed some acute infectious process, or in those stiff joints which are classified as arthritis deformans of the infectious type.

"Passive motions are made with less pain where the joint contains oil.

"It plays some part in preventing adhesions, so that the mobility of the joint is increased more rapidly."

In ankylosis of the temporomaxillary joint it was once the custom to wedge the jaws apart with a mouth-gag and afterward insert boxwood plugs of advancing size at frequent intervals. This method invariably fails. Esmarch's operation (removal of a wedge-shaped piece of bone from the ramus) is sometimes useful. Some operators excise the condyle and a portion of the neck. Swain saws the bone at an angle.

W. S. Baer ("American Jour. Orthopedic Surg.," August, 1909) reviews

the literature of the operative treatment to mobilize joints, and advocates the use of chromicized pig's bladder as the most satisfactory material to place between the surfaces of excised joints.

He refers to Hellerreich, who, in 1893, mobilized the temporomaxillary joint by the insertion of a flap from the temporal muscle. This was repeated by Lentz, Henle, and others. Mikulicz, in 1895, used a flap from the masseter muscle. Similar procedures were employed by Bilezgwski, Hoffa, and Kusnetzow. Rochet and Schnudt with Gluck, in 1902, used a skin flap and had previously employed ivory joints to take the place of the excised structures. Chlumsky, disappointed with the results of muscle flaps, used non-absorbable materials, zinc, rubber, celluloid, silver, and layers of collodion, but no permanent mobility was obtained. He then employed absorbable plates of deracified bone, ivory, and magnesium, with somewhat better results. Baer's method of inserting chromicized pig's bladder followed the unsuccessful employment by him of Cargile membrane. The pig's bladder is tightly stitched around the recently denuded bone with catgut sutures and the wound closed. A hip-joint two months after this procedure showed a voluntary flexion of 35 degrees; abduction, 15 degrees; adduction, 10 degrees; rotation, 25 degrees. Seven months after operation the mobility was better than that recorded at two months. Similar results are recorded in knee and elbow.

Baer emphasizes the necessity of having the pig's bladder absorbable in thirty to forty days. It should be pliable enough to be adapted to the contour of the joint. Every raw surface should be absolutely separated by it from that with which it would tend to come in contact.

Treatment of Extra-articular Ankylosis.—The treatment of false ankylosis depends upon the case. Recently contracted muscles or tendons require motion, massage, frictions with stimulating liniments, hot and cold douches, and the use of the hot air apparatus. Violent breaking up is not satisfactory, neither is tenotomy nor myotomy. Old contractions of tendons require tendon lengthening by tendoplasty or myoplasty. Chronic inflammation of tendon-sheaths with adhesion of tendons requires excision of the sheaths. Whenever possible, excise a cicatrix that causes false ankylosis, and fill the gap with subcutaneous tissue and fat. When the fixation is due to adhesive synovitis of the capsule, excise the capsule and attached ligaments; "the head and neck of the bone should then be surrounded by an aponeurosis or muscle to prevent the reforming of adhesions" (John B. Murphy, in "Jour. Am. Med. Assoc.," May 20-27 and June 3, 1905). Bony deposits are gouged away and tumors are removed. Contractures in cases of paralysis require electricity, passive motion, frictions with stimulating liniments, the hot air bath, and general treatment.

Loose Bodies in Joints (Floating Cartilages). The knee is the joint affected in 90 per cent. of cases, but the elbow, shoulder, hip, wrist, lower jaw, and ankle may suffer. There may be but one loose body in a joint, there may be two or more, there may be many or even hundreds. More than one joint may be involved. The condition is commonest in adult men. These bodies may be free or each may have a stalk or pedicle; they may move about and occasionally block the joint, or may lie quietly in a joint-recess or diverticulum. They may be flat or ovoid, smooth or irregular, as small as peas or as large as plums, and may be composed of fibrous tissue, of cartilage, or of bone. There are numerous different modes of origin of

these bodies, many being "detached ecchondroses or pieces of hyaline cartilage hanging by narrow pedicles" (J. Bland-Sutton), and they result from enlargement and chondrification of the villi of the synovial membrane.

Symptoms.—Many bodies give rise to no symptoms for a long time and others merely cause synovitis. A loose body may produce pain and interfere with joint-function. The joint is weak and a little swollen, and the patient can perhaps feel the body and often can push it into a superficial area of the joint, where it may be felt by the surgeon. From time to time the body may get caught, thus suddenly locking the joint and producing intense and sickening pain, extension and flexion being impossible until the body slips out. It may slip out in a moment, but may not for hours or even for many days. A rather small body seems more apt to cause locking than a very large one, but if a large one does cause locking, it is more difficult to dislodge than is a small one. Locking of a joint by a loose body is followed by inflammation and effusion. If the loose body is dense or long, the x-ray may disclose it. In some cases of loose body in the knee the diagnosis is impossible from dislocation of a semilunar cartilage, inflamed semilunar, and synovitis with proliferation of villi.

Treatment.—To relieve locking, employ forced flexion and sudden extension. Cure can be obtained only by operation. Let the patient bring the foreign body to a point where it can be felt by the surgeon, so that he can determine where it lodges. Asepticize the knee with the utmost care. Operate if possible under cocaine; if not, give ether. If the body is felt before operating, fix it with a pin. The joint is now opened, the foreign body extracted, and an exploration made to see that no other bodies are present. The wound is sutured and the leg is placed upon a splint. Asepsis must be most rigid. The operation does not cure the causative lesion, and these bodies are apt to form again. When the knee is involved, some surgeons saw the patella transversely, open the joint widely, remove all foreign bodies, and seek to cure any causative lesion.

LUXATIONS OR DISLOCATIONS.

A dislocation is the persistent separation from each other, partially or completely, of two articular surfaces. A self-reduced dislocation is called a sprain (Douglas Graham). There are three forms of dislocations: (1) traumatic; (2) spontaneous or pathological; (3) congenital.

1. Traumatic dislocations are due to injury. They are divided into—*complete* dislocation, in which the two articular surfaces are entirely separated and the ligaments are torn; *incomplete* or *partial* dislocation or *subluxation*, in which the two articular surfaces are not completely separated and the ligaments are rarely lacerated; *simple* dislocations, in which there is no wound leading from the surface to the articulation; *compound* dislocation, in which a wound leads from the surface to the joint; *complicated* dislocation, in which, besides the dislocation, there is a fracture, extensive damage of the soft parts, an opening which makes the case compound, or damage of a nerve or blood-vessel; *primitive* or *primary* dislocation, in which the bones remain as originally displaced; *secondary* dislocation, in which the dislocated bone assumes a new position; for instance, a subglenoid luxation of the humerus is primary, and it may become secondarily a subcoracoid luxation because of muscular contraction or attempts at reduction; *recent* dislocation, in which

the displaced bone is not firmly fastened by tissue-changes in its new situation, and its old socket is not obliterated; *old* dislocation, in which the displaced bone is firmly fastened by tissue-changes in its new habitat, and the old socket is to a great extent obliterated (whether a dislocation is old or new depends on the state of the parts rather than on the time which has elapsed since the accident); *double* dislocation, in which corresponding bones on each side are dislocated; *single* dislocation, in which only one joint is dislocated; *unilateral* dislocation, in which one articulation of one bone is out of place; *bilateral* dislocation, in which symmetrical articulations are dislocated; and *relapsing or habitual* dislocation, which recurs constantly from slight force because of relaxed ligaments or lack of complete repair after the ligamentous rupture of a first dislocation.

2. Spontaneous, Pathological, or Consecutive Dislocations.—

Spontaneous dislocation arises from such very slight force that the cause may not be identified, and it acts on a joint rendered lax by disease. It may arise in the course of chronic synovitis, tuberculous joint-disease, or rheumatoid arthritis. In Charcot's joint a spontaneous dislocation will occur sooner or later. In typhoid fever spontaneous dislocation is not uncommon. The hip-joint is most often the one attacked. *Dislocation in typhoid fever* generally occurs at the hip-joint, follows a severe joint inflammation, is usually upon the dorsum of the ilium, and is frequently not noticed until convalescence has set in. If a typhoid dislocation is seen early, reduction is easily effected, but if seen late, is impossible. The treatment for irreducible typhoid dislocation is the same as for any other irreducible dislocation.

3. Congenital Dislocation.—A congenital dislocation is due to a congenital joint-malformation which renders it impossible for the bone to maintain a normal position, or is due to external violence during the period of uterine gestation. Congenital dislocations should not be confounded with dislocations produced during delivery. The hip is the joint most often involved. The shoulder suffers occasionally. Lannelongue maintains that congenital dislocation of the hip is due to atrophy of the muscles and of the acetabulum following spinal-cord disease. Verneuil thinks the dislocation is partial. Broca says that in view of the fact that the head of the bone is larger than the cavity in which it belongs, it is useless to attempt reduction by manipulation or extension, but many successful cases by the Lorenz forceless method prove Broca's statement to have been too sweeping. Lorenz and Hoffa have each devised an operation for this condition (pages 713-724). Congenital dislocation of the shoulder requires incision, possibly excision, or the paring down of the head to fit the glenoid cavity (Phelps).

Traumatic Dislocations.—In the succeeding pages the traumatic form of dislocations will be particularly considered.

The causes of traumatic dislocations are divided into *predisposing* and *causing*.

Predisposing causes are: (1) *age*; dislocations are commonest in middle life, the usual lesion of the young being green-stick fracture, and that of the old being fracture; dislocations of the radius are not uncommon in youth; (2) *muscular development*, dislocations being commonest in those with powerful muscles; (3) *sex*, males being more predisposed than females, because of their occupations and muscular strength; (4) *occupation* predisposes as a cause

according as it demands the employment of muscular force, as in the carrying of burdens; (5) *nature of the joint*, ball-and-socket joints being more liable to luxation than are ginglymoid joints, because of their wide range of motion; (6) *joint-disease* predisposes by relaxing the ligaments; (7) *situation of the joint*, some joints being more exposed to injury than others.

Exciting causes are divided into—(1) external violence and (2) muscular action. *External violence* may be *direct*, as when a blow upon one of the bones forces it directly away from the other; or it may be *indirect*, as when a blow at a distant part of a bone transmits force to its end and drives the bone out of its socket. *Muscular action* is a cause when sudden and violent muscular contraction occurs during the maintenance of a position of the joint which gives the muscles full sway, and throws the head of the bone against the weakest part of its retaining ligaments.

Pathological Conditions.—In a recent complete traumatic dislocation the ligaments are damaged, and may perhaps show extensive laceration, or may show only a buttonhole laceration through which a bone projects. External force produces much laceration and little stretching of the ligaments; muscular action produces little laceration and much stretching of the ligaments. In some cases of dislocation due to external violence the structures about the joint are bruised or otherwise damaged; the old socket is filled with blood, and the bone in its new situation lies in a bloody area. Large vessels and nerves are rarely torn, though they may be compressed.

If a dislocation is not soon reduced, inflammation arises in the old joint and about the displaced bone, and the whole area is glued together, first by coagulated exudate, and finally by fibrous tissue. After a time, in ball-and-socket joints, the old socket fills with fibrous tissue, contracts, becomes irregular, and may even be obliterated; the head of the dislocated bone is altered in shape, its cartilage is destroyed or converted into fibrous tissue, and the pressure of the head of the bone forms a hollow in its new situation, which hollow becomes surrounded by fibrous tissue or even by bone. A new joint may form, the surrounding tissue becoming a compact capsule, and a bursa forming between the head of the bone and its new socket. In a dislocated hinge-joint the ends of the bone alter greatly in shape and their cartilage is converted into fibrous tissue. In an unreduced dislocation the muscles shorten or lengthen or undergo atrophy or fatty degeneration, as the case may be. An unreduced dislocation of a ball-and-socket joint may give a fairly movable new joint, but an unreduced dislocation of a hinge-joint rarely allows of much motion.

General Symptoms of Traumatic Dislocation.—In general, traumatic dislocations are indicated—(1) by *pain* of a sickening, nauseating character; (2) by *rigidity*, voluntary motion being impossible except to a slight extent in the direction of the deformity. (For instance, in dislocation of the inferior maxillary the jaw can be opened a little more, but it cannot be closed.) This rigidity brings about loss of function. When the surgeon attempts to move the joint he finds it very rigid; (3) by *change in the shape of the joint* (as flattening of the shoulder after dislocation of the humerus); (4) by *alteration in the mutual relations of bony prominences about a joint* (as the alteration of the relation between the olecranon and humeral condyles in dislocation of the elbow backward); (5) by *feeling the displaced bone in its new situation*; (6) by *missing the head of the bone from its proper situation*, (7) by *alteration*

in the length of the limb (in dislocation of the femur into the thyroid foramen the limb is lengthened, but in dislocation onto the dorsum of the ilium it is shortened), and (8) by alteration in the axis of the bone (in dislocation upon the dorsum of the ilium the axis of the injured thigh would, if prolonged, pass through the lower third of the sound thigh); (9) by seeing the dislocation with a fluoroscope or looking at a skiagraph of it.

Diagnosis of Traumatic Dislocation.—A dislocation may be mistaken for a fracture. In dislocation there is rigidity, in fracture there is preternatural mobility; in dislocation there is no true crepitus (may get tendon or joint-crepitus), in fracture there usually is crepitus; in dislocation the deformity does not tend to recur after reduction, in fracture it does recur after extension is relaxed. In a sprain the movements of the joint are only limited, not absorbed, by the almost complete rigidity encountered in dislocation. The change which a sprain may cause in the shape of a joint is due to effusion or to bleeding, there is no alteration in the relation of the bony prominences to one another; there is no notable alteration in the length of the limb (a slight increase in length may arise from joint-effusion, or the head of the bone may subsequently be absorbed and thus produce shortening after some weeks); there is no alteration in the axis of the bone; the bony head is not felt in a new position, and it is found in its normal place. Always remember that a fracture may exist with a dislocation. In any doubtful case—in fact, in most cases—give ether, for a dislocation should be reduced while the patient is anesthetized (except in dislocation of the jaw, of the fingers, of the carpus, etc.). In some cases swelling renders the diagnosis difficult or impossible. Always compare the injured joint with the corresponding joint of the sound side. The x-rays constitute a valuable aid to diagnosis.

Treatment of Traumatic Dislocations. Recent Simple Dislocations.—Reduce simple dislocations under ether, as a rule. Try *manipulation*, a procedure which seeks to make the bone retrace its own pathway. If this procedure fails, employ extension and counter-extension. If considerable force is needed, an assistant makes counter-extension, and the surgeon fastens to the extremity a *clove-hitch*, which he ties about his waist, and thus secures powerful extension. Counter-extension may be obtained by hands, or, in some instances, by the foot of the surgeon. The *clove-hitch* is used because it will not tighten by traction; a tightening band would lacerate the soft parts (Fig. 351). If great power is needed, compound pulleys may be employed, such as the Jarvis adjuster or some similar appliance, but at the present day pulleys are rarely used (see page 678). If these means fail, cut down upon the bone and restore it to position; operation is much safer than is the application of great force. After reducing a dislocation, immobilize the joint for a time, which varies for different joints, and for the first few days combat swelling and inflammation by rest of the part and the use of evaporating lotions or an ice bag. If there exists a fracture of the dislocated bone, apply splints and then try to reduce by manipulations, grasping the limb and the splints with one hand below and, if possible, with the other hand above the seat of the fracture. Allis believes that a dislocation can be reduced even when a fracture exists. It is possible to pull the dislocated head down to the joint, because a portion of periosteum and possibly tendinous material and muscle still hold the two fragments as a strap might unite two sticks. The head can

be forced into place by the fingers while traction is being made. If the fracture is near the joint and the fragments cannot be fixed, try to reduce the dislocation, first striving to press the bone into place. This attempt can be greatly aided by traction upon the lower fragment. In some cases with fracture reduction can be much aided by making a small incision, screwing a gimlet into the head of the bone, and using this tool as a handle. McBurney incises, drills a hole in each bone, inserts hooks into them, and pulls the dislocated bone into position (Figs. 250, 251, and 252). When the dislocation has been reduced, the bone fragments should be wired together.

Compound Traumatic Dislocations.—The opening in the soft parts may be due to external violence or to projection of a bone. Compound dislocations are very serious. Hinge joints are more liable to these injuries than are ball-and-socket joints. Many cases require excision: some, amputation; one that does not demand excision or amputation should be treated by sterilizing the parts, restoring the dislocated bone, making a counter-opening, draining, dressing antiseptically, and immobilizing. Considerable ankylosis generally ensues, except sometimes in the small joints. It is scarcely ever necessary to cut away any portion of the protruding bone to effect reduction. If a joint is badly splintered, or if the soft parts are extensively damaged, it may be necessary to excise or amputate; if the main vessels of a limb are seriously injured, amputation must be considered. If the patient is so old or so feeble that it is perilous to force him to combat a long illness, amputation should be performed.

Old Traumatic Dislocations.—The problem always presented in an old dislocation is, Shall reduction be tried or shall the bones be let alone? Sir Astley Cooper laid down this rule: "Do not attempt to reduce a shoulder-dislocation after three months, nor a hip-dislocation after two months"; but this rule was put forth before the days of ether. Do not select any fixed period of time to determine what action is advisable. In dislocation of a ball and-socket joint considerable motion may become possible and a new joint may form. If movement does not produce pain, a useful new joint may be obtained by the persistent employment of active and passive movements; if movement of the limb does produce pain, enough motion will not be attempted by the patient to produce a useful joint. In the former case it may be best to try to obtain a useful new joint, and in the latter case the surgeon should endeavor to reduce the old dislocation. Always remember that dislocation of a hinge-joint, if left unreduced, will never eventuate in a useful new joint.

In trying to reduce an old dislocation give ether, make movement to break up adhesions, and persist in making these motions until the head of the bone is felt to move; then try at once to reduce by manipulation or extension and counter-extension, not waiting for two days, as some suggest. If the head of the bone cannot be made to move, the Dieffenbach plan has been advised, which is to cut the tense restraining bands with a tenotome. Lord Lister, being much impressed with the danger inevitably linked with forcibly dragging old dislocations into place, prefers to cut down and restore the bone, employing, of course, the strictest asepsis, and surgeons in general have adopted this view. In some old dislocations excision of the head of the bone is the proper operation.

Special Traumatic Dislocations.—Lower Jaw.—A dislocation of the lower jaw, when there is no fracture, is almost invariably forward.

Backward dislocation without fracture is extremely rare, and some have maintained that it cannot occur. Croker King reported a case in 1858. Them has observed it seven times in five women. The condyle passes under the lower surface of the auditory canal.* The common dislocation is forward, and this is the form meant when we simply speak of dislocation of the jaw. There are two forms of forward dislocation—the *unilateral*, which is rare, and the *bilateral*, which is common. Dislocations of the jaw are commonest in women and during middle life. When the mouth is open, contraction of the external pterygoid muscle may pull the condyle over the articular eminence; this contraction may be brought about by yawning, vomiting, scolding, etc. When the mouth is open, dislocation of the lower jaw may be caused by a blow upon the chin; it may also be caused by forcing the mouth more widely open by pushing a bulky body between the teeth.

Symptoms of Lower-jaw Dislocations.—In the *bilateral* form the mouth is open and fixed, and it cannot be closed, though it can be opened a little more. The condyles are in front of the articular eminences, and are fixed by the action of the masseters and internal pterygoids, the coronoid processes being wedged against the malar bones. The lower jaw is advanced in front of the upper jaw and the face looks longer than natural. The lips cannot close, the saliva dribbles, swallowing and speech are difficult, there is a depression in front of each ear, the condyles are recognizable in their new abodes, the coronoid processes are detected by a finger in the mouth, and the masseters and temporals stand out in a state of rigidity. Pain may be severe, may be moderate, or may be absent. In the *unilateral* form the chin goes toward the sound side, and the mouth is not so widely open as in the bilateral form, neither is the jaw so fixed. The symptoms are similar to those of a bilateral luxation, but are not so pronounced. The hollow in front of the ear and the abnormal situation of the condyle are detected upon one side only. In an unreduced dislocation the patient may after a time establish some movement of the jaw, but the power of mastication will always be seriously impaired.

Treatment of Lower-jaw Dislocations.—In reducing a dislocation of the lower jaw the patient is placed with his head against the back of a chair or against the body of an assistant. The surgeon, after wrapping up his thumbs to protect them from being bitten, stands in front of the patient, puts his thumbs upon the last molar teeth, and grasps the chin with his free fingers. He now presses downward and backward on the jaw, and as soon as the condyle is loosened, closes the jaw over the thumbs by pushing up the chin, using his thumbs as levers. If this procedure fails, wedges should be put between the molar teeth and the chin should be pushed up either by the hands or by a tourniquet whose band is round the head and chin. In a unilateral dislocation the wedge should be used only on the injured side. In difficult cases Sir Astley Cooper pushed a round wooden ruler between the molar teeth, used the upper teeth as a fulcrum, and raised the end of the ruler as the handle of a lever. The forceps used by an anesthetist may depress the condyle from its point of fixation, whereupon the chin may be pushed up and back. Nélaton advises that the surgeon place his thumbs in the mouth of the patient and push the coronoid processes backward. After reduction a Barton bandage should be applied and worn for over two weeks. The dressing should be renewed once a day, and passive motion

* Them, in *Rev. de Chir.*, vol. viii, 1888.

is to be begun in the second week. The bandage may be discarded at the end of the third week. Liquid diet is advisable for three weeks after the accident. In an old dislocation reduction is always attempted, at least up to a period of six or seven months after the accident. An irreducible dislocation requires osteotomy of the neck of the bone if the part cannot be restored after incision.

Dislocation of the Clavicle.—Sternal End.—There are three forms of dislocation of the sternal end of the clavicle, namely: (1) forward; (2) backward; and (3) upward.

Forward Dislocation of the Sternal End of the Clavicle.—The causes of forward dislocation of the clavicle are blows, falls, or pulls which drive or draw the shoulder backward.

Symptoms and Treatment of Forward Dislocation of the Sternal End of the Clavicle.—The symptoms manifest in dislocation of the clavicle are:

Fig. 345.—Rhoads's apparatus for treating dislocation upward of the acromial end of the clavicle

prominence in front of the sternum; the acromion is nearer to the sternum on the injured than on the sound side; the clavicular origin of the sternocleidomastoid muscle is rigid; movement is difficult and painful. To reduce a dislocation of the clavicle, pull the shoulders back against the knee of the surgeon, which is placed between the scapulae. Dress with a posterior figure-of-eight bandage (Fig. 747) or a Velpeau bandage (Fig. 749), the dressing to be worn for three weeks. After removal of the dressing apply a truss, the pad of which is put over the head of the clavicle, and which instrument is to be worn for a month. Dislocation of the clavicle is difficult to keep reduced, but even if it becomes fixed in deformity, the motions of the arm will not be impaired permanently. It can be reduced and fixed by incision and wiring.

Backward dislocation of the sternal end of the clavicle is very rare. The causes are direct violence and indirect force, such as falls or blows which drive the shoulder forward and inward.

Symptoms and Treatment of Backward Dislocation of the Sternal End of the Clavicle—The symptoms are: pain; loss of function in the arm; inclination of head toward the injured side; stiffness of the neck; the shoulder passes

forward and inward, and often falls downward; a depression exists over the sternoclavicular joint; the head of the clavicle cannot be felt, or is found back of the sternum. The displaced clavicle may press upon the trachea, the esophagus, or the great vessels, inducing dyspnea, dysphagia, obliteration of pulse in the arm of the injured side, or great venous congestion of the head (see Pick). The usual method of treatment is to pull the shoulders backward and apply a posterior figure-of-eight bandage (Fig. 747), which must be worn for three weeks. If pressure-symptoms are urgent, it is the rule to incise, restore the bone to place and wire it, or resect the displaced head.

Upward dislocation of a clavicle is very rare. The *cause* is indirect force which carries the shoulder downward, inward, and backward (Smith).

Symptoms and Treatment of Upward Dislocation of the Sternal End of the Clavicle—The chief symptom is impaired function of the arm; the shoulder passes downward and inward, the clavicular axis is altered, and the displaced head is felt. Dyspnea may or may not exist. To treat this dislocation, put a pad in the axilla and press the elbow to the side in order to throw the bone out-

Fig. 346.—Dislocation upward of acromial end of clavicle.

ward, and try to push the head into place. Apply a Desault bandage (Fig. 748) and place a firm pad over the sternoclavicular joint. The deformity is apt to recur, but a useful limb will nevertheless be obtained. The best method of treatment is to wire the bones in place.

Dislocation of the acromial end of the clavicle is almost always upward, but it may be below the acromion. The *cause* is violent force, which, if so applied to the scapula as to drive the shoulder forward, may produce a dislocation upward. A dislocation downward is due to blows upon the upper surface of the outer end of the clavicle.

Symptoms and Treatment.—In dislocation of the acromial end of the clavicle upward there are noted: prominence of the clavicle upon the top of the acromion; impaired function of the arm (it cannot be lifted over the head); the shoulder falls downward and passes inward; there is apparent lengthening of the arm, the head is bent toward the injured side, and the clavicular origin of the trapezius is strongly outlined (Pick). In *dislocation downward* both the acromion and the coracoid are very prominent, the clavicular axis is altered, and there is depression over the sternoclavicular joint. The surgeon

Diseases and Injuries of Bones and Joints

usually endeavors to reduce a dislocation upward by placing the patient prone on a hard table, pulling the shoulder back, and pushing the bone into place. After reduction the old method of treatment was to apply a Desault bandage, which was kept on for three weeks, and decided deformity, enduring pain, and disability were looked for as inevitable. Stimson used to apply dressings of adhesive plaster. The author has seen one case treated by the apparatus of Thomas Leidy Rhoads. The apparatus completely corrected the deformity, and the patient made a most satisfactory recovery. The essential element of Rhoads's apparatus is a trunk strap applied as is shown in Fig. 345. If the deformity can be completely corrected, Rhoads's apparatus will serve a good purpose, but in many cases it is impossible really to reduce the deformity or after apparent reduction the deformity at once returns. This is due, as Moore points out ("Annals of Surgery," May, 1902) to the fact that the superior acromioclavicular ligament is torn from the clavicle but remains attached to the scapula, and when reduction is attempted, is pushed under the clavicle and nothing remains to hold the clavicle "in place but the skin and superficial fascia." I agree with Moore that the best treatment is incision, replacement, and suturing the acromion to the outer end of the clavicle. The bones are sutured with silver wire or kangaroo tendon, the acromioclavicular ligament is sutured with catgut, the wound is closed with sutures of silkworm gut, and the patient is kept supine in bed for three weeks. I have operated successfully on four of these cases.

Dislocation downward is reduced and treated in the same manner as dislocation upward.

Simultaneous dislocation of both ends of the clavicle is a very rare injury. It is treated as is single dislocation.

Fig. 347 - Axillary dislocation of the right humerus.

The so-called **dislocation of the lower angle of the scapula** is not, as was long taught, a dislocation at all. The lower angle and vertebral border deviate from the chest. This condition was thought to be due to the bone slipping from under the latissimus dorsi muscle, but it is now known to be due to *paralysis of the serratus magnus muscle*, the bone being acted upon by the trapezius, pectoralis minor, levator anguli scapulae, and rhomboid muscles. Examination shows that the scapula will not rotate normally forward. This is demonstrated by extending the arms in front to a right angle, the gliding forward of the scapula upon the sound side being marked and upon the diseased side being slight or absent.

Treatment of paralysis of the serratus magnus muscle comprises massage, electricity, passive motion, and deep injections of strychnine.

Dislocations of the Humerus (Shoulder joint). These injuries are quite frequent because of the free mobility of the shoulder joint, its anatomical insecurity, and its exposed situation. They occur in the very young and in the aged, and are oft-

encountered in muscular young adults. Shoulder dislocation is produced by throwing the arm into extreme abduction. In this position the head of the humerus presses against the lower and front part of the capsule, that is, against the thinnest and most poorly supported portion of the capsule. In almost all cases the tear in the capsule occurs between the tendon of the subscapularis and the triceps. Hence, most dislocations are *primarily* subglenoid, although the bone usually moves to some other position, being dragged or driven there by the injuring force or being pulled there by muscular action. Dislocation forward is much more common than dislocation backward because the long head of the triceps keeps the head of the bone from going posterior and because the anterior are stronger than the posterior muscles. Four chief forms of shoulder-

Fig. 245.—Subcoracoid dislocation of the left humerus (St. Joseph's Hospital case; photographed by Dr. Nassau).

joint dislocation exist, namely: (1) forward, inward, and downward, under the coracoid process—subcoracoid; (2) downward, forward, and inward, beneath the glenoid cavity—subglenoid; (3) backward, inward, and downward, under the spine of the scapula—subspinous; and (4) forward, inward, and upward, under the clavicle—subclavicular.

A very rare form of shoulder-joint dislocation has been described, which is known as the *supratoracoid*. Another rare form is the *luxatio erecta*.

Subcoracoid Luxation. The subcoracoid variety of dislocation embraces three-fourths of all the shoulder joint luxations. It may be caused by direct force driving the head of the humerus forward and inward, or by indirect force, such as falls upon the hand or the elbow. In this dislocation the

head of the bone lies against the anterior surface of the scapular neck below the coracoid process. A part of the anatomical neck of the humerus lies upon the anterior margin of the glenoid cavity, and the head of the bone is above the tendon of the subscapularis muscle.

Subclavicular luxation is very rare. It is caused by the same sort of violence which produces subcoracoid luxation. The head of the bone rests upon the thorax, below the clavicle, and underneath the pectoralis major muscle.

Subglenoid or Axillary Luxation (Fig. 347).—May be produced by contraction of the great pectoral and latissimus dorsi muscles when the arm is at a right angle to the body, but it is usually due to falls upon the hand or the elbow when the arm is raised and the head of the bone is against the lower portion of the capsule. In this dislocation the head of the bone rests upon the border of the scapula, below the tendon of the subscapularis, in front of the long head of the triceps, and above the teres muscles. Some observers hold that most dislocations of the shoulder are primarily subglenoid, the position having been altered by muscular action. *Luxatio erecta* is an unusual form of subglenoid dislocation. The arm is upright and the forearm rests behind the occiput or on the top of the head, and the patient holds it there to avoid pain. Judd, Hulke, and Cleland have related cases.

Subspinous Luxation.—Is a rare injury. Pick met with this accident in a man who, while having his hands in his pockets, fell upon the front of the point of the shoulder. The head of the bone reposes beneath the scapular spine, between the infraspinatus and teres minor muscles.

Supracoracoid luxation is seldom encountered. The head of the humerus rests upon the coraco-acromial ligament or upon the acromion process, and the acromion or the coracoid is always fractured.

Luxatio Erecta.—In this injury the arm is markedly abducted and in some cases the elbow is actually raised above the patient's head. In such an injury the head of the bone has passed under the subscapularis muscle and also under the teres major or the lower border of the great pectoral.

Symptoms of Dislocation of the Shoulder joint. Dislocation is diagnosed by—(1) pain of a sickening character; (2) flattening of the shoulder, the head of the bone having ceased to bulge out the deltoid muscle; (3) apparent projection of the acromion through sinking in of the deltoid; (4) hollow beneath the acromion, over the empty glenoid cavity, and the bone missed from its normal habitat. This hollow may be easily appreciated by the finger, especially when the extremity is somewhat abducted, (5) rigidity (some movement is possible, in the direction especially of an existing deformity, but mobility is strictly limited and attempts at motion produce great pain); (6) Dugas's sign: the elbow cannot touch the side when the hand is placed upon the sound shoulder, and the hand cannot be placed upon the sound shoulder if the elbow is to the side (this is due to the rotundity of the chest. In a dislocation the head of the bone is already touching the chest, and the bone, being approximately straight, cannot touch it in two places at the same time. If the elbow can be placed against the chest with the hand on the sound shoulder, there cannot be dislocation, if it cannot be so placed, there must be dislocation), (7) finding the head of the bone

in a new situation; (8) examining by means of the x -rays. Symptoms 1 to 5 inclusive may be grouped as Erichsen's list of signs. The form of dislocation is made out by a study of the direction of the axis of the limb, the existence and extent of lengthening or of shortening, and the situation of the head of the bone.

In a shoulder-joint dislocation the head of the bone may press upon the brachial plexus and produce pain and numbness, and occasionally traumatic neuritis or paralysis; sometimes pressure upon the axillary vein causes intense edema, and pressure upon the axillary artery diminishes or obliterates the pulse. The axillary vessels may be torn and the muscles may be lacerated badly. The capsule is torn and considerable blood is usually effused. Swelling is due first to hemorrhage, and secondly to inflammation. Partial dislocations sometimes, though rarely, occur. What is usually spoken of as "partial dislocation" or "subluxation" is a condition in which the head of the humerus passes forward under the coracoid because of rupture of the long head of the biceps or because this tendon slips out of its groove, the ligaments of the shoulder-joint being intact.

The following table from T. Pickering Pick's work on "Fractures and Dislocations" makes the above points clear:

	DIRECTION OF THE AXIS OF THE LIMB.	ALTERATION IN THE LENGTH OF THE LIMB.	PRESENCE OF THE HEAD OF THE BONE IN NEW SITUATION.
Subcoracoid.	The elbow is carried backward and slightly away from the side.	Very slight lengthening.	The head of the bone cannot easily be felt, it is found at the upper and inner part of the axilla.
Subglenoid.	The elbow is carried away from the trunk and slightly backward.	Very considerable lengthening.	The head of the bone can easily be felt in the axilla.
Subspinous.	The elbow is raised from the side and carried forward.	Lengthening intermediate in degree between the subglenoid and the subcoracoid.	The head of the bone can be felt and be grasped beneath the spine of the scapula.
Subacromial.	The elbow is carried outward and backward.	Shortening.	The head of the bone can readily be seen and be felt beneath the clavicle.

Diagnosis of Shoulder-joint Dislocation.—In fracture of the neck of the scapula the acromion is prominent, a hollow is detected below it, and a hard body is felt in the axilla; but the coracoid process descends with the head of the humerus, which it does not do in dislocation. Furthermore, in fracture there is mobility; in dislocation, rigidity. In fracture crepitus is present in dislocation it is absent. In fracture the deformity is easily reduced, but it at once recurs; in dislocation the deformity is with difficulty reduced, but does not recur. In fracture the elbow can be made to touch the side when the hand is upon the sound shoulder; in dislocation it cannot be so manipulated. In fracture of the anatomical neck of the humerus deformity is slight, the head of the humerus is found in place, does not move when the shaft is rotated, and is not in line with the axis of the bone. Crepitus

exists in the fracture if impaction is absent. In *paralysis of the deltoid muscle* there is distinct flattening, but the bone is felt in place and there is no rigidity. The x-rays are a great aid to diagnosis.

Treatment of Shoulder-joint Dislocation.—Reduction by manipulation is usually readily obtained in recent cases of shoulder-joint dislocation. If a simple trial without ether fails, an anesthetic should be administered. Ether is given, but not chloroform, for chloroform seems to be particularly dangerous to life when given to enable the surgeon to reduce a dislocation of the shoulder. *Forward dislocations* (subcoracoid, subclavicular, and axillary) are reduced by *Kocher's method* (Fig 349). This method was introduced by Kocher in 1870 ("Sammlung klin. Vorträge," No. 83). Reduction by this method can frequently be effected without the aid of ether. The patient should be recumbent. Slowly but forcibly adduct the abducted elbow and get it finally against the side. At the same time it is drawn slightly backward. The forearm is flexed. If there is much muscular resistance, follow Keetley's advice, and not only bring the elbow to the side, but push it backward and inward toward the spine. Grasp the elbow with one hand, and the wrist with the other, and slowly make external rotation until the forearm points outward from the body. We thus carry the head of the humerus to the margin of the glenoid cavity. External rotation must be done slowly and gently. When we first try it there is much muscular resistance. If enough force is used to overcome the resistance the surgical neck of the bone may be broken. By gently and gradually persisting in external rotation the muscles are finally tired out. Next lift the elbow anteriorly as far forward as it will go, so as to bring the head of the humerus to the glenoid margin just opposite the capsular tear (Keetley). Then throw the bone into place by gradually swinging the forearm inward across to the other side of the chest, that is, by internal rotation. The formula is, flexion of the forearm, external rotation, lifting the elbow forward, internal rotation of the arm, and lowering the elbow. The motions to unlock the bone and start it to retrace the steps it took when emerging should be gentle, not forcible, slow, not sudden, and rigid muscles should be tired out and made to relax by steady traction upon them. Sudden and violent motions increase rigidity. Adduction stretches the upper portion of the capsule and presses the head against the glenoid. External rotation opens the tear in the capsule. Elevation relaxes the untorn part of the capsule and coracohumeral ligament and stretches the torn portion. On this fulcrum, the head, which is the end of a lever, is forced into place. If in trying Kocher's plan external rotation of the humerus does not take place, abandon the method, as persistence will fracture the humerus. An other method of manipulation is as follows: if the *right* shoulder is dislocated, the surgeon stands behind the patient (who is sitting erect), if the *left* shoulder is dislocated, he stands in front of the patient. The surgeon holds the forearm flexed upon the arm with his right hand and makes external traction and rotation, and with the fingers of his left hand he tries to force the bone into place.

In *Henry H. Smith's method* for forward dislocations the surgeon stands in front of the patient. If the *left* shoulder is dislocated, the surgeon grasps it with his left hand, if the *right* shoulder is dislocated, he grasps it with his

right hand, the thumb resting on the head of the bone. With his disengaged hand the surgeon grasps the elbow, abducts it, makes traction and external rotation, and suddenly sweeps the elbow inward, aiming it at the sternum, and tries with his thumb to push the bone into place. In *subspinous luxations* reduction may be effected if the surgeon stands behind the patient, makes abduction, traction, and internal rotation, sweeps the elbow inward toward the spine, and with the thumb aids the bone in its return into position. Raising the elbow far above the head and sweeping it inward will reduce some dislocations. As the head of the bone slips back a distinct jar is felt and a snap is heard, the motions of the joint are again obtainable, and with the hand on the opposite shoulder the elbow may be made to touch the side.

Reduction by Extension.—Before attempting the reduction of a dislocation of the shoulder-joint by extension, the patient should be anesthetized and placed upon a low bed or upon the floor. The surgeon then places

Fig. 349.—Kocher's method of reduction by manipulation. *a*, First movement, outward rotation; *b*, second movement, elevation of elbow; *c*, third movement, inward rotation and lowering of the elbow. (Cappi)

his foot, covered only by a stocking, in the axilla. Place the sole of the foot, not the heel, against the chest high up, the instep being made to touch the humerus and the heel the border of the shoulder-blade, a towel being first put into the axilla to rest the foot against (Fig. 350). If the left arm is dislocated, use the left foot, and *vice versa*. The elder Gross approved of making extension while sitting between the patient's limbs. Make steady extension, which will in many cases bring about the reduction. If it fails to cause reduction, bring the patient's arm across the chest and use the foot as the fulcrum of a lever. If the humerus is pretty firmly fixed in its abnormal position, make counter extension with a foot in the axilla and make extension by fixing a clove-hitch (Fig. 351) *above the elbow* and fastening to it bands which go over one shoulder and under the other shoulder of the surgeon. The back may thus be used for extension, the hands being left free for manipulation (Allis's and Pick's plan). Lateral extension is used by some surgeons. The patient lies down, a large piece of canvas is split, the arm is passed through the split, and the body is thus fixed. The arm is pulled to a right angle with the body and traction is applied.

The late Prof. Joseph Pancoast favored Sir Astley Cooper's method of

placing the unanesthetized patient in a chair and using the knee as a fulcrum, pushing the elbow to the side (Fig. 352). Brunus, in the thirteenth century, devised the method of *upward extension*. In applying this method the

Fig. 350.—Reduction of shoulder-joint dislocation by the foot in the axilla (Cooper).

Fig. 351. Clove hitch knot applied above the wrist. In dislocation of the shoulder this knot is put above the elbow (after Erichsen).

surgeon takes his place behind the patient, steadies the scapula with his hand, and carries the patient's arm upward and backward above his head, making extension and external rotation (Fig. 353). *La Mothe's method* is applied with the patient supine upon the floor. The surgeon places his foot upon the shoulder to make counter-extension, and makes extension as in Brunus's method. It is a useful expedient, when either of these plans is applied, to have an assistant make the traction while the surgeon manipulates the head of the bone. Cork advises, when reduction fails, that an air-pad be placed in the axilla

Fig. 352.—Reduction of shoulder-joint dislocation by the knee in the axilla (Cooper).

Fig. 353.—Reduction of shoulder joint dislocation by upward extension (Cooper).

and the arm be bound to the side—a method by which reduction will sometimes take place after two or three days.

Pulleys should not be used to pull the bone into place, as they develop a dangerous force. In a dislocation irreducible by ordinary force, antiseptic incision is safer and better than the pulleys. After incision try to restore the bone to place.

In reducing a dislocation the axillary artery or vein may be ruptured, fracture of the neck of the humerus may take place, injury to the brachial plexus may occur, or the soft parts may be badly damaged. After reducing a dislocation apply a Velpeau bandage, keep the shoulder immobile for one week, then make passive motion daily, reapplying the dressing after each séance. The patient may wear a sling alone during the third week, after which period he may use the arm. (For compound dislocations see page 668.)

Unreduced and Irreducible Dislocations of the Shoulder.—In some cases where we find there is considerable movement without pain we can, by manipulation and active motion, seek to increase the range of movement and usefulness of the new joint.

As a rule, in a youth or a middle-aged person we attempt bloodless reduction if we see the case by or before the ninetieth day after the accident. Give ether, break up adhesions by forced flexion and extension, and try Kocher's method, and, if this fails, the other methods, but never use violent force. In reducing an old dislocation we may fracture the surgical neck of the humerus. I have seen this happen twice. The proper treatment is incision and pulling the head into place with McBurney's hooks. In attempting reduction of an old dislocation the brachial plexus may be lacerated or one or both of the axillary vessels may be torn. If an axillary vessel

is torn, it must be at once exposed by incision. A large tear in either vessel requires a ligature about the vessel on each side of the tear. A small tear may be sutured (Kestley, in "Lancet," Jan. 23, 1904). Rather than use sufficient force to endanger the vessels in attempting to reduce an old dislocation, practise incision. In some cases after incision the head of the bone can be pulled into place. In other cases the head must be resected. After reduction of an old dislocation immobilize for three weeks, and begin passive motion after seven days.

If a dislocation is complicated by a fracture of the humerus, try to pull the head of the bone opposite the joint. This may be possible if the two fragments are held partly together by a fair amount of periosteum and muscle. Traction is exerted upon the arm, and an attempt is made to manipulate the head into the socket (Allis's plan in the hip). McBurney incises, fixes a hook

Fig. 352.—Reduction of elbow joint dislocation.

in the scapula and a hook in the head of the humerus, pulls the head into place, and wires the fragments (Figs. 250, 251, 252). In an emergency gimlets may be used instead of the hooks. In some cases it is necessary to excise the head of the bone.

Fig. 354.—Dislocation of both bones of the forearm backward.

Habitual or Recurrent Dislocations.--Habitual or recurrent dislocation of the shoulder, following an original traumatic dislocation, results usually from a slight or trivial force. It usually takes place while the arm is in adduction, slight rotation frequently being necessary. In some cases rotation will produce a dislocation while the arm is near the side of the body. Little is known of the frequency with which these cases occur, but they are probably much more frequent than is generally supposed. The frequency of the recurrences in the individual cases varies widely. In some they occur more or less regularly every two or three years, while in others they have been known to take place daily and even several times a day. In most cases in the intervals between the recurrences the joint functions normally without difficulty, although the patient fears abduction because of its influence in favoring a recurrence. In rare cases pain persists a long time after each dislocation, so that if the recurrences are frequent, the patient may be compelled to give up work.

Cause. The essential cause is a relaxation of the capsule at the site of the original tear, due to the addition to the old or original portion of the capsule of a new or cicatricial portion bridging over the gap between the margins of the tear produced by the first dislocation. The failure of these margins to unite closely is due to the repeated emergence of the humeral head forcing them apart before union is complete. The defects in the head of the humerus which have been found at autopsy and operation have, probably, only a slight and secondary causal importance, while the fractures of the greater tuberosity of the humerus sometimes occurring in dislocations of the shoulder are probably not followed by recurrent dislocations.

Treatment.—Excisions of the head of the humerus have been abandoned. Capsulorrhaphy for the shortening of the relaxed anterior portion of the capsule has given excellent functional results. Dr. Dawbarn, of New York, did this operation in my clinic, upon a city fireman, and the result was a perfect success. The capsule may be exposed through the usual resection incision along the anterior margin of the deltoid. This may be modified by an additional incision outward at right angles to the first, and the insertion of the pectoralis major may be partially divided. T. Turner Thomas makes an axillary incision along the inner border of the coracobrachialis, passing between this muscle and the axillary vessels and nerves, and avoiding particularly the circumflex and musculocutaneous nerves. The subscapularis muscle is partially divided to give a freer exposure of the capsule. This route exposes the site of the original tear in the capsule by a small incision. It avoids division of the deltoid and gives dependent drainage if drainage is necessary.

The relaxed portion of the capsule may be shortened by taking up a reef with catgut or silk sutures, without opening and exploring the joint for loose pieces of bone, the capsule may be incised transversely to its longitudinal fibers and the margins of the incision overlapped; an oval piece may be excised and the edges united by sutures, or the margins of the original tear may be found and sutured together.

Dislocations of the Elbow-joint.—Dislocations of the elbow joint are not infrequent, and they are commonest in children. Both bones or only one

bone of the forearm may be dislocated, and the dislocation may be partial or complete.

Dislocation of Both Bones Backward.—The *causes* of backward dislocation of both bones of the forearm are falls upon the extended hand or twists inward of the ulna (Malgaigne). The coronoid process lodges in the olecranon fossa of the humerus.

Symptoms of Backward Dislocation.—In complete dislocation of both bones of the forearm the olecranon is very prominent (Fig. 354). The distance between the point of the olecranon and the apex of the inner condyle is notably greater than on the sound side; the forearm is flexed, supinated, and shortened; the lower end of the humerus projects in front of the joint, below the skin-crease, the head of the radius is found back of the outer condyle; and there are the general symptoms of dislocation. Fracture of the coronoid rarely occurs with backward dislocation, but if it does occur, there will be crepitus and mobility. Fracture at the base of the condyles is distinguished from dislocation of both bones of the forearm backward by the following points: in fracture there are found the ordinary symptoms; measurement from the

Fig. 350.—Forward dislocation of the radius.

condyles to the styloid processes does not show shortening; there is no alteration of the normal relation between the olecranon process and the condyles; and the projection in front of the joint is above the crease of the bend of the elbow.

Treatment of Backward Dislocation.—Reduction must be effected early in dislocation of both bones of the forearm, because it will soon become impossible and an unreduced dislocation means a limb without the powers of flexion, pronation, and supination. The surgeon may place his knee in front of the elbow-joint, grasp the patient's wrist, press upon the radius and ulna with his knee, and bend the forearm with considerable force, the muscle pulling the bones into place (Sir Astley Cooper's plan). Forced flexion, traction and extension may be tried (Fig. 355). Put the arm in Jones's position for two weeks, and make passive motion daily after the first few days.

Dislocation of Both Bones Forward.—The *cause* of forward dislocation of both bones of the forearm is a blow on the olecranon when the arm is flexed. It is an unusual accident.

Symptoms and Treatment.—The symptoms of forward dislocation of both bones of the forearm are—the forearm is flexed and lengthened, some slight

motion is possible; the olecranon is on a level with the condyles if unfractured hence its prominence is gone; the humeral condyles are felt posteriorly, and the radius and ulna are felt anteriorly. The *treatment* of this injury consists in early reduction, which is accomplished by means of forced flexion, extension, and pressure, placing the part in Jones's position for two weeks, and making passive motion daily after the first few days.

Lateral dislocation of both bones of the forearm is usually incomplete.

Symptoms and Treatment of Outward Dislocation.—The symptoms of outward dislocation of both bones of the forearm are—the forearm is flexed, fixed, and pronated; the joint is widened; the head of the radius projects externally and has a depression above it; the inner condyle projects internally and has a depression below it; the olecranon is nearer than normal to the external condyle and further than normal from the internal condyle. Reduction is effected by extension of the forearm and pressure inward upon the head of the radius. Apply an ascending spiral reversed bandage of the forearm, a figure-of-eight bandage of the elbow-joint, and a sling. Make passive motion after a few days. The bandages must be worn for two weeks.

Symptoms and Treatment of Inward Dislocation.—In dislocation inward of both bones of the forearm the position of the forearm is the same as that in dislocation outward; the sigmoid cavity of the ulna projects internally, and the external condyle projects externally. Reduction is effected by extension of the forearm and pressure outward on the ulna, subsequent treatment being the same as that employed in the preceding form.

Dislocation of the ulna alone is very rare, and can take place only backward.

Symptoms and Treatment—Dislocation of the ulna alone is indicated by the forearm being flexed and pronated. The head of the radius is found in place, and the olecranon projects posteriorly. The *treatment* of this injury is the same as that for dislocation of both bones.

Dislocation of the Radius Forward (Fig. 356) Dislocation of the radius forward is the commonest form of dislocation of the elbow. This injury is caused by a fall upon the hand with the forearm in pronation and extension, or is produced by blows on the back of the joint; forced pronation alone will not cause it.

Symptoms and Treatment—The symptoms in dislocation of the radius forward are—the forearm is midway between pronation and supination, and is semiflexed; attempts to increase flexion cause the radius to strike against the humerus with a distinct blow; the head of the radius is felt in front of the outer condyle and is missed from its proper abode. Reduction is effected by flexion over the knee, extension, and manipulation. The subsequent treatment is Jones's position and passive motion. Deformity is apt to recur after reduction, because of rupture of the orbicular ligament.

Dislocation of the radius backward is caused by falls on the hand or by blows on the front of the joint.

Symptoms and Treatment—Backward dislocation of the radius is indicated by the forearm being slightly flexed and fixed in pronation, by some impairment of flexion and extension, and by the head of the radius being felt behind the outer condyle. Reduction is effected by flexion over the knee, extension,

and manipulation, and the subsequent treatment is the same as that given for the preceding dislocation.

Dislocation of the radius outward is very rare. In this injury the head of the radius is distinctly felt. Reduction is effected by extension and pressure; the subsequent treatment is the same as that for the above-mentioned dislocations.

Subluxation of the Head of the Radius.—This name is given to an injury which is very frequent in children between two and four years of age. It results from traction upon the hand or the forearm, and often arises when the nurse or the mother pulls upon a child's arm to save it from a fall or to lift it over a gutter. Some writers hold that pronation as well as extension is required to produce the injury; many surgeons claim that extension and adduction are the causative forces. Hutchinson asserts that supination may cause subluxation. Bardenheuer assigned falls as causes.

The *symptoms* are very characteristic. The history points to the injury. Pain, and often a click, may be felt in the wrist at the time of the accident. The arm hangs by the side, with the elbow-joint slightly flexed and the forearm midway between pronation and supination. Flexion to an angle of less than 60° and complete extension are resisted and are very painful, but movements between 60° and 130° are free and painless.* The movements of the wrist-joint are free and painless. The elbow-joint presents no deformity. Pressure over the head of the radius causes pain. Strong pronation is painful; strong supination is very painful, and there seems to be a mechanical obstacle to its performance. Forced supination develops a distinct click at the head of the radius, and causes pronation and supination to become natural and free from pain. The condition will be reproduced if the parts are not immobilized for a time. The nature of the lesion is not understood, and various conditions have been thought to exist by different observers. Among them may be mentioned the following: a slight anterior displacement of a head of the radius; a slight posterior displacement; locking of the tuberosity of the radius behind the inner edge of the ulna; dislocation of the triangular cartilage of the wrist; intracapsular fracture of the radial head; painful paralysis from nerve-injury; displacement by elongation, the return of the bone being prevented by collapse of the capsule; and the slipping up of the margin of the orbicular ligament over the rim of the head of the radius.

Treatment.—In order to reduce place the forearm at a right angle to the arm and make forcible supination. Apply an anterior angular splint, and have it worn for four or five days, or put the part in Jones's position for an equal period.

Dislocations of the wrist are very uncommon and are caused by falls upon the hand.

Backward Dislocation of the Wrist.—*Symptoms.*—The deformity in backward dislocation of the wrist (Fig. 357, A) resembles that of Colles's fracture (Fig. 357, B). The fingers are flexed, the wrist is bent backward, the radius projects on the front of the wrist, the carpus projects on the dorsal surface of the forearm, the relation of the styloid process of the radius to the

* See the instructive article by W. W. Van Arsdale, in the *Annals of Surgery*, vol. 12, 1890.

styloid process of the ulna is unaltered (it is altered in Colles's fracture), there is rigidity, and crepitus is absent.

Forward dislocation of the wrist, which is very unusual, is caused by a fall upon the back of the hand.

Symptoms and Treatment.—In forward dislocation of the wrist the radius and ulna project posteriorly and the carpus projects in front. The *treatment* in both of these dislocations is reduction by extension and manipulation, the use of a Bond splint for ten days, and the employment of passive motion after five or six days.

Dislocation at the inferior radio-ulnar articulation, which is also very common, is caused by twists.

Symptoms and Treatment.—In *forward* dislocation at the inferior radio-ulnar articulation the forearm is pronated, the space between the styloid processes is diminished, and the ulna forms a projection posteriorly. In *backward* dislocation the forearm is supinated, the space between the styloid processes is diminished, and the ulna projects in front. Reduction is accomplished by extension and manipulation. Two straight splints (as in fracture of both bones) are to be applied for four weeks, and passive motion is to be made in the third week.

Dislocation of Individual Carpal Bones.—Pick says there is one weak spot, which is "between the head of the os magnum and the scaphoid and semilunar bones," and the os magnum may be forced up. This lesion is called by some dislocation of the os magnum backward. Codman and Chase

Fig. 357.—Deformity in dislocation of the wrist backward (A) and in Colles's fracture (B) (Stimson).

("Annals of Surgery," March and June, 1905) regard the injury as really *dislocation of the semilunar forward*, a dislocation which may be associated with fracture of the carpal scaphoid. The injury is caused by forcible overextension or by twisting of the wrist. According to Codman and Chase, the injury usually occurs in men between thirty and forty, results from violent force, produces severe pain immediately, and tenderness and ecchymosis quickly arise. On examination a silver-fork deformity is observed, the posterior projection being the os magnum, this projection being separated from the radius by a groove which marks the former situation of the dislocated semilunar. The dislocated bone is felt under the flexor tendons of the wrist, the palm seems shorter than its fellow, the fingers are partly flexed, active or passive motion causes pain, and the x-ray exhibits the dislocated bone ("Annals of Surgery," March and June, 1905).

Treatment.—According to Codman and Chase, recent dislocations (even after the fifth week) may be reduced by hyperextension followed by hyperflexion over "the thumbs of an assistant held firmly in the flexure of the wrist or the semilunar" ("Annals of Surgery," March and June, 1905).

If bloodless reduction fails, the authors advise palmar incision and reduction, and if this fails, excision of the bone. If in excising the semilunar the scaphoid is found to be fractured, the proximal part of the entire scaphoid must also be removed.

Dislocations of metacarpal bones are uncommon. The first metacarpal bone is most liable to dislocation.

Symptoms and Treatment.—Dislocations of the metacarpal bones are obvious because of projection. The dislocations are reduced by extension and manipulation, a straight splint and large pad for the palm are applied (as in fracture of the metacarpus), and the splint is worn for three weeks.

Dislocations at the metacarpophalangeal articulations are uncommon. Backward dislocation is the most common. The cause is a fall upon the hand.

Symptoms and Treatment.—Dislocated metacarpophalangeal articulations are obvious. Reduction is easily effected by extension and manipulation, except in the case of the thumb. A splint must be worn for three weeks.

Dislocation of the Metacarpophalangeal Joint of the Thumb.—In this dislocation the phalanx usually passes backward. In some cases the long flexor of the thumb gets to the ulnar side of the head of the metacarpal bone and hinders reduction (J. Hutchinson, Jr., in "Brit. Med. Jour.,"

Fig. 358.—Levi's splint for reducing dislocation of phalanges.

Fig. 359.—Levi's splint applied

Jan. 15, 1898). The chief impediments to reduction, as demonstrated by Fara Beuf, are the sesamoid bones and glenoid ligament, which accompany the base of the phalanx in the dislocation. It is not probable that the catching of the metacarpal bone between the two heads of the flexor brevis, which often happens, is an important impediment.

Symptoms.—The symptoms of *backward* dislocation are as follows: The base of the first phalanx rests upon the metacarpal bone, the head of the metacarpal bone projects forward and buttonholes the muscles of the thumb; the first phalanx of the thumb is strongly extended, and the terminal phalanx is *semi-flexed*. The symptoms of *forward* dislocation are as follows: The base of the first phalanx is felt in the palm, and the head of the metacarpal bone is felt posteriorly.

Treatment.—In treating backward dislocation of the metacarpophalangeal joint of the thumb reduction is difficult. Always give ether. Keetley's directions are to adduct the metacarpal bone into the palm (this relaxes the flexor muscles) and to have an assistant hold it, bend the thumb strongly back, extend, pull the thumb toward the fingers, and suddenly flex. To get a firm enough grasp for these manipulations use the apparatus of Charrière or of Levis (Figs. 358, 359). If the above maneuvers fail, incise freely on the dorsum and reduce. Tenotomy is seldom of service. After reduction of this dislocation a splint must be worn for three weeks. In forward dislocation reduction is easily effected by strong extension and forced flexion. A splint is to be worn for three weeks.

Dislocations of the phalanges may be complete or may be partial. They are commonest between the first and second phalanges.

Symptoms and Treatment.—Dislocations of the phalanges are obvious. In reducing such dislocations employ extension and manipulation. Use a splint for one week.

Dislocations of the Ribs and Costal Cartilages.—The ribs may be dislocated from the vertebrae. This accident is seldom uncomplicated, and cannot be differentiated from fracture. The diagnosis is rarely made, and the injury is treated as a fracture. The ribs may be dislocated from their cartilages, one or more ribs being displaced. The end of the rib forms an anterior projection, there is a depression over the cartilage, and crepitus is absent. *Treatment* is the same as that employed for fractured ribs. The costal cartilages may be displaced from the sternum, forming an anterior projection upon this bone. Reduction is brought about by placing the patient upon a table, with a sand pillow between the scapulae, pushing back the shoulders and chest, and forcing the cartilage into place. The dressings are the same as those used in fractured sternum. The cartilages of the lower ribs (sixth, seventh, eighth, ninth, and tenth) may be separated. The inferior cartilage goes forward and can be felt. Pick states that reduction is brought about by causing the patient to hold the chest full of air while efforts are made to push the cartilage into place. The injury is dressed as are fractured ribs (page 548).

Dislocations of the Sternum.—In dislocations of the body of the sternum the manubrium is separated from the gladiolus. The injury is a rare one, is usually associated with fracture, and is most common in the young. It is due in most cases to violent direct force inflicted by a fall or heavy blow; it may be due to indirect force and arose in one case of acute tetanus. The *symptoms* and *treatment* are the same as those of fracture (page 550). Dislocation of the ensiform process is one of the rarest of injuries. It is usually due to direct force, but Polaillon reports a case caused by tight lacing.

Pelvic dislocations are almost always complicated with fracture. A pubic bone can be dislocated by falls from a height or by applying violent force to the acetabula. The dislocation may be up or down, front or back, and it may damage the urethra or the bladder. The patient cannot stand; there are great pain and recognizable deformity. Treat by moulding the bones into place, by applying a pelvic belt, and by rest in bed for four weeks.

Dislocations of the sacro-iliac joint are produced by falls. Movement on the part of the patient is difficult or impossible, there is violent pain, and often paralysis (from pressure upon nerves). In dislocation backward there is apparent shortening of the leg, eversion of the foot exists, and the ilium moves posteriorly and upward. In dislocation forward the anterior superior iliac spine projects and the pelvis is broadened. Sacro-iliac dislocations are reduced by holding the pelvis firm and making extension with a pulley. The patient stays in bed for four weeks and wears a pelvic belt as in fracture.

Fig. 369.—Thyroid dislocation of the femur, eight weeks after the accident. Reduced by open section (Rugh).

Dislocations of the Femur (Hip-joint). These injuries are not often considered, as the hip-joint is very strong. They occur in young adults. In forced extension the head of the femur presses against the capsule of the joint, but the capsule here is very thick, and certain muscles, the rectus, psoas, and others, are pulled tight and serve to strengthen it. The head of the bone cannot go directly upward, because of the acetabulum (Edmund Owen). The weak point of the acetabular rim is below; the weak part of the capsule is anterior, hence forced abduction is apt to push the head of the bone through the lower part of the capsule, a dislocation occurring primarily into the lesser foramen. The signs of the dislocation depend upon the amount

portion of the capsule. The anterior portion of the capsule, including the Y-ligament, usually escapes laceration. Vessels are rarely injured. Muscles are often torn. In some cases the sciatic nerve is lacerated, bruised, or caught up on the neck of the femur during the circumduction of attempted reduction. Four forms of hip joint dislocation are usually described (1) upward and backward, on the dorsum of the ilium; (2) backward, into the sciatic notch; (3) downward, into the obturator foramen; and (4) inward, on the pubes.

All dislocations are primarily inward or outward. From these initial positions the head may be shifted to any region about the socket within reach of the remnant of un torn capsule (Oscar H. Allis). Allis rejects the old classification and suggests the following:

Low thyroid,	}	All present abduction and outward rotation.
Mid- "		
High "		

Reversed thyroid:

Low dorsal,	}	All present adduction and inward rotation.
Mid- "		
High "		

Dislocations upon the dorsum of the ilium comprise one-half of all hip-dislocations. They are caused by a fall or a blow when the limb is flexed and abducted (as in carrying a weight upon the shoulder), by a fall upon the knees or feet, by a weight striking the back while bending, etc. Allis says rotation inward is the chief element in their production. In these dislocations the head of the femur goes upward and backward, rests upon the ilium, and is always above the tendon of the obturator internus muscle. These dislocations are secondary to thyroid dislocation, muscular action shifting the bone from its initial seat of displacement.

Signs.—Dislocation on to the dorsum of the ilium is indicated by the following symptoms: the buttock appears flat and broad; the great trochanter is above Nélaton's line and is deeply placed; the head of the bone can be detected in its new situation; deep pressure in front of the joints finds a hollow, the leg is shortened by about two or three inches, as a rule; the fascia lata is relaxed; in some thin people the socket can be outlined; when the patient is recumbent the injured extremity can be brought to the perpendicular without flexing the leg (Allis); the knee is somewhat flexed, the thigh is slightly flexed, inwardly rotated, and adducted (Fig. 361) (this is shown by the fact that the axis of the thigh of the injured side, if prolonged, would pass through the lower third of the sound thigh); when the capsule is extensively lacerated there may be no adduction and may be eversion (Allis); the heel is raised, and the great toe of the foot of the injured side rests upon the front of the instep or the ankle of the sound side; rigidity exists; voluntary movement is impossible, though some passive motion is possible in the direction of the deformity (the deformity can be made more marked). If a patient is recumbent and the knees vertical, the foot of the sound extremity is free of the bed, but the foot of the injured extremity touches the bed (Allis's sign).

Diagnosis.—Examine first without anesthesia, and then again while the patient is anesthetized. The x-rays are valuable in diagnosis. Dislocation is distinguished from intracapsular fracture by noting the inversion, the great shortening, the absence of crepitus, the age of the subject, and the nature of the force. The nature of the force, the inversion, and the absence of crepitus mark the diagnosis from extracapsular fracture.

Treatment.—The chief obstacle to reduction in dislocation on to the dorsum of the ilium, Bigelow states, is the untorn portion of the capsule, especially the Y ligament. The ilio femoral, Y, or Bigelow's ligament resembles an inverted Y, arises from the anterior inferior spine of the ilium, is inserted into the anterior intertrochanteric line, and is incorporated into the front of the capsule. To reduce a dislocation this ligament must be relaxed by manipulation or be torn by extension. Manipulation makes the head of the bone retrace its steps over the same route it took in emerging. Give ether, place the patient supine upon a mattress on the floor, flex the leg on the thigh (to relax the hamstrings), flex the thigh on the pelvis, increase the adduction over the middle line, strongly abduct, perform external rotation and extension. This treatment may be summed up as flexion, adduction, external circumduction, and extension, or, as Pick puts it, "bend up, roll out, turn out, and extend." Allis's advice is to fix the pelvis to the floor, lift the head of the bone to the level of the socket, rotate outward by carrying the leg toward the pubis, and extend the femur. If extension and counter-extension are employed, make extension in the axis of the dislocated limb and obtain counter-extension by a perineal band. The extension band is fastened to the thigh by a clove hitch. After reduction put the patient to bed and use sand-bags (as in fracture of the hip) for four weeks. We may tie the knees together instead of using the sand bags. Passive motion is made in the third week. The pulleys must not be used in reduction. They may inflict great or even fatal injury. If the surgeon fails to reduce the deformity, there are two courses open to him. He may let it alone. He may operate. If he lets it alone, the limb will become ankylosed, though probably useful. Allis thinks the dorsal region will be the best place to leave it. If he determines to operate, he must recognize that tenotomy is useless. It is necessary to make a free incision in order to restore the bone.

Dislocation into the Sciatic Notch. In this dislocation the head of the bone passes backward and a little upward, and rests upon the ischium or the margin of the sciatic notch (not in the notch), below the tendon of the oburator internus muscle. The causes are the same as those given for the previous dislocation.

Signs. The signs in dislocation into the sciatic notch are like those of dislocation upon the dorsum of the ilium, but they are not so marked. There are flattening and broadening of the hip, ascent of the trochanter above Nelaton's line, shortening to the extent of an inch, relaxation of the fascia lata. If the knee of the injured side is vertical, the sole of the foot touches

Fig 361. Hip-joint dislocation on to the dorsum of the ilium (Cooper)

the bed. Flexion, inward rotation, and adduction exist, but the axis of the femur of the injured side passes through the knee of the sound side, and the ball of the great toe of the injured side rests upon the great toe of the sound side (Fig. 362). Other symptoms are identical with those of dislocation

Fig. 362.—Hip-joint dislocation into the sciatic notch (Cooper.)

upon the dorsum of the ilium, but are less pronounced. Allis's signs of this dislocation are of value: if, with the patient recumbent, the thighs are brought to a right angle with the body, shortening on the affected side is materially increased; if the dislocated thigh is extended, the back arches as in hip disease.

Diagnosis and Treatment. The signs of dislocation into the sciatic notch are similar to, but are less marked than, those of dorsal dislocation, and, being a backward dislocation, the reduction and treatment are the same as for dislocation backward upon the dorsum of the ilium.

Dislocation Downward into the Obturator Foramen. Downward dislocation is the primary position of most dislocations of the hip, the bone rarely remaining in the thyroid foramen, but usually mounting up as a result

of muscular action or of the initial violence. The cause is violent abduction by falls or by stepping from a moving car.

Signs.—Dislocation downward into the obturator foramen is indicated by flattening of the hip; the head of the bone is felt in its new position and is missed from the acetabulum; rigidity exists; passive motion is only possible in the direction of deformity, and that to a slight extent, a hollow is noted over the great trochanter, which process is well below Nélaton's line and nearer than normal to the middle line. The gluteal crease is lower than is the crease of the opposite side; there is lengthening to the extent of one to two inches, the body is bent forward by the traction upon the psoas and iliacus muscles, and is also deviated to the side, thus causing great apparent lengthening; the limb is advanced partially flexed and abducted, and the foot is pointed straight ahead or is a little everted (Fig. 363); when the patient is recumbent extension is impossible, the knees cannot be pushed together without great pain, and the abductor muscles are hard and rigid. Allis' sign is absent. Unreduced dislocations do well, the patient obtaining a very useful hip-joint (Sédillot).

Treatment. In treating dislocation downward into the obturator foramen give ether and effect reduction, if possible, by manipulation, and, if this fails, by extension. To reduce by manipulation, flex the leg on the thigh and the thigh on the pelvis, and then perform, in the following order, abduction, internal circumduction, and extension. Allis's rule of reduction is as follows: fix the pelvis to the floor, pull the head of the femur outward and above the socket, fix the head, push the knee toward sound knee and extend the femur. If extension is made, make traction in the axis of the limb by means of mushn fastened around the thigh by a clove-hitch. Do not use pulleys; incise rather than use them.

Fig. 363.—Hip-joint dislocation into the obturator or thyroid foramen (Cooper.)

Dislocation upon the pubis is a very uncommon accident. The head of the bone usually rests just internal to the anterior inferior spine of the ilium. The primary position of the bone is in the thyroid foramen; the pubic dislocation, when it occurs, is always secondary, and is due to the initial force and to muscular action.

Symptoms.—In pubic dislocation the head of the bone can be felt and seen in its new position; the hip is flattened; there is a hollow over the great trochanter, this process being found below the anterior superior spine of the ilium; there is shortening to the extent of an inch; the limb is in abduction with eversion (Fig. 364), and the knees cannot be approximated without great pain.

Treatment.—In the treatment of pubic dislocation give ether and employ manipulation as for thyroid dislocation. If this fails, employ extension. The limb is well abducted, extension made downward and backward, and the head of the femur pulled outward "by a towel around the thigh, just beneath the groin" (Keetley). The after-treatment is the same as that for the previous forms.

Anomalous Dislocations of the Hip. In *supra spinous dislocation* the dislocation of the hip is backward, the head of the femur resting upon the ilium above or even anterior to the anterior superior spine. In *ischial dislocation* the dislocation is downward and backward, the head of the femur resting on the ischial tuberosity or in the lesser sciatic notch. *Monteggia's dislocation* is a supra spinous dislocation with eversion of the limb. In *perineal dislocation* the head of the femur is in the perineum. In *suprapubic dislocation* the head of the femur passes above the pubes. In *subspinous dislocation* the femoral head rests on the horizontal ramus of the pubes.

Fig. 364. —Dislocation on pubis (Cooper)

Dislocation with Catching up of the Sciatic Nerve during Reduction.

—This accident causes severe pain. The leg is flexed on the thigh and the thigh is flexed on the pelvis. Allis tells us that the task of reduction is very unpromising. We must strive to put the neck of the femur in such a position that the nerve will "drop off," and yet often the nerve cannot drop off because it is held by adhesion to the injured muscles. Allis attempts reduction by the following plan:

1. **P**lace the patient upon his back and redislocate the femur.
2. **E**xtend the thigh.
3. **F**lex the leg on the thigh.
4. **T**urn the ankle out until the leg is horizontal (this causes the head of the bone to look downward).
5. **"S**hake, shock, jar, adduct, and abduct," to disengage the nerve.
6. **R**otate into socket without flexing the leg (without making the nerve tense).

7. **I**f this fails, make an incision above the popliteal space, and draw the nerve out of the wound. Detach the head of the bone from its entanglement and rotate it into the socket.*

* Allis's views will be found in "An Inquiry into the Difficulties Encountered in the Reduction of Dislocations of the Hip." By Oscar H. Allis, M.D. This highly original and valuable treatise received the Samuel D. Gross prize of the Philadelphia Academy of Surgery in 1895.

Dislocation of the Head of the Femur with Fracture of the Shaft of the Bone. We may incise and replace and wire the fragments. We may use McBurney's hooks as in the shoulder. We may be forced to do a resection of the head.

Allis maintains that it is possible to reduce it by manipulation. He states that the upper fragment is the entire lever, and the lower fragment "is only the agent through which we apply our force." The fragments are not completely separated, but are connected at one side by material which is "partly periosteal, partly tendinous, and partly muscular." This connecting material enables us to make traction upon the upper fragment, but does not allow "rotation, circumduction, and leverage through the agency of the lower fragment." Hence "the only agency at our command is traction." If the dislocation is inward (forward), draw the head outward and have an assistant make direct pressure upon the head of the bone. If this fails, the assistant holds the head of the bone to prevent its slipping into the thyroid depression, and the surgeon makes traction inward or inward and downward. If the dislocation is outward (backward), make traction directly upward to lift the head of the bone to the level of the socket, and try to place the head over the socket by traction obliquely upward and inward. During all these manipulations an assistant presses upon the trochanter to prevent the head of the bone slipping back. Traction is now made downward and inward, and the tightened ligament drags the head of the bone into place.

Dislocations of the Knee.—These dislocations are rare. There are four forms—forward, backward, inward, and outward. They may be complete or incomplete; the commonest dislocations are lateral. The *cause* is violent force, such as a fall, or in jumping from a moving train, or in being caught by the foot and dragged.

Dislocation Forward of the Knee-joint.—In the *complete* form of forward dislocation the deformity is obvious. The limb is usually extended, but it may be flexed. Much shortening exists, the condyles are felt posterior and below, the head of the tibia is felt anterior and above, the patella is movable and the quadriceps is lax; pressure of the condyles upon the contents of the popliteal space arrests the tibial pulse and causes edema and intense pain. In *incomplete* dislocation the symptoms are identical in kind, but are less pronounced.

Treatment. Compound dislocation of the knee joint often demands excision or amputation. In simple dislocation give ether, have one assistant extend the leg while another makes counter extension on the thigh, and the surgeon pushes the bone into place. Reduction is easy because of ligamentous laceration. Place the limb on a double inclined plane, and combat inflammation by the usual methods (see Synovitis, page 625). Begin passive motion in the third week. The patient must wear a knee support for months. If the popliteal vessels are much damaged, gangrene will supervene and amputation will be demanded.

Dislocation Backward of the Knee-joint. In the *complete* form of knee joint dislocation backward, displacement is not so great as in dislocation forward. The head of the tibia projects posteriorly and above, the femoral

condyles anteriorly and below; the leg is, as a rule, partly flexed, but it may be extended, and there is moderate shortening. In *incomplete* dislocation the symptoms are less marked.

Treatment. The treatment of backward dislocation of the knee-joint is the same as for forward dislocation.

Dislocation Outward of the Knee-joint.—Is usually incomplete. The inner tuberosity of the tibia in outward dislocation lies upon the outer condyle of the femur (Pick); the inner condyle of the femur projects internally; the outer tibial tuberosity and fibular head project externally, the former having a depression below it, and the latter above it; the leg is semiflexed, but shortening is absent.

Dislocation Inward of the Knee-joint. Is usually incom-

plete. The outer tuberosity of the tibia in inward dislocation lies upon the inner condyle of the

femur; the outer condyle of the femur forms an external prominence, and the inner tuberosity of the tibia forms an internal prominence. Pick cautions us not to mistake a separation of the lower femoral epiphysis for lateral dislocation (the former is reduced easily, the deformity tends to recur, and there is soft crepitus).

Treatment. In treating lateral dislocation of the knee joint, effect extension and counter extension as in anteroposterior dislocations. The leg is moved from side to side and attempts are made at rotation. The after-treatment is the same as that for anteroposterior luxations.

Dislocations of the Patella.—Are usually acquired. There are thirty-five congenital cases on record (Bajardi). There are three forms: outward, inward, and edgewise. The so-called dislocation upward is in reality rupture of the ligamentum patellæ (page 732).

Dislocation outward (Fig. 365) may be due to muscular action or to direct force, and occurs during extension of the leg. It occasionally happens in a person with knock-knee. If dislocation is complete, the bone lies upon the external surface of the external condyle; if incomplete, the patella rests upon the anterior surface of the external condyle. The leg is extended, flexion is impossible, and attempts at flexion produce great agony. In the patient shown in Fig. 365, flexion became possible in an unreduced dislocation, but not until months after the accident. The knee is wider than normal. There is a hollow in front of the joint. The bone is felt in its new position.

Dislocation inward is very rare. The signs are like those of dislocation outward, except that the patella rests upon the inner condyle.

Fig. 365.—Out dislocation of the patella outward.

Treatment.—Give ether. Raise the body upon a bed-rest, and flex the thigh. Grasp the patella and depress the margin which is farthest from the center of the joint (Pick). The muscles pull the bone into place. Immobilize for three weeks, and then begin passive motion. Incision may be necessary in order to effect reduction.

Dislocation of the Patella Edgewise.—The patella rotates vertically, one edge resting between the condyles. As a rule, the outer border is in the intercondyloid notch (Pick). This condition is produced by direct force when the extremity is partly flexed. Twisting and muscular action have been assigned as causes. The condition is obvious at a glance.

Treatment.—Give ether. Pick recommends "sudden and forcible bending of the knee." In some cases the bone can be pushed into place, the limb being extended and flexed as in the reduction of a lateral dislocation. In some cases incision will be necessary.

Dislocation of the Semilunar Cartilages of the Knee-joint (*the Internal Derangement of Hey; Subluxation of the Knee-joint*). The condition was described by Hey of Leeds in 1803. The interarticular cartilages of the knee-joint are attached in front of and behind the tibial spine, and the convexity of each cartilage is attached to the edge of the corresponding tibial tuberosity by means of the coronary ligament. The internal cartilage is fastened to the internal lateral ligament and has a moderate freedom of movement. The outer cartilage is not connected with the internal lateral ligament and is not freely movable. It has been stated that the outer cartilage is more frequently dislocated than the inner, but modern experience indicates that this is not true, and that the internal cartilage is the one most apt to suffer. In 17 cases operated upon by Barker, the internal cartilage was involved in every case ("Lancet," Jan. 4, 1902). Those persons whose occupations force them to pass considerable time upon their knees are predisposed to this accident (Annandale). The derangement of the cartilage is usually caused by a sudden external rotation of the tibia, while the knee-joint is in partial flexion, for instance, when the patient stumbles over an obstacle, the knee-joint being partially flexed, the tibia is twisted outward. When the joint is flexed, a normal cartilage moves backward, and when it is extended, moves forward again. When the cartilage is thrown out by the sudden eversion and flexion of the tibia, it is caught and does not move into place readily when the leg is extended. The tear takes place in the direction of the fibers of the cartilage.

Symptoms. The indications of interarticular cartilage displacement are a sudden, violent, sickening pain in the knee, which may be so severe as to cause the patient to fall to the ground. The knee is in a position of fixed semiflexion. Further flexion is possible, but extension is impossible. In some cases the patient can voluntarily make further flexion, in others, the pain is so severe that he either cannot or will not do it; but increase of flexion can be obtained by passive motion. The joint is, however, blocked both to passive and to voluntary extension. Attempts at passive motion are productive of fierce pain. If either cartilage is displaced away from the tibial spine, a prominence may be found on one or the other side of the knee joint. If the displacement takes place toward the tibial spine, a prominence may be found on one side of the ligament of the patella. Subluxation is rapidly followed by inflammation of the synovial membrane of the joint and of the cartilages themselves; and swelling quickly masks the projection of the

cartilage. This accident is frequently mistaken for the blocking of the joint by a floating cartilage; but a dislocated cartilage always remains in the same position, and a loose cartilage changes its position from time to time (Turner). Loose bodies in a joint produce pain of a shifting character, and interference with both flexion and extension, or with either flexion or extension in an irregular way (Cotterill). In regard to the diagnosis, Cotterill points out that in a sprain of the joint extension is not painful, but flexion is interfered with; whereas, in the dislocation of a cartilage of the joint, flexion is still possible, but extension cannot be carried out ("Lancet," Feb. 22, 1902).

Treatment.—I have used with satisfaction to reduce a displaced internal semilunar cartilage a method described by Henry W. Jacob ("Brit. Med. Jour.," March 7, 1908). It is not followed by severe synovitis unless the patient has walked or has made repeated efforts to reduce the displacement, and as it is a painless method ether is not required. Jacob describes it as follows:

"The patient lies on a bed or couch, the surgeon standing on the outer side of the limb affected, with his face toward the patient's foot; the patient then raises his leg off the couch in the semiflexed condition, the surgeon grasps the patient's leg in both hands, and using his own thigh as a fulcrum, by means of a steady pulling movement draws the patient's leg outward while the surgeon's thigh keeps the patient's femur in a fixed position; directly this movement is effected the patient must steadily extend the limb, and the displaced cartilage will probably go back with a slight click; if the first movement of extension is not successful the maneuver must be repeated without any hurry or unnecessary force and after a few attempts the cartilage can usually be felt to slip in without pain or inconvenience."

In treating dislocation of a semilunar cartilage of the knee it is customary to give ether and reduce by forced flexion and external rotation. Extension becomes possible if the cartilage is freed. During these maneuvers an assistant endeavors to push any projection of cartilage into place. After reduction apply a splint for two weeks and combat inflammation by proper remedies (see Synovitis); then begin passive motion. At the end of two weeks apply a firm knee-cap made of leather and let the patient get about on crutches. After a couple of weeks the crutches can be laid aside. As recurrence of the displacement is usual, the patient should wear a knee cap during the day for many months. A partial tear may entirely heal when thus treated by rest and support; an extensive tear will not, although even in such cases a useful but somewhat stiff joint may be obtained. If it is found impossible to unlock the blocked joint, or if the tear is extensive and redislocation is prone to occur, an operation is advisable. The joint is opened and the loose cartilage is pushed into place and held by stitches or the loosened portion is excised.

Dislocations of the Fibula: Dislocation at the Superior Tibio-fibular Articulation.—This injury is rare. The head of the fibula may go forward or backward. The causes are direct force and violent adduction of the foot with abduction of the knee (Bryant).

Symptoms.—After dislocation of the fibula the position is one of semiflexion of the knee, voluntary extension and flexion being impaired or lost. A distinct movable projection is readily noticed in front or behind, which is found to be continuous with the fibula. There is a depression over the normal position of the head of the fibula.

Treatment. In treating dislocation of the fibula bend the knee to relax the biceps, and proceed to push the bone into place. Put a compress over the head of the fibula, apply a bandage, and put the limb on a double inclined plane for three weeks. At the end of this time put a lacing knee support upon the knee and let the patient up. Displacement being liable to recur, a knee-cap must be worn for a year.

Dislocations of the Ankle-joint. These injuries are not unusual. Fracture is a frequent complication. There are five forms of ankle-joint dislocation—outward, inward, forward, backward, and upward.

Lateral dislocations of the ankle-joint are either outward or inward, and may be complete or incomplete. In these dislocations the astragalus rotates. In incomplete dislocations "there is no great separation of the trochlear surface of the astragalus from the under surface of the tibia, but the outer or inner margin of this surface is brought into contact with the articular surface of the tibia, and the whole foot presents a lateral twist" (Pick). The *causes* of these dislocations are twists of the joint.

Symptoms.—Incomplete outward dislocation of the ankle-joint is known as *Pott's fracture* (see page 620). Complete outward dislocation, in which the articular surface of the astragalus is completely displaced outward from the articular surface of the tibia, and which condition is associated with a fracture of the fibula and separation of the inferior tibiofibular articulation, is known as *Dupuytren's fracture*. In incomplete dislocation the foot goes outward and upward, the fibula is fractured, and the tibiofibular ligaments are torn off. In Dupuytren's fracture the ankle is broad, the inner malleolus projects and looks lower than natural, the outer malleolus ascends with the foot, the foot rotates outward, and crepitus can be detected. In inward dislocation which is associated with fracture of the inner malleolus there is inversion, the outer malleolus projects, and crepitus can be detected. In incomplete separation the symptoms are similar, but are not so marked.

Treatment.—In treating a case of dislocation of the ankle joint the deformity is reduced by flexing the leg on the thigh and the thigh on the pelvis, an assistant makes counter extension from the knee; the surgeon makes extension from the foot, and at the same time rocks the astragalus into place. Dupuytren's fracture is treated in the same manner as Pott's fracture (page 621). Dislocation inward is treated in a fracture box for the same period as Pott's fracture.

Anteroposterior dislocations of the ankle-joint are rare. The *cause* is the catching of the foot in jumping or falling—direct violence. In dislocation forward the foot is lengthened, the heel is not conspicuous, the tibia and fibula project against the tendo Achillis, and the relation of the malleoli to the tarsus is altered. In incomplete dislocation the symptoms are similar, but less pronounced. In dislocation backward the foot is shortened, the tibia and fibula project in front, the heel is prominent, and the relation between the malleoli and the tarsus is altered. In incomplete dislocation the symptoms are similar, but less marked.

Treatment. In anteroposterior dislocation of the ankle joint, reduce as in lateral dislocations. Sometimes the tendo Achillis must be cut. Apply a plaster of Paris dressing, and let it be worn for two weeks, then begin passive motion, and let the patient wear side splints for a week longer.

Dislocation upward of the ankle-joint, or Nélaton's dislocation,

a very rare injury. The astragalus is wedged between the widely separated tibia and fibula. This dislocation is usually associated with fracture. The cause is a fall upon the feet from a great height.

Symptoms.—Upward dislocation of the ankle joint is indicated by the widening of the ankle and by the flattening of the foot. The malleoli are nearly on a level with the plantar surface of the foot, and there is absolute rigidity.

Treatment.—In treating upward dislocation of the ankle joint give ether, and try to reduce by powerful extension and counter extension. Treat the injury afterward in the same manner as an anteroposterior luxation.

Dislocation of the Astragalus. The astragalus may be displaced from the bones of the leg and at the same time be separated from the rest of the tarsus. The displacement may be forward, backward, outward, inward, or rotary.

Dislocation of the astragalus forward or backward is caused by falls or twists.

Symptoms.—In forward dislocation the astragalus projects strongly; there is shortening of the foot, and the malleoli approach the plantar aspect of the foot, the foot is deviated to one side or to the other, and there is absolute rigidity of the ankle joint. In incomplete luxations the symptoms are similar, but less marked. This dislocation may be obliquely forward. In backward dislocation of the astragalus the foot is not deviated to either side; the astragalus projects between the malleoli and above the os calcis, and the tendo Achillis is stretched over the projection. Rigidity is absolute. This dislocation may be obliquely backward.

Lateral and Rotary Dislocations of the Astragalus.—Lateral dislocations of the astragalus are rare, are always compound, and are always associated with fracture. In rotary dislocation the astragalus remains in its normal habitat after rotating on its own axis, either horizontal or vertical. The causes of rotary dislocation are twists of the foot when it is at a right angle to the leg (Barwell). The symptoms of rotary dislocations are obscure. There is rigidity, but sometimes portions of the astragalus may be made out.

Treatment of Dislocations of the Astragalus.—In treating astragalus dislocation reduce under ether by flexing the knee to relax the gastrocnemius, extending the foot, and pushing the bone into place. It may be necessary to cut the tendo Achillis. After reduction put up the foot and leg in a plaster-of-Paris dressing for two weeks, and then begin passive motion and apply antiseptics, which are to be worn for one week more. If reduction fails, support the limb on splints, combat inflammation, and endeavor to bring about union between the dislocated bone and the tissues. Often, in unreduced dislocation, the skin sloughs over the projecting bone. Excision is demanded the moment sloughing is seen to be inevitable. Cases of compound dislocation of the astragalus require immediate excision.

Subastragaloid Dislocation. This condition is a separation of the astragalus from the os calcis and scaphoid, without separation from the bones of the leg. Pick states that the usual classification for these dislocations is forward, backward, inward, and outward, but that the displacement is, as a rule, oblique, the foot passing backward and outward or backward and inward. The cause is twisting.

Symptoms.—In subastragaloid dislocation the astragalus projects on the dorsum; the foot is everted in outward dislocation and inverted in inward dislocation, the relation of the malleoli to the astragalus is unaltered; the ankle joint is not absolutely rigid; the foot "is shortened in front and is elongated behind" (Pick).

Treatment.—To treat subastragaloid dislocation make extension in the direction opposite to that of the displacement. In dislocation of the tarsus backward fix a bandage around the foot, on a level with the heads of the metatarsal bones, which bandage the surgeon ties around his shoulders. The surgeon puts one knee in front of the ankle and thus fixes the leg, raises himself up to make extension upon the tarsus, and moulds the bone into position. Tenotomy may be necessary. After reduction apply a plaster of Paris dressing and have it worn for three weeks. The ankle joint, fortunately, is not involved, and stiffness of this articulation need not be apprehended. If reduction is impossible, take the same course as in luxations of the astragalus.

Dislocations of the other tarsal bones are very rare. Single bones may be dislocated, or the luxation may occur at the mediotarsal articulation.

Symptoms and Treatment. Projection is an obvious symptom in dislocation of the other tarsal bones. The *treatment* is to reduce by extension and moulding, the part being put up in plaster-of-Paris dressing for two weeks.

Dislocations of the metatarsal bones are rare.

Symptoms and Treatment.—Shortening of the toes and projection of the dislocated bone are symptoms of dislocation of the metatarsal bones. To *treat* these dislocations reduce by extension under ether and put up in a plaster-of-Paris dressing for two weeks. If reduction fails, the functions of the foot will not be much impaired.

Dislocations of the phalanges are very rare. The first phalanx of the big toe is the one most liable to dislocation.

Symptoms and Treatment.—Dislocations of the phalanges are obvious. The treatment is by reduction as in dislocations of the thumb. Immobilize for two weeks.

OPERATIONS UPON BONES AND JOINTS

Osteotomy.—By the term *osteotomy* the modern surgeon means literally the sectioning of a bone for the purpose of straightening a limb ankylosed

Fig. 366.—Adams's large saw

in a bad position, correcting a bony deformity, or amending a vicious union of a fracture. In a *linear osteotomy* the bone is transversely or obliquely divided at one spot, in a *cuneiform osteotomy* a wedge-shaped portion of

bone is removed. The operation of osteotomy may be performed with a saw (Fig. 366) or with an osteotome. The saw creates dust, draws much blood from the wound, and lacerates the tissues to a considerable degree. Most surgeons prefer the chisel or the osteotome. The osteotome slopes down to a point from each side (Fig. 367), the chisel is straight on one side and on the other is bevelled to a point.

Fig. 367.—Osteotome.

Fig. 368.—Rawhide mallet.

Osteotomy for Genu Valgum, or Knock-knee (Macewen's Operation).

Fig. 369.—In this operation the instruments required are the scalpel, hemostat forceps, osteotomes of several sizes, a mallet (Fig. 368), and a sand bag stuffed in an aseptic towel.

Positioning.—The patient lies upon his back, being rolled a little toward the diseased side. The leg of the diseased side is partly flexed upon the thigh and the thigh upon the pelvis, and the extremity is laid upon its outer side, the sand bag being placed between the extremity and the body, opposite to the incision. The flexion of the knee relaxes the popliteal

Fig. 369.—Position of the right knee joint for Macewen's operation. The sand bag is placed between the leg and the body, opposite to the incision.

Fig. 370.—Macewen's operation for genu valgum. The chisel is held in the position shown, and the bone is cut in the direction of the arrow. The bone is then bent back to make a wide gap in the bone after the cut.

veins and arteries from injury. The surgeon, if operating on the right leg, stands on the right side of that extremity; if operating on the left leg, he stands opposite the right leg. The knife is inserted into the incision and carried to the bone at the inner side of the knee, just in front of the anterior cruciate ligament and at a level with the upper border of the patella. The knife is then bent back to make a wide gap in the bone after the cut. At the same time the osteotome is inserted and the bone after

insertion is turned to a right angle with the shaft of the femur, half an inch above the epiphysis (Fig. 369). The osteotome is struck several times with a mallet; the handle is moved several times toward and from the body, so as to widen the cut in the bone (Fig. 370), the osteotome is again struck with the mallet several times; it is again moved toward and from the body, and this process is continued until the bone is cut two-thirds through. If the osteotome becomes tightly fixed, it should be withdrawn and a smaller one introduced. In the soft bone of a young child this to-and-fro movement of the chisel, if carefully executed, is not liable to break the instrument. In dense bone it may break the instrument; hence, when doing an osteotomy in dense bone, the osteotome is moved to and fro across the limb and slight downward pressure upon the handle will to a great extent prevent binding. When the bone is cut two-thirds through, the osteotome is withdrawn, a piece of wet antiseptic gauze is held over the wound, and the surgeon fractures the femur by strong adduction. The wound is neither sutured nor drained, but is dressed antiseptically, the entire extremity is wrapped in cotton, and a plaster of Paris dressing is applied and carried up to the groin. The dressing may be removed in two weeks, and the patient may subsequently be treated with sand bags, as for an ordinary fracture of the thigh, but without extension. This operation is scarcely ever fatal.

Ogston's Operation (Fig. 369). In this operation the internal condyle is sawed off obliquely with an Adams saw—a proceeding which permits the straightening of the knee. The objection to the procedure is that it opens the knee-joint, and that this cavity fills up more or less with a mixture of blood and bone-dust. Macewen's operation is decidedly the safer.

Osteotomy for a Bent Tibia. In this operation the instruments required are the same as those used in the above operation. The tibia is divided transversely or obliquely (linear osteotomy), or a wedge shaped piece is removed (cuneiform osteotomy). The oblique incision is the best. If the convexity of the tibial curve is inward, cut the bone from above downward and from in front backward; if the curve is forward, section the bone from above downward and from within outward. The fibula need rarely be interfered with. After the osteotomy the limb is treated just as it would be for a fracture.

Osteotomy for Faulty Ankylosis of the Hip-joint. This operation is performed in order to allow straightening of a limb that has undergone bony ankylosis in a faulty or an inconvenient position. In some cases an attempt is made to obtain a movable joint, but in most cases the surgeon must be satisfied with an ankylosis in extension. Osteotomy may be performed through the neck of the femur or through the shaft of the femur below the trochanters.

Osteotomy through the neck of the femur is performed (1) with a saw (Adams's operation) or (2) with an osteotome.

1. *Adams's Operation* (Fig. 371). In this operation the instruments required are a scalpel, hemostatic forceps, a long, blunt-pointed tenotome, and an Adams saw.

Operation. The patient lies upon his sound hip; the surgeon stands upon the side to be operated upon, and back of the patient. The knife is entered a finger's breadth above the great trochanter, is pushed in until it strikes

the neck of the bone, is then carried across the front of and at a right angle with the neck, and is withdrawn, enlarging the wound, in the soft parts as it emerges, to the extent of an inch. The saw is then introduced and the neck of the femur is entirely divided. After the osteotomy dress the wound antiseptically and place the extremity straight. To straighten the limb it may be found necessary to cut contracted tendons and fascial bands. After securing extension and applying dressings use the weight extension apparatus and the sand-bags. Begin passive movements from the start if movable joint is desired; few patients can tolerate the pain necessary to bring this about. If it is determined to aim for a stiff joint, treat the case as an intracapsular fracture would be treated.

With an Osteotome.—The instruments required in this operation are the same as those used for genu valgum. A sand bag is not needed. The position of the patient is the same as that in Adams's operation. An incision one inch long is made, starting just above the great trochanter, ascending in the axis of the femoral neck, and reaching to the bone. An osteotome is introduced, is turned to a right angle with the neck of the bone, and is struck with a mallet until the bone is completely divided. (It is not to be divided partially and then broken.) The after treatment is the same as that for Adams's operation. The operation with the osteotome is to be preferred to that by the saw.

Osteotomy of the Shaft of the Femur below the Trochanters (Gant's Operation)—In this operation (fig. 371) the saw may be used, but the osteotome is to be preferred. The instruments employed are the same as those used for Adams's operation, plus an osteotome operation. The position in Gant's is like that in Adams's operation. A longitudinal incision one inch long is made upon the outer aspect of the femur and on a level with the lesser trochanter. The osteotome is inserted and the bone is completely divided below the lesser trochanter. The after treatment is the same as that for Adams's operation. Gant's operation is the best method for correcting faulty position in bony ankylosis, and Adams's operation can only be employed in those cases where the femur still has a neck which is practically unchanged.

Osteotomy for Faulty Ankylosis of the Knee-joint. This operation is performed for bony ankylosis of a knee in a position of flexion. The instruments employed are the same as those used for genu valgum.

Operation. The patient lies upon his back with his thighs flat upon the bed; the leg hanging over the end of the bed. The surgeon stands on the patient's right side. Just above the patellar articular surface upon the femur a transverse incision is made, one inch in length and reaching to the bone. The osteotome is introduced and the bone is cut *nearly* through. The leg is then forcibly extended. It must not be extended too violently, or the popliteal vessels may be injured. In cases where the structures of the popliteal space are tense, the leg must not be brought at once into extension, but this position should be attained gradually by means of weights. The

Fig. 371. Osteotomies through the neck of the femur: A, Adams's operation; B, Gant's operation.

wound is dressed aseptically, and the extremity is placed upon a double inclined plane and is treated as for fracture near the knee-joint.

Osteotomy for vicious union of a fracture is performed in case of angular deformity, and is carried out in the same manner as are the above procedures. It is best, when possible, to enter the osteotome upon the concavity of the bent bone, so that the periosteum will not rupture when extension is made, and the patient will in consequence gain a longer limb.

Osteotomy for Hallux Valgus.— In this operation a linear osteotomy is made through the neck of the metatarsal bone of the great toe, the toe is forcibly adducted, and a splint is applied to the inside of the foot and the toe.

Osteotomy for Talipes Equinovarus. The instruments required in this operation are a scalpel, hemostatic forceps, a narrow, blunt pointed saw, special directors, bone-cutting forceps, sequestrum forceps, and scissors.

Operation (after Barker). The patient lies upon his back, the thigh is semiflexed, the knee is bent, and the sole of the foot rests upon the table. The surgeon stands to the right side if it is the right limb which is to be operated upon, or to the left side if it is the left limb. The surgeon feels for the outer surface of the cuboid bone, and cuts away from over the latter a piece of skin corresponding in size with the bone wedge intended to be

Fig. 372.—Davy's director (Pyc).

removed (this piece of skin must include the bursa which forms in these cases). The foot is then turned outward, the astragaloscaphoid articulation is located, and over this an incision is made "from the lower to the upper dorsal border of the scaphoid bone" (Barker), reaching through the skin only; the foot is placed again in the first position, all the soft parts are raised from off the superior surface of the tarsus, and a triangular surface corresponding with the base of the wedge to be removed is cleared; a "kite shaped" director (Fig. 372) is passed into the external wound and projected from the internal wound, the saw is pushed through the groove of the director nearest the toes, and is made to cut through the tarsus, from the dorsum to the sole, at right angles to the metatarsal bones; the saw is pushed through the groove of the director nearest the ankle, and is made to cut from the dorsum to the sole, at right angles to the long axis of the calcaneum; the wedge-shaped piece of bone is grasped with sequestrum forceps and cut out with scissors, with bone forceps, or with a blunt bistoury. The wound is well irrigated, the foot is straightened, the internal wound is sewed up, the external wound is sutured except at its lowest portion, where a drainage tube is to be retained for twenty four hours, and the wound is dressed antiseptically. The foot is put up in plaster or upon a Davy splint.

Osteotomy for Talipes Equinus. This operation is described by Mr. Davy, who devised it as follows: * "Taking the line of the transverse tarsal joint as a guide, on the outer and inner sides of the foot and immediately over the joint, two wedge shaped pieces of skin are removed, equal in extent to the amount of bone demanded. The soft structures are freed on the dorsum of the foot in the way previously described, but, as the base of the

* Barker's "Manual of Surgical Operations."

osseous wedge for equinus cases is at the dorsum and its apex at the sole, the parallel wire director, instead of the kite-shaped varus one, is used. The saw is successively inserted in its grooves, and by keeping in mind the idea of a keystone a clean wedge of bone is cut out from the dorsum to the sole of the foot. The wedge is extracted, and the foot is straightened and is put up in plaster of Paris or is placed on a Davy splint.

Operative Treatment of Recent Fractures.—We have learned from radiographs that the common treatment by splints usually results in more or less permanent displacement. In many cases this does not interfere with function; in some cases it does. There is much impairment of function after a fracture of the patella with wide separation of the fragments, and after a fracture of a long bone with marked angulation or with decided overlapping of the fragments. The most perfect results are obtained by operation, exposure of the fragments, correction of deformity, while we see the fragments and fixation. Practically all surgeons agree that for fracture of the patella and for fracture of the olecranon treatment by operation gives the best results. All compound fractures require operation. In a fracture of a long bone with incomplete reduction or with a deformity which recurs in spite of splinting, operation should be performed. In most fractures of long bones perfect apposition of the fragments is not obtained, although we may think it has been. The x-rays illustrate the error and we often find it on incision. Bloodgood points out that in fractures near joints there is great difficulty in reduction and little evidence of deformity. Oblique fractures of the upper third of the femur should be operated upon because of the difficulty or impossibility of reduction by any other method.

In some cases of fracture of the bones of the forearm operation is indicated to preserve pronation and supination. If the ends of the fragments do not glide when they are apparently in contact and are rubbed to and fro, it means that some of the soft parts are caught between them and operation is necessary in order to remove the intervening tissue. If this is not done there will be non-union or delayed union. Many comminuted fractures should be treated directly after incision of the soft parts. If an important nerve or blood-vessel has been divided, operation is required for that reason. During the operation the seat of fracture should be exposed and the fragments fixed. In a fracture of the neck of the femur in a youth or a person of middle age the fragments should be nailed together, otherwise there will probably be much lameness. Many fractures of the clavicle should be exposed by incision and wired. This should always be done when sharp ends endanger or have wounded vessels.

Some cases of fracture of the humerus near the elbow and some cases of fracture of the surgical neck of that bone require operation. Most cases of fracture with dislocation require it.

In any case of fracture, if it seems that non-operative treatment will fail to give a good functional result, operation should be advised if it is not contra-indicated by the condition of the patient.

There is, of course, some risk in treatment by incision and it is only justifiable in competent hands and amid proper surroundings. It can never be routine treatment and will never be extensively employed outside of a hospital. The occasional operator should look to it with less confidence than does

the daily operator. If infection should occur it will be a catastrophe and may cause death, hence, perfect asepsis is imperatively required.

Bone fragments may be held together by wire, nails, screws, plates, bone ferrules, chromic catgut, clamps, etc., according to the needs of the case. As a general thing silver wire is used, but it has defects. It fails to retain fragments in rigid apposition and unless very thick wire is used it is liable to break. Silver wire was used for this purpose in 1775 by Lapeyrolle and Sicre of Toulouse (Geo. W. Guthrie, "Amer. Medicine," March 7, 1903). In most cases I prefer the silver plate perforated for short silver screws as employed by Prof. Halsted. This gives rigid fixation and the screws do not project from the wound. The plate is not removed unless it causes trouble.

After operation there must be careful fixation by splints or plaster of Paris, the circulation must be guarded and maintained, massage should be used, and passive movements instituted as in a case treated without incision.

If rigid fixation of the fragments was secured, repair takes place with very little callous formation.

Recent Transverse Fracture of the Patella. (See page 612.)

Bone-grafting, or Transplantation.—(See page 508.)

Operative Treatment of Ununited Fracture.—The instruments required in this operation are a scalpel, hemostatic forceps, dissecting forceps,

Fig. 373.—Hamilton's improved bonesdrill.

Fig. 374.—Brannan's drills with Wyeth's adjustable handles.

retractors, Allis's dissector, an awl or special drill (Figs. 373, 374), chisels, a mallet, a fine saw, lion-jaw forceps, and silver wire.

In operating, incise longitudinally down to the seat of fracture, retract the periosteum from the bone, drill the bones before cutting them, chisel away the material of imperfect union, saw through each bone end far enough from the seat of fracture to reach sound tissue, pass large silver wires through the holes (this wire should be one tenth inch in diameter for the femur, one sixteenth inch for the patella, etc.) (Fig. 377), twist the wires a fixed number of times (two complete turns) in the direction that the hands of a watch move (this is Keen's direction. In case removal of the wires should be demanded later we know how to untwist them), sever the ends of the wires and hammer their stems against the bones. The wires may never require removal. Dress the part as a recent fracture. Various plans besides wiring have been employed in ununited fracture. Gussenbauer's

clamp is used by some. Clayton Parkhill's bone-clamp is a very useful appliance, and holds the fragments firmly in contact (Fig. 255). Menard and Lannelongue inject a 1 : 10 solution of chlorid of zinc between the fragments and around their ends, and then immobilize the parts. Some surgeons unite the fragments with kangaroo-tendon instead of wire (suturing of bone), others use nails of bone or ivory; others use screws. Senn asserts that the above methods will not hold fragments in contact if these fragments have a tendency to become displaced. Senn fastens the bones together by hollow cylinders of decalcified bone or ivory, the cylinders being perforated in many places (bone ferrules). The soft parts are sutured, no drain is used, and the limb is encased in plaster of Paris.

Ununited Fractures of the Femoral Neck.—Loreta did the first successful operation for this condition about seventeen or eighteen years ago. The operation is not adapted to the aged, but should certainly be employed in youths and middle-aged individuals if the general condition of the patient or

Fig. 375.—Method of securing screw of Freeman's apparatus in fracture of neck of femur; the wooden plates embracing screws (Freeman, in "Annals of Surgery," Oct., 1904).

some particular diseased state does not forbid, and if pain is severe and disability is pronounced.

Leonard Freeman advises an anterior incision beginning below and external to the anterior superior iliac spine and extending downward, external to the sartorius, for 3 or 4 inches ("Annals of Surg.," Oct., 1904). When the fragments are exposed, the connective tissue between them is cut away by means of scissors, the surfaces of the fragments are freshened with a chisel or a curet, bleeding is arrested by pressure and hot water, and loose osseous splinters are removed (Freeman). Some surgeons have fixed the fragments together by nails, screws, or pegs of bone or ivory, access to the trochanter being best obtained for this purpose by making a second incision over the outer portion of that bony process. As Freeman points out, however, the head is often so very soft that none of these appliances will obtain fixation.

Freeman has devised a clamp for this purpose (Figs. 375, 376). An additional incision is made over the trochanter and holes are bored for the clamp

screws, one hole being drilled "through the base of the trochanter, the external fragment of the neck, and into the head of the bone" ("Annals of Surgery," Oct., 1904). The wound is closed, dressings are applied, and extension is made on a long side splint, a pad being placed beneath the trochanter to prevent the disposition to pass backward, which movement, if it occurs, will cause external rotation of the limb and separation of the fragments. In about eight weeks the extension is removed and the patient is allowed about on crutches. Dr. H. Augustus Wilson has succeeded by nailing the fragments together. He gets such a patient up on crutches in two weeks ("Amer. Jour. Orthopædic Surgery," Jan., 1908).

In Freeman's case the screws were removed in two weeks because of infection of the cancellous tissue. A similar condition arose in Davis's case in which two steel drills were used.

According to Freeman, 14 operations for ununited fracture of the femoral neck are on record ("Annals of Surgery," Oct., 1904). Four of these cases were done by G. G. Davis. Cobb finds six additional cases and reports one of his own (Farrar Cobb, in "Boston Med. and Surg. Jour.," May 10, 1906). Dr. H. Augustus Wilson has collected 36 cases of direct fixation of old intra-capsular fractures ("Amer. Jour. Orthopædic Surg.," Jan., 1908).

Ununited Fracture of Patella.—An incision is made in the long axis of

Fig. 376.—Completed screw and clamp of Freeman's apparatus for fixation of fracture of neck of femur (Freeman, in "Annals of Surgery," Oct., 1904).

the limb, over the middle of the space between the fragments, from well above the upper fragments to well below the lower piece; this incision divides all the soft parts. The soft parts are retracted, but the periosteum is undisturbed; each fragment is bored (Fig. 378, 1) in one or two places; the surfaces of the fragments are cut square through sound bone with a saw; all old reparative material is cut away; the wires are passed through the perforations, twisted, cut off, and hammered down (Fig. 378, 2). If the bone fragments cannot be approximated, it may become necessary to incise the muscle around and above the patella or partially to separate the tuberosity of the tibia and bend this process upward. A small drain is inserted above the bone, the wound is sutured, aseptic dressings are applied, and the limb is put upon a Macewen splint.

Treves's Operation for Caries of the Lumbar and Last Dorsal Vertebrae.—The instruments required are a scalpel, hemostatic forceps, grooved director, an Allis dissector, sequestrum forceps, curet spoons, and a sand-bag. We will describe the operation as performed on the right loin.

Operation.—The patient lies upon his left side, with the knees drawn up and a sand-bag under the left loin. The surgeon stands behind the patient (Barker). An incision is made at the outer border of the erector spinæ mass, reaching from the last rib to the iliac crest and going down at once to the lumbar fascia. The lumbar aponeurosis is opened, the erector spinæ muscle is retracted inward, and the anterior portion of the erector spinæ sheath is incised. The quadratus lumborum muscle is next cut, and then the anterior leaflet of the lumbar aponeurosis is slit. The abscess is thus reached and opened and tuberculous pus flows out. The cavity is carefully irrigated. The abscess cavity is irrigated with quantities of warm corrosive sublimate solution (1:5000). The cavity is filled, the fluid is allowed to flow out, its exit being aided by pressure in front and changes of posture; the cavity is filled again, and so on, and, after all loose debris is removed, the bodies of the vertebrae are carefully examined with the finger and diverticula are opened. Loose pieces of bone are removed with spoons or forceps, and cavities are thoroughly but lightly curetted, as in some places the wall is very thin. By means of properly shaped spoons

Fig 377.—Wiring of bones for unioned fracture. *a a*, Sawen surfaces approximated after removal of old material which was interposed between the fragments, *d d*, *b b*, perforations drilled completely across the bone; *c, c*, wires ready for twisting.

Fig 378.—Wiring of the patella: 1. Fragments cut and cleaned and the wires passed, 2. wires twisted and secured down upon the bone after Barker.

carious bone can be removed even from the anterior surface of the column (Treves). Thus the wall of the abscess is completely removed. Finally all debris is washed out by irrigation with mercurial solution; any mercurial solution which might remain is washed out with warm water or salt solution, and the interior of the cavity is wiped dry. At this stage most operators introduce iodoform emulsion. Whether or not this is done, "the wound is closed by a series of silkworm-gut sutures, passed sufficiently deep to include the greater part of the muscular and tendinous structures with the skin" (Treves's "Operative Surgery").

Aspiration of Joints.—In certain cases of joint-effusion from inflammation, tuberculous or otherwise, and sometimes in hemorrhage into a joint, it is desirable to remove the fluid by aspiration. The pneumatic aspirator is used (Fig. 379). The trocar and cannula are thoroughly aseptitized and the joint is prepared as for a set operation. The needle is entered at a surface

free from vessels. The directions for using an aspirator are as follows. insert the stopper firmly into a strong bottle (preferably a clear glass one), then attach the short elastic hose to the stopcock *B* of the tube projecting from the stopper, and attach the other end of the same elastic hose to the exhausting or inward-flowing chamber of the pump. Next attach one end of the longer elastic hose to the stopcock *A* projecting from the stopper and the other end to the needle. Care should be taken that all the fittings or attachments are placed firmly into their respective places. Now close the stopcock *A* and open the stopcock *B*. By giving from thirty-five to fifty strokes of the pump a sufficient vacuum can be produced to fill with the fluid from the joint a bottle holding from a pint to a quart. After having formed the vacuum, close the stopcock *B*, and insert the needle in the joint. When the stopcock *A* is opened, suction through the needle draws the fluid from the joint. The trocar may also be used to inject antiseptic agents. After the completion of aspiration the part is dressed antiseptically and the extremity is put at rest upon a splint.

Excisions of Bones and Joints.—The ancients practised excision and resection for compound dislocations and fractures. The operation was first formally advised as a substitute for amputation in joint disease by Mr.

Fig. 379.—Aspirator and injector.

Park in 1782. The terms excision and resection are usually employed as synonymous, but such a use is not strictly accurate. According to Professor Ashhurst, the term excision means "the removal of an offending part without that total ablation of the affected portion of the body which is implied by the term amputation. Hence we speak of excisions of tumors, of joints, of the eyeball, etc." *Resection* has a more restricted meaning; it signifies "an operation which takes away a middle portion and brings the ends together again, and is thus in strict surgical language limited to partial excisions of the long bones" (International Encyclop of Surgery, edited by John Ashhurst, Jr.). Excision of a joint is the removal of the articular portions of the bones of the joint, and also the cartilage and synovial membrane. In the hip-joint and shoulder-joint only the head of the long bone may be removed, and not the articular surfaces of both bones. In partial excision of a long bone excision (resection) for bone disease enough bone is known to have

been removed only when the remaining bone bleeds. *Complete excision* of a bone is the removal of an entire bone. *Partial excision* or *resection* is the removal of a portion only of a bone. Excision is a conservative operation which often averts amputation.

Excision may be performed by the *open* method, in which the periosteum is not preserved, or it may be performed by the *subperiosteal* method, in which the periosteum is carefully separated by a rugine and the capsular ligament is preserved. *Arthrectomy*, or *erasion*, is the excision of the diseased synovial membrane and ligament, and also small foci of disease of bone and cartilage.

Excision may be employed for compound dislocation, and in compound dislocations of the elbow and the shoulder it is usually performed. Excisions for compound dislocations in other large joints are very dangerous; they are rarely attempted in battle field practice, and are to be avoided even in civil practice unless the patient is young and vigorous and every advantage can be given him during the operation and convalescence. Excision for deformity is rarely performed except upon the hip, the knee, and the shoulder, and these excisions must not be employed if the patient's condition leads one to fear the result of a protracted convalescence. Excision of the elbow, however, is usually a safe operation. In excising for deformity always consider the patient's trade and the demands of habitual position which it makes upon him.*

Excision is largely employed for joint-disease, especially for tuberculous joints. Bell states that attempts to preserve the limb without excision are more justifiable in the lower than in the upper limbs, because operation in the lower extremity is more dangerous than in the upper, and because a cure without operation in the lower limbs, if this cure can be brought about, gives as good a result as a cure by excision. In the upper extremities the danger from operation is less than is the danger from waiting. In a young subject an excision may remove the epiphysis, and thus lead to permanent shortening, which is productive of less inconvenience and deformity in the arm than in the leg. The great danger of excision operations is that the section may be made through cancellous bony tissue; hence disastrous suppurations, phlebitis, myelitis, septicemia, or pyemia may follow; further, in excision the cut is often made through diseased tissue, and a protracted convalescence is often inevitable. Amputation is effected through healthy tissue, and the convalescence is short. Excision, however, when successful, gives the patient a very useful limb.

Erasion, or Arthrectomy.—Erasion is the complete removal of diseased synovial membrane, ligaments, etc. This operation seeks to remove a depot of infection in an early stage of tuberculous synovitis, and it possesses the conspicuous merit of not interfering with the epiphysis. The term *erasion* is also used to designate the operation of removing healthy synovial membrane, ligaments, etc., for the purpose of producing fixation of a flail joint due to infantile paralysis. Erasion is oftentimes practised upon the knee-joint. The instruments required are a scalpel, hemostatic forceps, dissecting forceps, toothed forceps, volsellum, scissors, bone gouges, curets, and an Esmarch apparatus.

Erasion of the Knee joint.—The patient lies upon his back; the leg is

* Joseph Bell, in his "Manual of Surgical Operations."

flexed with the sole of the foot planted upon the table, and an Esmarch bandage is applied at a point well up on the thigh. The surgeon stands to the right of the patient. The incision is begun in the mid-line of the thigh (on the side opposite to that occupied by the surgeon), about three inches above the patella; it is carried down across the ligament of the patella and up to a corresponding point on the opposite side of the thigh. This incision goes down to the bone; the flap is turned up and the joint exposed, the knee-joint is strongly flexed, and the synovial membrane and diseased ligaments are dissected away with scissors and forceps, great care being taken that the posterior ligaments (which, fortunately, are rarely implicated early

in the case) are not divided and that the contents of the popliteal space remain intact. After removing the diseased ligaments and synovial membrane the cartilage is examined and any diseased portion is removed. The bone is then examined and any tuberculous foci are gouged away. Any exposed vessels are ligated. The wound is irrigated with salt solution, the extremity is straightened, and the ends of the ligamentum patellæ are sutured, a drainage-tube is inserted at each angle of the wound, the skin is sutured, and antiseptic or sterile dressings are applied. The limb is placed upon a posterior splint for a few days, then the drainage tubes are removed, the dressings are changed, and a plaster-of-Paris cast is applied, trap-doors being cut on

each side, and the joint is kept immobile for two or three weeks. This operation is only suited to early cases in which the lesion involves chiefly or purely the synovial membrane and ligaments, and in these cases it frequently gives a good result, some capacity for motion being not unusually preserved.

Excision of the Shoulder-joint.—In the shoulder joint *partial* excision is often performed, the head of the humerus being removed and the glenoid cavity undisturbed; but some patients require complete excision, the entire glenoid depression, as well as the head of the humerus, being removed by the surgeon. Excision of the shoulder-joint is made, if possible, an intra-

capsular operation, the capsule being opened, but the capsular attachment to the anatomical neck of the humerus not being interfered with. In advanced cases, however, the capsular attachment must be destroyed. Excision of the shoulder joint is seldom performed in civil, but is a common operation in military practice; it is performed for gunshot-wounds, compound dislocations, tuberculous disease, and tumors of the head and upper portion of the humerus. The instruments required are a scalpel, an Adams saw and a metacarpal saw, an osteotome or chisel, a mallet, an Allis dissector, a periosteum elevator, hemostatic forceps, dissecting forceps, toothed forceps, lion-jawed forceps, sequester forceps, metal retractors, curets, and cutting bone forceps.

Operation by Anterior Incision.—The patient lies supine: a pillow is placed beneath the shoulders, and a sand pillow is put beneath the shoulder to be operated upon. The arm is held to the side with the outer condyle forward and the bicipital groove inward (Barker's directions). The surgeon stands by the affected side. An incision three or four inches in length is made from just external to the coracoid process of the scapula, running straight down the humerus (Fig. 382, A). This incision divides the border of the deltoid muscle and brings into sight the long head of the biceps. The tendon of the biceps is retracted inward, unless it is diseased, in which case it is resected. The knife is carried up the groove and opens the capsule of the joint. The periosteum is lifted from the neck of the bone while an assistant rotates the elbow to make the muscles tense. In some places, if the periosteum tears, muscular insertions must be cut with a knife. The head of the bone is sawn off while the bone is in place, or the elbow is strongly pulled back, and the head of the bone is forced out of the wound, and is then sawn off at the point required. In ordinary cases only the articular head is removed, in other cases the section is made just above the surgical neck; in yet others a portion of the shaft must also be cut away. If the glenoid cavity is found slightly diseased, the dead bone must be removed by the chisel and mallet or by the cutting forceps. If the cavity is seriously diseased, the entire glenoid should be removed. Scrape away all damaged tissue, ligate bleeding points; irrigate the wound with corrosive sublimate solution; swab it out with a solution of chlorid of zinc (gr. xx to 3j); dust with iodoform; close the upper portion of the wound and insert a drainage-tube in the lower angle; dress the wound antiseptically; place a small pad in the axilla; apply the second roller of Desault; and put the patient in bed with a pillow under the affected shoulder. In seven days the hand sling is substituted for the bandage, and with the elbow hanging free the patient is permitted to get up and is advised to move his arm frequently. Drainage is maintained until the wound is well healed from the bottom. Great limitation of movement inevitably follows a shoulder joint resection.

Excision by the deltoid flap is performed when the head of the bone is much enlarged (as by a tumor) or when the tissues are thick and indurated. The deltoid flap is in the shape of a U or is semilunar (Fig. 383, A). Raising this flap exposes the head of the bone most satisfactorily. Bell states that when the glenoid cavity is chiefly involved the incision should be posterior (Fig. 383, B).

Senn's Method.—Senn has recently described* an incision which does not damage any important vessels, muscles, tendons, or nerves, and which is followed by good functional results. A semilunar skin flap is formed, the incision running from the coracoid process to the posterior border of the axillary space. The flap is turned up, exposing the upper half of the deltoid muscle. The acromion is sawn off and turned down with the attached deltoid. The capsule is now freely exposed; it is opened, and either arthrocentesis or excision is performed, according to conditions. In closing the wound it is not necessary to bore the acromion and pass silver wires to join the fragments; it is enough to suture the periosteum with catgut.

Excision of the Elbow-joint.—This operation is performed for wounds,

* Phila. Med. Jour., Jan. 1, 1893.

factly ankylosis, and chronic articular disease. Excision must be complete. Endeavor to make a subperiosteal resection; this maintains the shape of the articulation and gives the best chance for a movable joint. The instruments used are the same as those for the shoulder, plus a Butcher saw.

Operation. The patient is "supine, but inclining to the sound side, the affected arm being held almost vertical, with the forearm flexed and nearly horizontal" (Barker). The incision is made on the posterior surface of the joint. A single posterior incision is usually employed (Fig. 383, D). An incision is made a little internal to the long axis of the olecranon, beginning two inches above and terminating two inches below the tip of the olecranon. This incision goes down to the bone, and throughout the entire operation the surgeon must guard and shield the ulnar nerve. The periosteum and soft parts are well separated; the olecranon is sawn off, forced flexion exposes the joint-cavity freely, and enables the surgeon to lift the periosteum and soft parts from the humerus, the humerus is sawn through at the beginning of its condylar processes, the radius and ulna are cleared and are sawn at a level below that of the base of the coronoid process of the ulna. Diseased tissues are cut and scraped away; the wound is irrigated, sutured, drained, and dressed. In some cases an H-shaped incision is employed (Fig. 383, C), but the matrix of a transverse cut will limit flexion of the limb.

After excision of the elbow the patient is put to bed and the arm is laid upon a pillow, the elbow being placed midway between a right angle and complete extension, the forearm being placed midway between pronation and supination. No splint is used, as a rule. Esmarch used the splint shown in Fig. 384. The aim in treatment is to obtain a freely movable

Fig. 384.—Esmarch's splint for the treatment of a limb after excision of the elbow-joint

joint. Passive motion is begun in one week, at which time the patient gets up. The hand is carried in a sling for a time after healing of the wound is complete.

Excision of the Wrist-joint.—Bell states that, whatever method of excision is chosen, three cardinal rules must be borne in mind. (1) remove all the diseased bone, including the portions of the radius, ulna, carpus, and metacarpus which are covered with cartilage, (2) interfere with the tendons to the least possible degree, and (3) begin passive motion of the fingers very early. Many surgeons prefer the simple gouging away of diseased foci and the scraping of sinuses instead of a formal resection of the wrist, amputation being employed in severe cases or when scraping fails.

after several trials. Formal excision is not frequently performed, and the results cannot be regarded as very favorable.

Lister's Open Method of Excision. The instruments required in this operation are the same as those used for any resection. Break up adhesions as completely as possible by forcible movements. Apply a tourniquet or an Esmarch apparatus. The patient lies upon his back, the arm and the forearm being brought, from stage to stage, into the most desirable positions. Begin an incision over the middle of the dorsum of the radius, on a level with the styloid process; carry it downward in the direction of the inner edge of the articulation of the thumb with its metacarpal bone, and when the knife reaches the radial side of the second metacarpal bone alter the direction of the incision and carry it downward in the long axis of the metacarpal bone to about its middle (Fig. 381, A). This is known as the *radial incision*, and the only tendon divided is that of the extensor carpi radialis brevis muscle. The tissues upon the radial aspect of the incision are dissected up, the tendon of the extensor carpi radialis longior muscle is divided at its point of insertion (Bell), and all the soft structures are retracted outward, exposing the trapezium, which is cut off from the rest of the carpus, but which is left in place, as its removal at this stage endangers the radial artery (Barker). By extending the hand the tendons are loosened and the carpus is cleared in the direction of the ulnar border of the hand.

Another incision is made, starting upon the inner surface of the wrist, two inches above the articular surface of the ulna, and midway between the ulna and the flexor carpi ulnaris tendon. This incision, which is known as the *ulnar incision*, is carried down until it is opposite the middle of the fifth metacarpal bone in the palm (Fig. 381, B). "The dorsal lip of this incision is raised" (Bell), and the extensor carpi ulnaris tendon is divided and dissected from its depression, but is not separated from the integument. The extensor tendons are lifted; the ligaments upon the dorsum and sides of the wrist-joint are cut; the flexor tendons are raised from the carpal bones; the pisiform bone is cut from the carpus, but is not yet removed, and the unciform process of the unciform bone is cut with forceps. The anterior radiocarpal ligament is divided, the carpometacarpal articulations are cut through, and the carpus is pulled out with bone-forceps. The ends of the radius and ulna are forced out of the ulnar incision. All that portion of the ulna which is crusted with cartilage is to be removed, the saw cut is to be oblique, and the base of the styloid process is to be left behind. A thin section is to be sawn from the radius, and the tendon grooves are not to be impinged upon. The articular surface of the ulna is cut away with pliers (Bell). If foci of disease are discovered beyond these points, they are to be gouged out. The ends of the metacarpal bones are sawn off, and their articular facets are cut away by means of pliers. The trapezium is dissected out, the end of the first metacarpal bone is sawn off and its facet is cut away with pliers, and a portion of the pisiform bone is removed (the entire bone being removed if it be diseased). The wound is irrigated, vessels are tied, the radial incision is closed, the ulnar incision is partly closed, a drainage tube is inserted by way of the ulnar incision, the wounds are dressed antiseptically, and the Esmarch apparatus is taken off. The forearm and hand are placed upon a splint which immobilizes the wrist and leaves the fingers

semiflexed. Passive motion of the fingers is begun after thirty-six hours. The splint is worn for many months, until the wrist joint is immobile and solid. Esmarch uses the splint shown in Fig. 385.

Excision of Metacarpal Bones and of Phalanges.—Excision of a metacarpal bone except in cases of necrosis with the formation of large

Fig. 385. Esmarch's interrupted splint applied

quantities of new bone, usually leaves a useless finger; hence amputation is preferred usually to excision. This rule does not apply to the metacarpal bone of the thumb, which is occasionally resected. The incision for this operation is made upon the dorsum, and is straight. Excision of the proximal phalanx of the thumb is sometimes performed. Excision for disease is rarely performed upon the finger-joints, amputation being preferred, though the operation is sometimes undertaken for compound dislocation. In the metacarpophalangeal joint of the thumb excision, if it can be performed, is preferred to amputation. The incision for resection of this joint is placed upon the radial aspect.

Excision of the Hip-joint.—Some surgeons advocate this operation; others, notably Marsh, are emphatically opposed to it. Excision should be performed in the early stage of tuberculous disease if less radical treatment has failed. In this stage the usual position of the limb is one of flexion, abduction, and eversion. In cases of long duration, especially where dislocation exists, excision is an easy and a comparatively safe operation; in recent cases it is difficult and carries with it decided dangers, but the peril of delay may be greater than the peril of an early resection. In cases of hip disease with involvement of the acetabulum the mortality is 50 per cent., whether operation is or is not attempted. Excision is performed especially for tuberculous disease and for gunshot-injuries. The instruments required are those used for other excisions.

Operation by Anterior Incision (Fig. 386) (Barker's Operation).—In this operation the patient is supine, with the thighs extended as thoroughly as circumstances permit. The surgeon stands to the right of the patient. An

Fig. 386.—Excision of the hip-joint. A, iliofemoral muscle; B, tensor vaginae femoris muscle; C, sartorius muscle; D, anterior incision.

incision is begun half an inch below and half an inch external to the anterior superior iliac spine, and it is carried downward and a little inward for about three inches (Fig. 386, D). If dislocation exists, the incision must not be so long. This incision is carried at once deeply between the muscles, and the capsule of the joint is opened. The neck of the bone is divided from its upper surface downward with a saw or an osteotome, and without dislocating the bone through the wound by forcible extension and eversion. The head of the bone is removed. All tuberculous foci must be scraped away, and the flushing gouge is used upon tuberculous areas of the acetabulum. All sinuses should be thoroughly scraped. Bleeding is arrested, the wound is irrigated with normal salt solution, mopped out with chlorid of zinc solution, and dusted with iodoform. A drainage tube is inserted at the lower angle of the incision, and the upper portion of the cut is closed. The wound is dressed antiseptically. Extension is made with the extension apparatus until healing has obtained good headway, when a double Thomas's splint is applied, so that the patient can be taken out daily in the air and sunlight. As a rule, rigid ankylosis results from resection of the hip, but occasionally a joint results with a small range of movement.

Operation by Lateral Incision (Langenbeck's Operation).—In this operation a straight incision two inches long is made in the direction of the axis of the femur, and passing downward from the apex of the great trochanter. From the beginning of this incision a curved incision is carried toward the head of the bone, the convexity of the curve being backward (Fig. 380, A). Bell advises the use of the saw after bringing the head of the bone into the wound by abduction and eversion of the thigh. Barker applies the saw with the bone *in situ*, and strongly opposes wrenching the bone out of the incision, because of the danger of peeling off the periosteum, which peeling, if it takes place, favors necrosis.

Incision of Gross.—In Gross's operation a semilunar flap is made with the convexity backward (Fig. 383, E).

Excision of the Knee-joint.—In this operation a complete excision should be performed, and the patella ought to be removed. This operation is performed for tuberculous disease, some compound fractures and compound dislocations, and some cases of angular ankylosis, but it is rarely employed for gunshot injuries, amputation being usually preferable. The instruments required are the same as those for the shoulder, plus Butcher's saw.

Operation by Anterior Semilunar Flap. The patient lies upon his back, and the joint, if not ankylosed in extension, should be semidexed. The surgeon stands to the right side. An incision is made which at once opens the joint. The incision begins at one condyle and reaches the other condyle by a curve which passes through the ligamentum patellæ midway between the tuberosity of the tibia and the inferior margin of the patella (Fig. 382, B). The flap is dissected up, the knee is thrown into forced flexion, the lateral ligaments and crucial ligaments are cut, and the end of the femur is well cleared. The blade of Butcher's saw is passed beneath the bone, which is sawn from below upward (Ashhurst). The end of the tibia is cleared and a portion is sawn off. If, after sawing, diseased foci are discovered, another section can be sawn off or

the fori can be gouged away. Ashhurst, who has had a vast experience with this operation, insists that in sawing through the femur the natural obliquity of the bone must be borne in mind and the section must be made in "a line parallel to that of the free surface of the condyles." If the section is made transverse to the axis of the femur, "the limb, after adjustment, will be found to be markedly bowed outward." The same surgeon says that the epiphyseal line is somewhat higher on the front than it is on the back of the femur, and in consequence the following rule is formulated for section of the condyles: the section of the condyles should be "in a plane which, as regards the axis of the femur, is oblique from behind forward, from below upward, and from within outward." Ashhurst advocates section of the tibia "in a plane transverse to the long axis of the bone, with a slight anteroposterior obliquity, so as to correspond with that of the section of the condyles," and he further says that the patella must be removed, whether it is diseased or not, and quotes Pénicé's observations to the effect that excision of the patella diminishes the risk of death one third, and its retention doubles the probability of an amputation becoming necessary in the future.

Fig. 387.—Watson's plaster-of-Paris swing-splint

After removing the patella the diseased synovial membrane is clipped away with scissors and all sinuses and diseased territories are well curetted. The posterior ligament of the joint is not removed unless it is diseased; its retention prevents displacement and guards the popliteal space. In children the fragments should be wired together; in adults this need not be done. After hemostasis, irrigate, dust with iodoform, insert a drainage-tube, suture, dress antiseptically, and adjust the limb upon Price's splint or Ashhurst's bracketed wire splint. In some cases tenotomy is required to permit extension. Instead of the bracketed splint, a long fracture box may be used. If the femur tends to project anteriorly, use an anterior splint. If there be a tendency to outward bowing, adopt Ashhurst's expedient of carrying a strip of adhesive plaster around the outside of the limb and fastening it to the inner side of the splint. The splint is kept on until bony union is complete, as in this operation a movable joint is never sought. Many surgeons use a plaster of Paris splint, which is employed until the parts have become firm and solid (Fig. 387).

Excision of the Ankle-joint.—This operation is performed chiefly for gunshot wounds, compound dislocations, and in some cases of tuberculous

joint-disease. Excision of the ankle is an operation which is seldom performed. The instruments used are the same as those employed for any resection.

Operation (Hancock's Method).—In this operation the patient lies upon his back, the foot rests upon its inner side, and the surgeon stands to the outer side of the damaged limb. Begin an incision just behind and two inches above the external malleolus, and carry it across the front of the joint to a corresponding point above and behind the internal malleolus (Fig. 380, B); this incision goes only through the skin, and the flap thus marked out is reflected. "Cut down upon the external malleolus, carrying the knife close to the edge of the bone both behind and below the process, dislodge the peronei tendons, and divide the external lateral ligaments" (Joseph Bell). Cut the fibula one inch above the malleolus by means of pliers; divide the tibiofibular ligament; turn the foot upon its outer side; dissect from their habitat back of the inner malleolus the tendons of the posterior tibial and the common flexor of the toes; carry the knife around the inner malleolus, close to the bony edge; separate the internal lateral ligament, and dislocate

Fig. 388.—Volkmann's dorsal splint for excision of the ankle.

the lower end of the tibia through the wound by turning the sole of the foot downward; saw off the lower end of the tibia and the articular process of the astragalus, sawing away from the tendo Achillis, and remove the fragments with bone forceps. Cut away diseased synovial membrane, and curet all sinuses and tuberculous areas. Arrest bleeding, irrigate, and drain. Sew up the wound, insert a tube at the outer angle, and cause it to emerge at the inner angle. Apply antiseptic dressings, and put up the foot in fixed dressing or in splints at a right angle to the leg (Fig. 388). In Langenbeck's operation the excision is subperiosteal. If, in an excision of the ankle joint, the astragalus is found extensively diseased, remove the entire bone.

Excision of the Os Calcis.—In caries limited to the os calcis most surgeons prefer to gouge away the dead bone, leaving the periosteum and, if possible, a shell of healthy bone, and draining thoroughly. Others advocate excision in some cases. Extensive disease limited purely to the os calcis is rare, and most surgeons advise gouging for limited caries, and Syme's amputation in the event of the disease extending beyond the periosteum or reaching adjacent bones.

Operation by Subperiosteal Method.—In this operation the position as

sumed by the patient is supine with the leg extended and the foot resting on its inner side. The incision, which cuts the tendo Achillis and reaches the bone at once, is begun at the upper border of the os calcis and the inner margin of the tendo Achillis, and is taken outward and horizontally forward to a point in front of the calcaneocuboid articulation (Fig. 383, F). A vertical incision is begun near the forward termination of the initial incision, is carried across the outer edge and plantar surface of the foot, and terminates at the external margin of the inner surface of the os calcis. Some surgeons carry the vertical incision a little upward, toward the dorsum. The periosteum is entirely stripped with an elevator, the os calcis is removed, the cavity is packed with iodoform gauze, the wound is stitched, a drain is inserted posteriorly, and the foot is dressed antiseptically, is placed at a right angle to the leg, and plaster of Paris is applied, trap doors being cut for drainage.

Astragalectomy, or excision of the astragalus, is seldom performed. Astragalectomy is employed occasionally for relapsed and inveterate cases of club foot. The indications are pointed out by Willard ("International Clinics," vol. iii, 12th series): "(1) Adults with great bony deformity, (2) neglected children of five to fifteen years, who have markedly distorted their feet by locomotion; (3) relapsed cases which have resisted the milder forms of operation, or which have been neglected by parents after previous operation, 4, only occasionally, young children in whom from infancy the bones of the foot have been exceedingly rigid and unyielding, and where there is practically but little motion either at the ankle joint or in the tarsus."

Operation by the Subperiosteal Plan.—Barker advises an incision going at once to the bone, from the "tip of the external malleolus forward and a little inward, curving toward the dorsum of the foot." The foot is extended and turned inward, the periosteum is lifted, the astragalus is removed, and the wound is treated and the foot is dressed as is done in excision of the os calcis.

Excision of the Metatarsophalangeal Articulation of the Great Toe.—In this operation make a lateral incision and cut off or saw off the proximal end of the first phalanx and the distal third of the first metatarsal bone.

Excision of the Metatarsal Bone of the Great Toe (Butcher's Method).—In this operation a lateral straight incision is made, the periosteum is elevated, and the shaft is sawn from each extremity and removed.

Excision of the clavicle may be required for dislocation, caries, necrosis, gunshot-wound, tumor of this bone, as a preliminary to ligation of the artery and vein in certain cases of amputation at the shoulder-joint, or in cases of removal of the entire upper extremity. In excision of the clavicle the position of the patient is the same as that for ligation of the third part of the subclavian artery (page 479). An incision is made down to the bone, from the sternoclavicular joint to the acromioclavicular articulation. If the case is suitable, the periosteum is stripped and the bone is sawn and removed; if not, the bone is sawn and each half is separately articulated. The wound is sutured and dressed, and the limb is put up in a Velpeau bandage.

Excision of the Scapula.—Complete excision of the scapula is usually performed for tumors. Partial excision requires no detailed description.

In excision of the scapula the patient lies upon his sound side. Treves suggests the following incisions: one outside the vertebral border of the scapula, from its superior to its inferior angle; another from over the acromioclavicular joint, along the acromion process and spine of the scapula, to meet the first incision. Syme used an incision carried transversely inward from the acromion process to the vertebral border of the scapula, and another cut directly downward from the center of the first incision (Fig. 383, G). In the method of Treves* the upper flap is reflected and the trapezius muscle is divided; the lower flap is reflected and the deltoid muscle is divided. The patient's hand is placed on the sound shoulder; the muscles of the vertebral border are divided, the posterior scapular artery is tied, and while the vertebral border of the scapula is pulled toward the surgeon, the serratus magnus muscle is cut, the upper border of the shoulder-blade is cleared, and the suprascapular artery is tied. The hand is now brought down to the side; the acromioclavicular joint is disarticulated; the conoid and trapezoid ligaments are divided, the muscles of the coracoid process are cut; the capsule is incised, with the supraspinatus and infraspinatus, the subscapularis, and the scapular origins of the biceps and triceps muscles; and finally the teres major and minor muscles are divided, the subscapular artery is tied, and the bone is removed. The wound is stitched, a drain is introduced, and antiseptic dressings are applied. The patient lies upon his back until healing is well under way, when the arm is placed in a sling. The drainage tube may be removed in twenty-four hours.

Excision or Resection of a Rib (Fig. 494) —In *caries* the gouge and rongeur may remove the disease. In other cases excision is performed. In this operation the patient lies upon his sound side unless the operation is performed for empyema, in which case he lies on his back or only partly on the sound side. (See Emphyema, Operation for.) The surgeon faces the patient. Make an incision down to the bone, in the long axis of the rib. The periosteum, if not diseased, is lifted from the bone, and the intercostal artery is lifted out of the way with the periosteum and is thus saved from being cut. After dividing the bone beyond the limits of disease, remove it. During the sawing a metal retractor is held beneath the rib, between the rib and the periosteum. It is better to saw it than cut it with ordinary biting forceps, because the latter splinter the bone. The author usually uses a forceps known as a *costotome*, which cuts the rib without splintering. If the periosteum is diseased, remove it after tying the intercostal artery. It should be removed in a case of empyema, otherwise bone-formation may interfere with drainage. In *empyema*, after removing the periosteum, open into the pleural cavity, allow pus to flow out slowly, remove fibrinous masses, employ a finger to feel if there are adhesions and if the lung will probably expand, and insert a drainage-tube. In resection for rib disease curet sinuses and pack with iodoform gauze for some days. Sew up the wound except at one end. Dress antiseptically and apply a binder. (See Operations upon the Chest and Estlander's Operation.)

In *removing a cervical rib* make an incision along the posterior edge of the sternocleidomastoid, avoid the pleura, subclavian vessels, and tracheal plexus, and remove the periosteum with the rib in order that the bone will not be reproduced.

Complete Excision of One-half of the Upper Jaw.—The whole upper

*Treves's "Manual of Operative Surgery."

jaw has been removed, but in what follows only resection of one-half the jaw will be described. This operation is performed for malignant tumors of the superior maxillary bone or its antrum. Up to 1826, at which time Lums. of Edinburgh, suggested the operation, tumors of the antrum were treated by scraping them away with a sharp spoon. Gensoul, of Lyons, in 1827 performed the first operation for resection of the upper jaw. This operation is not justifiable, except as a palliative measure, if the orbit is invaded, if the skin and subcutaneous tissues are infiltrated, or if the disease extends widely beyond the superior maxillary and palate bones. The instruments required are: a mouth-gag; scalpel, strong scissors; tracheotomy tubes; dissecting, toothed, and hemostatic forceps; bone-cutting, lion-jaw, sequester, and tooth-extracting forceps; a volsella; a narrow-bladed saw, a chisel and mallet; a periosteum-elevator; a spatula or metal retractor; Paquelin's cautery; sponges which are tied to sticks, needles, curved and straight, large and small; silk and catgut ligatures; silk worm-gut sutures; and Horsley's antiseptic bone-wax.

Preliminary Closure of the External Carotid Artery.—Some surgeons ligate the external carotid artery or compress it temporarily. In a number of excisions of the upper jaw I have always found the hemorrhage readily controllable as soon as the bone is removed, and have never felt it necessary to resort to preliminary ligation or compression.

Fig. 389.—1. Excision of the upper jaw. A B, Section of the maxilla; C, section of the nasal bone and orbital process; D, section of the alveolar and hard palate; E, section of the lower jaw; F, section of the interior maxillary; G, section of the ramus in partial resection.

Fig. 389.—A B, Incision of the soft parts preliminary to excision of the upper jaw; C D E, incision of soft parts preliminary to excision of the lower jaw.

Operation by Median Incision.—The patient, whose face has been shaved, is placed in the Trendelenburg position, thus avoiding the possible need of instant tracheotomy. The surgeon stands to the right side of, and faces, the patient. The incisor tooth on the diseased side is pulled out. The incision, which is known as Weber's incision (Fig. 389, line A B), is begun half an inch below the inner canthus of the eye, and is carried along the side of the nose, around the ala of the nose, by the margin of the nostril, and through the middle of the lip. While the lip is being incised the assistant arrests hemorrhage by grasping the corners of the mouth, and after the lip is divided, the coronary arteries are at once ligated. Some operators approach the mucous membrane cautiously and ligate the vessels before opening the cavity of the mouth. The upper portion of the wound having been compressed by another assistant during these manipulations, pressure is now removed and bleeding points are ligated. Another

incision is now carried outward from the beginning of the first incision, along

the orbital margin to well over the malar bone. The flap is lifted from the periosteum, and the bleeding from the infraorbital artery and the small vessels is restrained by pressure. The nasal cartilage is separated from the bone, and the nasal process of the superior maxillary is sawn (line A B, Fig. 390). The orbital periosteum is lifted up, and the orbital plate is cut with forceps from the saw-cut in the superior maxillary bone to the sphenomaxillary fissure (line B C, Fig. 390). The malar bone is sawn or is bitten through about its center, the cut running into the sphenomaxillary fissure and taking a downward and outward direction (line C D, Fig. 390). The soft parts covering the hard palate are incised in the median line, a corresponding incision is made along the floor of the nose near the septum, and the soft palate is separated from the hard palate by a transverse cut. The saw is introduced through the nose, and the palate is sawn (line E, Fig. 390). The upper jaw-bone is grasped with Fergusson's lion-jaw forceps and removed, the removal being aided by the use of the scissors and bone cutters, the latter are used to separate the upper jaw from the pterygoid process (Treves). Every vessel that can be seen is tied, and severe bleeding from bone is arrested by antiseptic wax. Oozing is controlled by hot water and pressure or by Paquelin's cautery. Examine carefully to see if all the diseased area is removed; if it is not, use the gouge, scissors, chisel, and saw until healthy tissue is reached. The wound is packed with iodoform gauze, and the end of the strip is so placed as to be accessible through the mouth. The wound is sutured (the mucous membrane of the lip must be stitched, as well as the skin) and is dressed antiseptically (the eye being protected by aseptic gauze), and a crossed bandage of the angle of the jaw is applied.

Excision of One-half of the Lower Jaw.—In some rare instances the entire inferior maxillary bone is removed. The lesions necessitating removal of the lower jaw are of the same nature as cause us to remove the upper jaw. The instruments required for removal of the lower jaw are those used for excision of the upper jaw, plus a metacarpal saw (having a movable back).

In this operation the patient is placed in the same position as for excision of the upper jaw, the chin having been previously shaved. A vertical cut is made through the chin tissue, starting below the margin of the lip and reaching to below the border of the jaw (C D, Fig. 389). From the point D an incision is carried outward below the border of the jaw and then back of the ramus, as shown in the line D E (Fig. 389). Treves's advice is to carry this incision down to the bone, except at the line of the facial artery, at which point it must go through the skin only. The facial artery is now to be sought for, tied in two places, and divided. The periosteum is lifted from the external surface of the bone, from the symphysis outward. Hemorrhage is arrested. The buccal mucous membrane is cut from the alveolus. A lateral incisor tooth is pulled, and the bone is sawn in the line G (Fig. 390). The bone is grasped in a lion-jaw forceps and is drawn outward. The mylohyoid insertion is cut; the internal pterygoid muscle is cut or the periosteum at this spot is lifted, the inferior dental artery is cut and tied, the jaw is pulled down; the insertion of the temporal muscle upon the coronoid process is cut away; and the external pterygoid muscle is divided. The capsule of the joint is opened, and the bone is separated from the ligaments which still

hold it in place. Bleeding is arrested, the wound is sutured, a tube is introduced in the posterior portion of the wound and retained for twenty four hours, and antiseptic dressings and a Gibson or a Barton bandage are applied. Partial excisions of the alveolus may be performed through the mouth by means of chisels and rongeur forceps, and Wyeth has thus removed half of the jaw, but if any considerable part of the body of the jaw is to be removed, it is usually best to make an incision below the inferior maxillary.

Barker's Operation for Dislocation of the Semilunar Cartilages of the Knee-joint.* Begin the incision over the ligament of the patella, half an inch above the articular surface of the tibia, and carry it in a curve downward and outward to the anterior edge of the internal lateral ligament. The periosteum should be divided by the cut. This incision forms a flap the lower edge of which is half an inch below the border of the articular surface of the tibia. The flap is lifted until the cartilage is seen "under the attachment of the meniscus, which if partially attached will rise with the flap until its under surface is seen." If partially torn anteriorly it is stitched to periosteum by a few silk sutures. The periosteum is then stitched in place, no drain is used, the joint is immobilized, and for one week ice is kept upon the part. If the meniscus is found completely separated and curled up, it may, if the injury was recent, be reduced. If the injury was old and if the cartilage is shrunken, it should be completely cut away (Barker).

Operation for Congenital Dislocation of Hip. —Lorenz's Bloodless Method of Reduction. The method of reducing by manipulation a congenital dislocation of the hip was devised by Paci and modified and improved by Lorenz. It has long been known that reduction is easy at birth, because an acetabulum, though probably a shallow one, exists and the head of the bone is not firmly held in its new situation. In an older child the problem is far more difficult, because, even if reduction is effected, the acetabulum may be extremely shallow or absent, and redislocation may readily occur. Lorenz aims to effect thorough reduction and then fixes the limb in abduction for months, so that the acetabulum will deepen and the bone will become firm in its proper socket. This operation is rarely successful in children over six years of age. The child is anesthetized and an attempt is made to draw the femoral head on to a line with the acetabulum. If the child has never walked, this is readily accomplished. If it has walked, the procedure may be very difficult, and it may be necessary to make extension with a fillet fastened above the knee, and counter extension with a screw and a perineal band. The drawing down of the head is made easier by stretching and massaging the adductor muscles. The next step is to strongly flex the thigh, rotate it a trifle internally, and then abduct it while flexion is maintained. This causes the head of the femur to pass around the posterior margin of the acetabulum and frequently produces reduction. "Full abduction being kept up, the thigh is rotated out, thus forcing the head of the femur more firmly into the socket" (see the description of the Lorenz method in J. Jackson Clarke's "Orthopaedic Surgery"). The strongly abducted limb is put up in plaster of Paris. In about three months the plaster is removed, the abduction is diminished, the plaster is reapplied and is retained for another three months. During the continuance of immobilization of the hip, the child

*¹Lancet, Jan. 4, 1902

walks about, with the knees bent. When the plaster is finally removed, manipulation, massage, and exercise strengthen the muscles and give freedom to the joint. In a double dislocation one joint can be cured before the other is operated upon, or both may be operated upon at the same séance. In double dislocation plaster must be worn more than six months. The Lorenz operation is safe when applied to very young children, but has elements of danger which increase with the years of the subject. A patient may suffer grave lacerations of muscles and ligaments, and even vessels and nerves. Death may result from shock, and extensive deep-seated hemorrhage may occur. In fact, it is a mistake to call it a bloodless method. The blood flows, though we do not see it. An untrained man may do fearful mischief by this operation, and it should only be attempted by a very skilful manipulator and upon properly selected cases, when it is a very successful procedure. I am satisfied

Fig. 301. Lorenz method. Unilateral congenital dislocation of hip (reduced). Cast applied with leg in "frog position."

that, except in the case of a very young child, in whom reduction is easy, one who performs the Lorenz operation should be something more than skilful and experienced. He should be physically strong, so that traction and abduction will be powerful and steady. A weak man will jerk, will throw his weight upon the part, and will be apt to tear structures instead of stretching them. Sudden forcible movements are apt to break the bone.

Hoffa's Operation. The instruments used are the same as for a resection. Make the external incision of Langenbeck to open the joint (page 716). The capsule is incised at its insertion into the neck, and the periosteum and muscles are lifted from the great trochanter. Hoffa claims that in children less than five years of age the head of the bone can be readily replaced into the acetabulum by flexing the thigh and making direct pressure upon the head of the bone. After replacing the femoral head it is held in place while an assistant extends the leg in order to stretch the muscles. In children over five years of age cut the muscles which spring from the ischial tuberosity and also the adductors with a tenotome; cut the fascia lata and muscles which arise from the anterior superior iliac spine by incision, open the joint and liberate

the head of the bone; remove the ligamentum teres; scrape out the acetabulum, removing "cartilage, fat, and considerable spongy tissue" (Tubby); and replace the head of the bone in the acetabulum. The limb is maintained in inversion, abduction, and extension for several weeks, when it is straightened. Massage and passive motion are begun in the fifth week. The patient now gets about, wearing an apparatus for many weeks. This apparatus permits the head of the bone to move in the socket, but prevents redislocation.

Lorenz's Operation.—This is a modification of Hoffa's. The muscles inserted into the greater and the lesser trochanter are not cut; the sartorius, the hamstrings, and the external portion of the fascia lata are cut (Tubby).

The incision of Lorenz is longitudinally from the anterior superior spine. Another incision is carried inward from this at the level of the lesser trochanter. The capsule is opened by a crucial cut; the acetabulum is enlarged; the head of the bone, if it remains, is inserted into the acetabulum; if there is no true head, a new one is formed and inserted into the cavity. The limb is immobilized in a position of moderate abduction. Massage and passive motion are begun in the fifth week, and are continued for months.*

*I have drawn upon the very lucid description of these operations in A. H. Tubby's treatise upon "Deformities."

XX. DISEASES AND INJURIES OF MUSCLES, TENDONS, AND BURSÆ.

Myalgia, or muscular rheumatism, is a painful disorder of the voluntary muscles and of the fibrous and periosteal areas where they are attached. The term "muscular rheumatism" is not strictly correct. It is possible that in some cases the muscular structure is inflamed, but it is certain that in many cases the pain is distinctly neuralgic. Muscular rheumatism may be due to cold and wet, to over-exertion and strain, to acute infectious disorders, to syphilis, to chronic intoxications (lead, mercury, and alcohol), and to disturbances of the circulation. Gouty and rheumatic persons are especially predisposed, men being more liable to the disease than women. The disease is usually acute, but it may be chronic.

Symptoms. Muscular rheumatism is apt to come on suddenly. The pain, which may be very acute and lancinating or may be dull and aching, is in some cases constantly present; in other cases it is awakened only by muscular contraction, and it is frequently relieved by pressure, though there is often some soreness. The skin above the muscle is sometimes tender to light pressure. The disease usually lasts for a few days, but it tends to recur. There is little, if any, fever.

Lumbago is myalgia of the muscles of the loins. *Rheumatic torticollis* is myalgia of the muscles of the neck. Usually one side of the neck is attacked. The chin is turned from the affected side and the neck is stiff. *Pleurodynia* is myalgia of the intercostal muscles. The pain is very severe, is aggravated by deep respiration, by coughing, and by yawning, there may be tenderness, and the patient tries to limit chest movement. In *intercostal neuralgia* the pain is limited, is not constant, but occurs in distinct paroxysms, and is linked with the presence of the tender spots of Valleix. *Pleurodynia* lacks the physical signs of pleurisy. *Cephalodynia* is myalgia of the muscles of the scalp. The muscles of the shoulder, upper dorsal region, abdomen, and extremities may also be attacked by myalgia. Myalgia must not be confused with the pains of locomotor ataxia.

Treatment.—Remove any obvious cause. Treat any existing diathesis, such as gout or rheumatism. Rest is of the first importance. For lumbago, put the person to bed. For pleurodynia, strap the side of the chest. A hypodermatic injection of morphia and atropin into the affected muscles at once allays the pain, and a deep injection of distilled water is sometimes curative. Relief may be afforded by painting the surface with 30 drops of a mixture of equal parts of guaiacol and glycerin and covering the painted area with cotton. The introduction of four or five aseptic needles into the muscles, and their retention for a few minutes, sometimes acts most favourably. Ironing the skin above the painful muscles with a very warm iron, a piece of flannel being interposed, is a useful domestic remedy. Vigorous rubbing of the area with a piece of ice allays the pain. Hot poultices do good. If the pain is widely diffused, alters its seat, or is very obstinate, order hot baths or Turkish baths and administer diuretics. In chronic cases employ blisters or counter irritation by the cautery, give iodid of potassium and nux vomica, and have the patient take a Turkish bath every week. The

constant electric current finds advocates. In an ordinary severe case order a hot bath, put the patient to bed with a hot-water bag over the part, and administer 10 grains of Dover's powder; the next morning order to be taken four times daily a capsule containing 5 grains of salol and 3 grains of phenacetin, until the pain disappears. Citrate of potassium, citrate of lithium, chlorid of ammonium, or the salicylate of colchicin may be ordered instead of salol and phenacetin.

Infective myositis is a wide-spread inflammation of the voluntary muscles, due to an unknown infective cause. It is a disorder accompanied by pain and stiffness, by cutaneous edema, and by various paresthesiæ. Myositis resembles trichinosis, and is distinguished from it only by spearing out a bit of muscle and examining it microscopically. Occasionally diffuse suppuration occurs.

Ordinary myositis arises from injuries, from syphilis, or from rheumatism, and it presents the usual inflammatory symptoms. Contraction and adhesions may follow. I operated upon a case of myositis of the rectus abdominis in a boy of eight. There was a large mass like a full bladder. There had not been an attack of typhoid and there was not hereditary syphilis. Caseation existed. The condition was possibly tuberculous, although no bacilli were found.

Treatment of Myositis.—Infective myositis is treated by anodynes, stimulants, nutritious food, hot applications, and rest. If pus forms, it should be evacuated. Rheumatic myositis calls for the administration of the salicylates, the alkalies, or salol. Syphilitic myositis is treated with mercury and iodid of potassium. The remedies employed for myalgia are used in traumatic myositis.

Hypertrophy of the muscles may arise from their increased use. In *pseudohypertrophic paralysis* the bulk of the muscle is greatly augmented, but it contains less muscle-structure and more fat or connective tissue.

Atrophy of the muscles arises from want of use, from injury, from continuous pressure, from interference with the blood-supply, from disease of the nerves or their centers, or from lead-poisoning.

Degeneration of Muscles.—The muscles may undergo granular degeneration, waxy degeneration, fatty degeneration, and calcareous degeneration, and may become pigmented.

Local Ossification and Myositis Ossificans.—It is not unusual for a small portion of bone to form in the periosteal insertion of a muscle which is subjected to frequent strain. In persons who ride many hours a day there not infrequently develops the "*rider's bone*," which is an area of ossification in the adductor muscles of the thigh. *Myositis ossificans*, a wide-spread ossification of the muscles, is a rare disorder the cause of which is unknown, and which, if not congenital, at least begins in early life. In some cases a traumatic origin seems probable. It is seen more often among males than females. Columns of inflammatory swelling and induration slowly develop, each column running in the direction of the muscular fibers, and ossification of the indurated columns takes place. It is stated that the thumbs and great toes shorten (J. Jackson Clarke's "*Orthopaedic Surgery*").

Tumors of the Muscles.—Primary tumors of the muscles are rare. Among those which may occur are sarcoma, fibroma, lipoma, osteoma,

angioma, myxoma, and enchondroma. Most cases of supposed primary sarcoma of muscle are in reality cases of syphiloma (Eismarch).

Syphilis may cause inflammation. Gummata may form, or gummatus infiltration may take place.

Trichinosis or **trichiniasis** is a disease due to the embryos of the *trichina spiralis*. The disease originates from eating meat which contains the trichinae and has been insufficiently cooked. These nematodes are carried into the intestine, there to develop and multiply. In from seven to nine days a horde of embryos develop in the bowel, and leave the alimentary canal by passing through the peritoneum or by means of the blood, and finally reach the connective tissue of the muscles. From the connective tissue the embryos migrate into the primitive muscle-fibers, where they dwell and enlarge. Myositis develops, and in the course of five or six weeks the parasites become encapsuled and develop no further. The cyst-walls may calcify and the worms may become calcified, or may live for years. The eating of infected meat is not inevitably followed by the disease, and a few embryos lodged in muscle may cause no symptoms.

Symptoms.—The symptoms of trichinosis often appear in a day or two after eating infected meat. The symptoms of acute gastro-intestinal catarrh or of cholera morbus are common, but in some cases no gastro-intestinal manifestations usher in the disease. In from seven to fourteen days after the infected meat is eaten the migration of the parasites develops obvious symptoms. A chill may be noted; there is usually fever; muscular pain, tenderness, swelling, and stiffness are complained of. This condition may be wide-spread. Involvement of the muscles of mastication interferes with chewing; of the larynx, with talking and respiration; of the intercostals and diaphragm, with respiration. Skin-edema and itching are marked. In some cases delirium exists. The writer saw in the Philadelphia Hospital one fatal case which was mistaken for erysipelas because of the high fever, the delirium, and the edematous redness of the face and neck. Dyspnea is frequent. Mild cases get well in a week or two; severe cases may last many weeks. The mortality varies in different epidemics from 1 to 20 per cent. (Oster). The diagnosis is made by spearing out a piece of muscle, which is then examined for trichinae under a microscope; or the worms may perhaps be detected in the feces by means of a pocket-lens. In a case under the care of the author, in St. Joseph's Hospital, there was no record of any attack of gastro-intestinal disturbance and the first manifestation was enlargement of the calf of the left leg. In most cases of trichinosis there is eosinophilia, but in the author's case, previously referred to, eosinophilia was not present.

Treatment.—To treat trichinosis employ purgatives (senna and calomel) early in the case, and give glycerin, and also santalin or filix mas. When muscular invasion has taken place, sedatives, hypnotics, nourishing diet, and stimulants are indicated.

Ischemic Myositis, or Volkmann's Contracture (Volkmann's paralysis; *Ischemic paralysis*; *Ischemic muscular atrophy* with contractures and paralysis, Fergusson calls it).—It is occasionally noticed, particularly in children, after prolonged fixation of the forearm, especially after prolonged fixation of the elbow-joint by some appliance that impedes the freedom of circulation in the part. Contracture of the fingers occurs and per-

hips rigidity and flexion of the wrist. In 1875 Volkmann described severe contractures of the hand observed in some cases as a result of the use of tight bandages to hold splints in place in treating fractures of the arm. He believed that the condition was due to deprivation of arterial blood, that the muscles perished for want of oxygen, and that rigor mortis occurred. He pointed out that paralysis and contracture occur simultaneously, whereas, in primary nerve lesion paralysis precedes contracture. The condition may come on after the application of an Esmarch band, after a severe injury in the neighborhood of the elbow-joint, may follow ligation of the main artery of a limb, venous embolism, venous thrombosis from injury or infectious disease, Raynaud's disease, or exposure to cold. One of Jones' cases followed a rapidly developing traumatic myositis ossificans, two followed crushes; in one an elastic tourniquet had been kept on a child's arm to prevent bleeding after an operation for webbed fingers, in one pad pressure had been maintained for twenty-four hours to check bleeding ("Am. Jour. Orthop. Surg.," April, 1908). There are two forms, one due to almost complete arterial ischemia, lasting for several hours at least, another due to interference with venous return. Volkmann's contracture is due to a muscular degeneration, infiltration, induration, and contraction, the result of marked and prolonged arterial ischemia or interrupted venous return, and it is frequently spoken of as ischemic myositis (Dudgeon, "Lancet," Jan. 11, 1902). In some cases distinct neuritis with paralysis also exists. One characteristic of ischemic contracture is the rapidity with which it comes on. Dudgeon points out that in half a day, or even in less time in some cases, the symptoms appear, these symptoms being paralysis of the part with contracture. Pain is unusual, unless the nerves are seriously involved. In some cases the fingers and hand swell and become discolored. The absence of pain frequently prevents the recognition of the condition, therefore, the causative splint or bandage pressure may be maintained for days after the trouble has become serious. When the splints and bandages are removed and the forearm is examined, there is almost always tenderness over the muscles and the nerve-trunks; and in the majority of cases in which a splint was the cause, a portion of the skin will have sloughed. Dudgeon points out the characteristic position of the deformity, as follows: When the wrist is extended, the metacarpophalangeal joints are also extended; but the interphalangeal joints of the fingers and the terminal joint of the thumb are so strongly bent that the tips of the fingers touch the palm, and this position cannot be corrected by any justifiable amount of force. As soon as the wrist-joint is bent to a right angle, the interphalangeal joints can readily be extended. In a very severe case the wrist itself will become markedly flexed, and it will be impossible to extend it. The forearm is usually semiflexed and the hand pronated. The ulceration or sloughing so frequently present is called a *splint sore*. There is always marked induration about a splint-sore. The flexor muscles themselves are indurated and usually wasted. The condition of sensation depends upon the state of the nerves of the part. When neuritis is absent, sensation will be normal; but in accordance with the amount of neuritis and degeneration there will be hyperesthesia, partial anesthesia, or complete anesthesia. A curious feature of these cases that is dwelt upon by Dudgeon and commented upon by Turner is the fact that in young children there is a cessation of growth of the bone. Robert

Jones ("Am. Jour. Orthop. Surg.," April, 1908) reports that 19 cases out of 30 were associated with fracture. In 13 of the 19 cases there was pronounced malunion.

Treatment.—The old view of this condition was that it is practically hopeless. Anderson and Dudgeon, however, maintain that restoration may usually be obtained, the treatment consisting in regular, active motion, passive movement, massage, and electricity. Forcible extension under ether is of no benefit whatever.

Jones' plan of treatment is very beneficial ("Am. Journ. Orthop. Surg.," April, 1908).

Operative procedures on arms that necessarily have deficient circulation are hazardous, and Jones has discontinued all operative correction and relies upon purely mechanical and manipulative routine, as follows:

Five splints are cut out of zinc, tin, or sheet wire, to fit each finger and thumb. The wrist is forcibly flexed and held while each finger is separately splinted. It

Fig. 392 —Rugh's splint for Volkmann's contracture

will be observed that in the fully flexed position of the wrist the fingers are all relaxed.

When the finger splints have been applied the wrist is released, and the patient is directed to systematically extend the carpophalangeal joints. In a few days the second splinting may usually be employed by embedding the entire hand to the wrist and the already splinted fingers in plaster of Paris, while the wrist is again flexed. Several days are devoted to systematic voluntary efforts at extension of the hand in a similar manner employed for the metacarpophalangeal joints.

The third splinting embraces that already employed and in addition embraces the wrist in the fullest extension possible, which in a few days may be increased until full extension is obtained. The latter position of full extension of wrist, hand, and fingers is maintained for some weeks until all contractile elasticity has disappeared.

It is usually observed that when the hand can be held in hyperextension without tendency to relapse, the circulation will almost invariably improve and the fingers resume their normal function and appearance except in cases of nerve destruction. Jones has found that in many cases where the nerves had lost their function during contracture, the extension of the hand was the starting point of recovery.

R. H. Sayre ("Volkmann's Ischemic Paralysis and Contracture, *Am. Jour. Orthop. Surg.*," Nov., 1908, p. 221) advocates the Jones method in all cases, inasmuch as cutting operations may be employed later when the results of Jones' treatment are not entirely satisfactory. The improvement in the circulation and function obtained by the Jones method will make the operative field more capable of rapid recovery.

In a persistent and long-continued case an operation may be necessary. The operation may consist in dividing in the forearm the flexor muscles of the fingers, as advised by Davies Colley, and then, at a later period, dividing the flexor tendons. The objection to his procedure is that it destroys the capacity to flex the fingers for all time. Another suggestion has been to excise a piece from both the radius and the ulna, and wire the fragments together. The best surgical treatment is probably exposing the nerves, separating them from adhesions, stretching them, and then doing tendon-lengthening, but this should not be done until all the improvement possible to secure by conservative treatment has been obtained by at least three months of effort.

Wounds and Contusions of the Muscles.—Wounds of muscles may be either open or subcutaneous. In a longitudinal wound the edges lie close together, and hence drainage must be provided for by the surgeon. In a transverse wound the edges separate widely, and catgut stitches must be inserted. Contusions of muscles, like contusions of other tissues, vary in extent and in severity. There are pain (which is increased by attempts to use the muscle), loss of function, swelling beneath the deep fascia, and discoloration, which may appear at once because of superficial damage from the initial injury, or which may appear in dependent parts after many days by gravitation of the blood and the blood-stained serum. As a result of contusion, suppuration, inflammation, or atrophy may arise.

Treatment.—In a longitudinal wound, drain; in a transverse wound, suture the muscle. The further indications in wounds and contusions of muscles are to obtain rest by means of splints and to secure relaxation. Limitation of swelling is secured by bandaging. Inflammation is combated first by cold and lead-water and laudanum; later by iodine, blue ointment, ichthyol, and intermittent heat. To prevent loss of function, employ, as soon as the acute symptoms subside, massage, passive motion, and stimulating agents, and, later in the case, electricity (galvanism if the reactions of degeneration exist; faradism, if absent).

Strains.—A muscular strain is a stretching of a muscle with a small amount of rupture. It is caused by traction in the long axis of the muscle. The muscle becomes swollen, tender, stiff, weak, and sore, and attempts at motion produce sharp pain. A strain of a tendon is a trivial or partial rupture. It leads to the development of acute tenitis, with fluid swelling and pseudorepitation. Strains are common in the deltoid, the hamstring muscles, the back, the calf, the biceps, and the great pectoral.

Strain of the psoas muscle causes pain on voluntary flexion of the thigh, and is associated with tenderness in the iliac fossa. Strain of the right psoas may be mistaken for appendicitis, but it lacks the intense local tenderness, the abdominal rigidity, and the constitutional symptoms. "*Latent-tennis arm*" is a strain of the pronator radii teres muscle. "*Rider's leg*" is a strain of the adductor muscles of the thigh. A strain of the long head of the biceps flexor cubiti produces the condition called by ball players a "glass arm." A strain may be the only injury, or may be associated with some other condition (fracture of bone, dislocation, sprain, contusion, etc.). A strain may be followed by periositis at the point of insertion of the muscle. Atrophy of the muscle occasionally follows a strain.

A strained muscle is usually rigid, is tender, and pains greatly when an attempt is made to use it. The skin over it, especially over its point of insertion, is usually tender.

A *strain of the back* is a very common accident which is often associated with sprains of the vertebral articulations. There is great pain when the patient voluntarily straightens up. If the vertebral ligaments are not damaged, the patient can be straightened by passive motion without pain. The skin is tender in certain areas. The muscles are often rigid. There may be unilateral rigidity. In a back injury make a careful examination to be sure no damage has been inflicted upon the vertebrae or cord.

Treatment.—Relaxation by suitable position; rest by the use of splints or by putting the patient to bed; bandages for compression; hot fomentations or a hot-water bag, and ichthyol. As soon as acute symptoms subside employ frictions and massage. If there is much pain after a strain, administer Dover's powder, or even morphia.

Rupture of Muscles and Tendons.—**Rupture of a muscle** is announced by a sudden and violent pain and by loss of function, arising during powerful muscular contraction or strong traction in the long axis of a muscle. The rupture may be announced by a clearly audible snap (A. Pearce Gould). A distinct gap is felt between the ends; great pain develops on movement; there are tenderness, loss of power, and swelling. Rupture may be followed by atrophy, as is a contusion. Among the muscles which occasionally rupture we may mention the quadriceps, biceps, triceps, deltoid, plantaris, etc.

Rupture of the biceps flexor cubiti or its tendon is not very common; 72 cases have been collected (W. W. Keen, in "Annals of Surgery," May, 1905). It is much more common in men than in women. Lusk's table of 66 cases contains records of only 2 women (Dixie, in "Jour. of American Med. Assoc.," May 16, 1908). The rupture may be where the muscular belly passes into the lower tendon, through the muscular belly, in the muscular part passing either to the long or short head, or at the part where the muscular belly joins the long or short head. The tendon of the long head may be torn through or the long head may be torn from the glenoid cavity. The muscular portion is far more often injured than the tendinous. In rupture of the muscle belly a part of the muscle, in rupture of the long head the entire muscle, becomes soft and relaxed. In rupture of the belly there is a gap between the two portions and each portion causes a lump. In rupture of the tendon there are not two lumps with a gap between, but there will be

single muscular lump. In rupture of the long head the muscular belly is much nearer the elbow than in health (Figs. 393 and 394). If rupture takes place at the lower part of the belly, the muscle passes toward the shoulder. Rupture of the long head of the biceps allows the humerus to pass somewhat forward and upward.

Fig. 393. Author's case of rupture of the long head of the biceps

Flexion with the forearm supinated is much less powerful than flexion with the forearm pronated (*Hüter's sign*)

In a case of my own in the Blockley Hospital the accident had occurred while carrying a heavy bucket. Forearm flexion was possible, but slow, feeble, partial, and incomplete. On flexion the short head contracted, but the muscular "bunch" of the belly was nearer the elbow than normally. Rupture of the plantaris muscle (*coup de foudre; lawn-tennis leg*) is an injury which is frequently not diagnosed. It occurs during exercise (walking, bicycling, jumping, playing tennis) or is first complained of after exercise. It produces sudden pain in the middle of the calf, swelling, and often ecchymosis and inability to walk except with a rigid ankle and everted toes. Rupture of the quadriceps extensor femoris tendon results occasionally from force which in other cases fractures the patella. The rupture is just above the patella. The patient cannot extend the thigh and cannot walk or stand and there is severe pain. A gap can be felt just above the patella, unless it is hidden by serous effusion, and the muscle is bunched above.

Treatment.—In limited rupture treat as a severe strain. In treating extensive rupture of an important muscle, when the ends are widely separated, expose by a septic incision, unite the divided ends with sutures of chromicized catgut (Fig. 100), and sew up the skin with silkworm-gut. Treat the part in any case by rest and relaxation and combat inflammation by appropriate means. Passive motion and massage are employed as soon as union is firm. In rupture of the quadriceps extensor femoris, operation should be undertaken,

because mechanical treatment gives frequently a bad result and confines the patient to bed for weeks. *Rupture of the biceps* requires incision and suture. In a case in the Blockley Hospital (Figs. 393 and 394) I operated and found that the long head with a portion of periosteum had been torn off from the glenoid cavity. A portion of the upper end of the tendon was cut away and the tendon was fastened to the short head by splitting and suture. Nine months later the result was perfect (Keen, in "Annals of Surgery," May, 1905). *Rupture of the plantaris* is treated at first by rest in a posterior splint and compression and later by massage and the use of an elastic bandage. The patient is allowed to walk with a cane in one week, but does not raise the heel for several weeks.

Hernia of Muscles.—When a tear takes place in a muscular sheath, a portion of the muscle protrudes. The treatment is incision, extirpation of the protruding mass of muscle, and suturing of the muscle wound and of the sheath.

Fig. 394.—Author's case of rupture of the long head of the biceps.

Contractions of muscles may result from injury, from joint disease, from malposition of parts (as in old dislocation or torticollis), or from diseases of the nervous system. The treatment in some cases is sudden extension, in other cases gradual extension, tenotomy, or myotomy. MacCewen recommends the making of a number of V shaped incisions in the muscle. In some cases of spasmodic contraction nerve-stretching is of value.

Dislocations of Muscles and Tendons.—The long head of the biceps is oftenest displaced. The flexor carpi ulnaris, the peroneus brevis, the peroneus longus, the tibialis posticus, the sartorius, the plantaris, the quadriceps extensor femoris, and the extensors back of the wrist may be dislocated. What is known as dislocation of the latissimus dorsi, a condition in which that muscle no longer lies upon the angle of the scapula, is not a dislocation, but a paralysis. Most of these accidents are associated with chronic joint-disease or with fracture, but displacement may exist as a solitary injury. *Dislocation of the long head of the biceps* may occur tolerably early in the progress of rheumatoid arthritis of the shoulder joint, and the displaced tendon may be absorbed.

Symptoms. After dislocation of a tendon the muscle of the tendon can still contract, but it acts at a disadvantage; thus the corresponding joint exhibits partial loss of function. The displaced tendon can be felt, and a hollow exists where it normally resides.

When the muscle contracts, the tendon is felt to slip from its groove. When the tendon of the biceps is dislocated, the head of the bone passes forward (so-called *subluxation of the humerus*).

Treatment. In tendon-dislocation reduction is easy, but the displace-

ment is apt to recur because of laceration of the sheath. The treatment usually advised is to effect reduction by relaxation of the limb and manipulation of the tendon, to place the part upon a splint so that the muscle belonging to the tendon will be relaxed, and to apply pressure over the point of injury. This treatment generally fails, and if the tendon does not become firmly anchored in its proper situation in four weeks, we should operate. In some tendons it is enough to incise, freshen the edges of the torn sheath, and sew up with kangaroo-tendon or chromicized catgut. In a tendon lying in a long groove make a halter for the tendon by incising the periosteum and suturing it over the tendon.* Passive movements are begun at the end of the first week. Even if the tendon will not remain reduced, a useful joint will be obtained.

Wounds of Tendons.—Subcutaneous wounds of tendons are usually inflated by the surgeon, and they heal well. Open wounds require rigid antiseptics and suturing of the tendon. In wounds of the wrist especially always suture the tendons (Fig. 101), and be sure to bring the proper ends into apposition.

Rupture of Tendons.—A violent muscular effort may rupture a tendon, and as the accident occurs, a snap may often be heard. The symptoms are sudden pain and loss of power, fullness of the associated muscle from retraction, and absolute inability to bring the tendon into action. A gap may often be felt in the tendon.

Treatment. The best procedure in treating rupture of a tendon is exposure by incision and the introduction of sutures. Some surgeons relax the parts and apply splints.

Thecitis, or tenosynovitis, is inflammation of the sheath of a tendon.

Acute thecitis may arise from a contusion, from a wound, from repeated overaction in working or while engaged in some sport, from rheumatism, from gonorrhea, from pyogenic infection, from influenza, from the continued fever, or from syphilis. In early syphilis certain tendon-sheaths may rapidly develop effusion because of hyperemia of the sheaths (Taylor).

Symptoms.—In non-suppurative cases of thecitis the symptoms are pain, swelling, tenderness, and moist crepitus along the tendon-sheath, due to inflammatory roughening. The crepitus disappears as the swelling increases, but it reappears as the swelling diminishes. In suppurative cases (*phlegmon of the tendon-sheaths*) the symptoms are great swelling, pulsatile pain, dusky discoloration, inflammation spreading up the tendon-sheaths, and often the constitutional symptoms of sepsis.

Treatment. In treating non-suppurative thecitis, employ splints and apply locally iodine, blue ointment, or ichthyol, and administer suitable remedies to combat any causative constitutional disease. In the suppurative form make free incisions, irrigate, drain, dress with hot antiseptic fomentations, and employ Bier's method (page 116). (See Felon, page 740.)

Palmar Abscess.—We mean by this term an abscess beneath the palmar fascia and not a superficial collection of pus. Palmar abscess may arise after wounds, abrasions, burns, or inflammations of the skin of the palm. A thecal abscess in a flexor tendon of a finger travels rapidly upward and may produce a palmar abscess. A thecal abscess of either the index,

* Walsham's case of dislocation of the peroneus longus, Brit. Med. Jour., Nov. 2, 1895

ring, or middle finger is usually arrested at the lower end of the palm, but suppurative thecitis of the thumb or the little finger conducts pus along the tendon sheath and up the arm (Fig. 396). If the theca ruptures, pus is diffused over the palm. It produces great swelling of the hand and fingers, the dorsum being swollen as well as the palm. The fingers become flexed and rigid. Violent pulsatile pain and decided constitutional disturbance exist. Discoloration is late in appearing. Adjacent lymph glands enlarge. Palmar abscess is a most serious affection. The pus may dissect up all the structures of the palm, may pass between the bones and reach the dorsum, or may pass beneath the anterior annular ligament into the connective-tissue planes of the forearm. In some cases it leaves a clawed, stiff, and useless hand.

Treatment. A palmar abscess demands radical treatment at the earliest possible moment; delay will be responsible for stiff and contracted fingers and hyperesthetic skin, resulting in a damaged and perhaps a useless hand. The patient should be placed under the influence of ether. The incision is made

Fig. 395.—Tuberculous thecitis (compound ganglion).

in the line of the metacarpal bone and, if possible, below the palmar arches. A line transverse with the web of the thumb is below the palmar arches. In an incision above this line try not to cut either arch, but if one be cut, at once take means to arrest the hemorrhage (page 415). In a severe case it may be necessary to make several palmar incisions, to open the tendon sheaths on the flexor surface of the forearm above the wrist, and to make counter-openings in the back of the hand, and it is sometimes necessary to introduce tubes, and drain through and through the hand. After operation apply hot antiseptic fomentations and put the part upon a splint. Bier's passive hyperemia is very useful. When granulations begin to form, dry dressings are substituted for the hot moist dressing. It may be necessary to give morphin for pain, and stimulants may be needed. There is great danger of stiffness of the fingers occurring, the tendons becoming adherent to their sheaths. Hence passive movements are inaugurated as soon as granulations begin to form.

Chronic thecitis may follow acute thecitis, but may be due to injury to rheumatism, to gummatous infiltration, to rheumatoid arthritis, or to tuberculous inflammation of a tendon-sheath. Chronic thecitis is commonest in the tendons of the fingers, the ankles, and the knees, it may spread to a joint or it may arise from a tuberculous joint. This condition causes very little pain. In ordinary non-tuberculous thecitis the part is weak, tender,

painful, and stiff, crepitates on motion, and is swollen. In *tuberculous* cases there is at first distention of the tendon sheath with serum. The serum contains *rice*, *riceiform*, or *melon-seed* bodies, and the wall of the tendon sheath is here and there thickened and caseating. Later in the case the interior of the tendon sheath becomes lined with tuberculous granulations and a tuberculous abscess may form. Rice bodies are sometimes fibrinous masses, are sometimes pieces of separated and dead recently formed fibrous tissue, and are sometimes masses of proliferating cells. In these tuberculous cases the swelling is firm or doughy when due to granulation tissue, but is fluctuating when due to fluid. Grating is marked. Tubercle bacilli are present in the fluid or in the granulation tissue. Tuberculous thecitis is most common about the wrist, constituting the so-called *compound ganglion* (Fig. 395).

Treatment.—*Tuberculous cases* are treated as follows: If there is a fluid effusion and no rice bodies, make a small incision, wash out with salt solution, introduce some iodoform emulsion, and close the wound. In cases in which there are rice bodies, open the sheath, evacuate the contents, scrape the walls thoroughly, inject with iodoform emulsion, and close the wound. If the annular ligament requires division, divide it before closing the wound—(Fig. 401). In cases with extensive thickening apply an Esmarch bandage, make a large incision, and remove all infected tissue from the sheath, around the sheath, and from the tendon. In tuberculous thecitis Bier's method (page 249) may be of service and so may the x-rays. In *ordinary traumatic thecitis* use for the first few days rest associated with applications of ichthyol. Later employ hot and cold douches, massage and passive movements, strapping of the part, injections of ichthyol, and the hot-air bath. If effusion is persistent or rice bodies exist, make an incision and scrape the interior of the tendon sheath. In rheumatic cases give antirheumatic remedies and employ the hot-air bath. In syphilitic cases administer mercury and iodid of potassium.

Ganglia.—In connection with tendon sheaths and joints simple ganglia may develop. They are small, tense, round swellings, which are firm, grow progressively though slowly, are painless when uninflamed, and contain a fluid of the appearance and consistence of glycerin jelly (Bowly). Ganglia are commonest upon the dorsum of the wrist and they occur especially in those who constantly use the wrist muscles. Ganglia are occasionally seen on the dorsum of the foot. Paget states that a *simple ganglion* is due to cystic degeneration of a synovial fringe inside a tendon sheath, and that the fluid of the ganglion does not communicate with the fluid of the tendon sheath. Other pathologists have maintained that a simple ganglion is a hernia of synovial membrane through a rent in a tendon sheath, all communication between the

Fig. 396.—Palmar synovial sheaths (vaginal tendons), normal adult type (Poirier and Charpy).

herniated part and the tendon-sheath being soon obliterated. The belief is now general that a ganglion is due to cystic degeneration of an area of connective tissue adjacent to a joint or a tendon, this area of tissue having been rendered extremely cellular by traumatism. A number of minute cysts form and they coalesce into one cyst. The cyst may form a secondary communication with the interior of a tendon sheath or joint. Ganglia occasionally diminish in size or even disappear spontaneously. *Compound ganglion* is an old name for tuberculous thecitis.

Treatment.—A ganglion is treated by aseptic puncture with a tenotome evacuation, scarification of the walls, antiseptic dressing, and pressure. An

Fig. 397 — Ganglion of extensor tendon-sheaths of the wrist

old-time method of treatment was subcutaneous rupture brought about by striking with a heavy book. Duplay treats a ganglion by injecting a few drops of iodine through a hypodermatic needle. The cyst is not evacuated before injection. The parts are dressed antiseptically, and cure is obtained in one week. Recurrent ganglia, very large ganglia, and ganglia with very thick contents should be dissected out.

Felon, or whitlow, is a violent, rapidly spreading pyogenic inflammation of a finger or a toe which resembles cellulitis, and which is sometimes followed by gangrene of the soft parts or by necrosis of bone (Fig. 398). As a rule, an injury precedes the whitlow—an abrasion of the surface which admits pus organisms or a contusion which creates a point of least resistance. The commonest seat of a felon is the last digit of a finger or the thumb. An abrasion of the surface at this point absorbs pus organisms and the superficial lymphatics carry the bacteria directly inward, the micro-organisms lodging, it may be, in the skin, in the subcutaneous tissues, in the tendon-sheath, or beneath the periosteum. The perpendicular direction of the fibers of the subcutaneous tissue favors this passage inward.

Felons are very rare in infants, but may occur in children. Women are more liable to them than are men. The fingers are much more prone to infection than are the toes, because they are more exposed to injury. Several fingers may be attacked at once or successively in persons of dilapidated constitution. Whitlow is most apt to occur and is most severe in persons broken down by disease, alcoholism, overwork, or worry. In certain cases of neuritis painless suppuration may arise. In *syringomyelia* *painless felons* are common, and they are apt to be associated with necrosis of bone. Pain-

less and destructive whitlows constitute a characteristic part of *Morvan's disease*.

There are two forms of felons, the *superficial* and the *deep*.

Superficial Felons.—One form of superficial felon is between the cuticle and the true skin and is rarely followed by involvement of deeper parts. The infection is in the skin. The point of infection becomes dark red, swollen, painful, and tender. The epidermis is lifted up into a pustule by the sero-pus which forms, and a considerable area may be attacked before the spread of the process is arrested. The commonest form of superficial felon is subcutaneous suppuration, the pus collecting in the fibro-fatty pad at the palmar surface of the last digit (G. B. Mower White, in "Brit. Med. Jour.," Feb. 24, 1906). This form often spreads deeply. If the subcutaneous tissues only are involved, the symptoms are those of an ordinary cellulitis. There is severe pain, increased by motion, pressure, and a dependent position. Swelling and discoloration

are early and marked. Pus forms within forty-eight hours. *Paronychia*, or "ring around," is a cellulitis starting at the end or side of the digit, and involving the parts around and below the nail. The pus-organisms obtain entrance by means of an abrasion, a puncture, or an ulcerated "step-mother." In paronychia pain is throbbing and violent; is increased by motion, pressure, or a dependent position; the skin is dusky red, but the swelling is slight. In about forty-eight hours pus forms in the superficial parts, the epidermis being

Fig. 398.—Deep felon, with sloughing of soft parts and necrosis of bone.

lifted into pustules or blebs, and pus may also form under the nail. A portion of the nail or the entire nail may be lost.

If the tendon-sheath becomes involved as well as the subcutaneous tissue, the symptoms are those of suppurative thecitis, with more marked discoloration of the skin.

Deep Felons (Fig. 398).—There are two forms of deep felon. One is a thecal abscess involving the flexor tendon-sheath, arising secondarily to subcutaneous suppuration and spreading widely. In suppurative thecitis of the three middle fingers the process seldom reaches the palm; in suppurative thecitis of the theca of the thumb or little finger the pus may pass above the wrist and a true palmar abscess may form (Fig. 399). Another form is suppuration beneath the periosteum. This form is the so-called *bone felon*. It is occasionally primary, but more often arises secondarily to suppurative thecitis or to subcutaneous suppuration. In some cases a deep felon involves most of the struc-

tures of the finger (periosteum, bone, tendon, tendon-sheath, and cellular tissue), and may destroy the digit or the finger. The bacteria causative of a deep felon are lodged in the deeper parts. The pain is agonizing, entirely preventing sleep, pulsatile in character, associated with excruciating tenderness, greatly aggravated by motion or a dependent position, and often extending up the hand and forearm. The skin is dusky red and edematous, and

the part is enormously swollen. Pus forms quickly; diffuse cellulitis may arise; sloughing of the tendon and subcutaneous tissue may take place; necrosis of one or more bones may ensue, and in some cases gangrene of the finger follows.

In deep whitlow lymphangitis of the forearm and arm is not unusual, adenitis of the axillary glands is common, and almost always there is fever. In superficial felon constitutional symptoms are slight or absent, and lymphangitis and adenitis arise in a minority of cases.

Treatment.—In a subcuticular felon, after cleansing, soften the parts well in an antiseptic fluid and then pare off the cuticle with a very sharp knife. This plan of White's is an excellent one; it gives vent to pus and prevents the inoculation of the deeper tissues which may follow incision. In subcutaneous suppuration

Fig. 399.—1, 2 and 3 Incisions for felon of finger and for ordinary suppurations, 4, palmar incision

incise the abscess, but be careful not to open the tendon-sheath or periosteum, as this would diffuse infection (White, in "Brit. Med. Jour." Feb. 24, 1906). In neither of the above instances is it necessary to give an anesthetic. After operating the parts must be irrigated, dressed with hot antiseptic fomentations, the hand must be placed upon a splint, and Bier's passive hyperemia is to be induced daily. In a deep felon I am convinced that we should operate immediately. Allay tension and prevent pus-formation by early incision. Do not waste time with poultices; to wait means agonizing pain, sleepless nights, constitutional involvement, and, perhaps, sloughing of tendons or death of bone. Incision and drainage constitute the treatment, but incision conducted in a particular manner. I have only lately learned how to treat a deep felon. I formerly treated all cases by incisions down to the bone alongside of the tendon (Fig. 399) and was frequently disappointed by a spread of the suppuration in spite of incisions, by necrosis of bone, or by extensive sloughing of tendons. A few months ago I obtained new light upon this subject from an article on "Whitlow," by G. B. Mower White ("Brit. Med. Jour.," Feb. 24, 1906). I immediately put in practice the common-sense suggestions in this valuable article and have seen a surprising improvement in results. The chief points in White's plan of treatment are as follows: To plunge a knife through an area of infection into a tendon-sheath if that sheath is not infected will lead to infection, and the way to be sure whether it is or is not infected is to look through a carefully made incision and see. After careful sterilization, anesthetize, drain the extremity of blood by ele-

vation, and apply an Esmarch band to the arm. This enables us to see what we are doing. Make an incision by the side of the tendon-sheath (Fig. 309), slowly and carefully, and on reaching it see if it is distended. If in doubt, insert a hypodermatic needle and withdraw fluid. If we get turbid serum, the theca is infected. If the theca is not infected, do not open it but incise the subperiosteal area of suppuration if it exists. If the theca is infected, remember that this infection has surely ascended more or less, and we must not only open at the lower point, but must also incise at the upper point. Do not incise the theca over the length of the tendon, as sloughing will follow. If one of the three middle fingers is involved, incise the distal end of the theca and also the proximal end over the head of a metacarpal bone in the mid-line, wash from opening to opening, and drain. If the theca of the thumb or little finger is involved, open distally and then proximally above the wrist. To reach the proximal end of the theca of the thumb cut at the radial side of the tendon of the flexor carpi radialis. Also open the palmar sac of the flexor longus pollicis, making the cut along the inner border of the outer head of the flexor brevis pollicis.

To reach the proximal end of the theca of the little finger begin an incision at the upper margin of the annular ligament and carry it up along the inner border of the flexor sublimis. Retract the tendons and pus will usually be found between the tendons of the superficial and deep flexor. Look beneath the profundus tendons for the bursa and open it. Then open the palm by an incision in the line of the axis of the ring-finger. Thus three openings are made in either case, and the theca can be thoroughly washed and drained. If either the thumb or little finger bursa is found infected, the other must be exposed and examined, as they usually communicate at their proximal ends or a communication may form as a result of suppuration. Rupture of either bursa may diffuse pus widely. White, in order to prevent secondary hemorrhage, ligates the radial artery in two places and removes $1\frac{1}{2}$ inches of it (if operating on the thumb bursa); and ligates the superficial arch and removes 1 inch of it (if operating on the palmar expansion of the little finger theca). These arterial ligations seem a serious and perhaps unnecessary addition to the operation and I have not practised them. After thorough irrigation apply antiseptic fomentations, splint the extremity, and induce Bier's passive hyperemia daily. If the patient cannot sleep, give morphin. See that the bowels are moved once a day. Give quinin, iron, and milk-punch. As soon as granulations begin to form, use dry dressings and make passive motion daily. If bone undergoes necrosis, let it loosen and then remove it. Amputation is sometimes necessary.

Bursitis is inflammation of a bursa. *Acute bursitis* arises from strain or from traumatism. The symptoms of acute bursitis are pain, limited swelling, moist crepitus, fluctuation, and discoloration in the anatomical position of a bursa. In *chronic bursitis* there is intermittent pain, tenderness, and progressive, fluctuating swelling. *Bursitis of the retrocalcaneal bursa (Albert's disease)* is a painful affection which is often overlooked. It is rather common in storekeepers who rise often on the toes to reach shelves, in mailmen who use a foot gong, in street-car conductors, and clerks who stand at desks. It may follow gonorrhea. Walking causes great pain in the heel. Raising up on the toes is exceedingly painful. It is usually associated with flat-foot. In these cases osteophytes often form within the

bursa. There are numerous bursæ about the hip. Some anatomists count twenty-one.* The two most important bursæ and the ones usually affected are the iliac and the deep bursa over the great trochanter.† Inflammation of the *iliac* or *ilio-psoas bursa* produces swelling below Poupart's ligament which swelling is tense, but exhibits fluctuation on careful examination. Often the swelling attains large size. In some cases the sac can be emptied by pressure, the fluid passing into an adjacent bursa or into the joint. The swelling is beneath the femoral artery and consequently lifts that vessel (F. B. Lund, in "Boston Med. and Surg. Jour.," Sept. 25, 1902). The enlargement often presses on the anterior crural nerve and causes spasmodic pain throughout the nerve's trajectory. The limb, according to Zuelzer, is usually slightly flexed, abducted and rotated outward, and movement in an opposite direction causes pain. Inflammation of the bursæ about the hip may produce symptoms resembling those of incipient coxalgia, but in bursitis the symptoms do not remit, as in hip-disease. Ilio-psoas bursitis occasionally results from gonorrhea. The bursa is sometimes involved in joint-disease. In inflammation of the iliac bursa flexion is not so marked as in coxalgia, and the trochanter is never above Nélaton's line. In inflammation of the great trochanteric bursa the position is the same as in iliac bursitis, and resembles that of coxalgia. In coxalgia, however, there is pain on pressure upon the front of the joint or directly on the trochanter or on tapping the sole of the foot. These manipulations do not cause pain in bursitis (Zuelzer). In inflammation of the *gluteal bursa* there is moderate pain at the back of the thigh and knee, which disappears when the patient is at rest; there are a marked limp, limitation of motion, and an area of deep fluctuation in the buttock (Brackett).

Fig. 400. —Olecranon bursitis.

It is difficult to differentiate between inflammation of a deep bursa and synovitis; indeed, in bursitis the joint is apt to be secondarily affected. The difficulty is especially vexatious in distinguishing between joint-injury and injury of the bursa beneath the deltoid. Suppuration may take place in the bursa. Direct force may rupture a bursa. The bursa beneath the deltoid is frequently ruptured. When this accident happens, there are pain, marked swelling, a large area of moist crepitus, and later extensive discoloration from blood. Chronic bursitis may follow acute bursitis, or the disease may be chronic from the start. It may be due to tuberculosis. Bursæ particularly apt to become tuberculous are those about the hip, the subdeltoid, olecranon, the prepatellar, and the retrocalcaneal. In tuberculous bursitis during the first stage the bursa is distended with fluid, due to oversecretion; the walls are thickened here and there, and perhaps contain caseous foci.

* Synnæstvedt, of Sweden.

† Zuelzer in Zeit f. Chir., vol. 1.

rice bodies are found in the bursal fluid. In a more advanced stage the bursal wall is lined with caseating granulation tissue and the bursa may become a

Fig. 401.—Housemaids' knee.

Fig. 402.—Bursitis of left olecranon bursa of three years' duration

tuberculous abscess, the walls may give way with diffusion of the process, or mixed infection with pyogenic organisms may occur. In some cases of

tuberculous bursitis tending to cure the bursal walls become enormously thickened by fibrous tissue. The **symptom** of chronic bursitis is swelling with little or no pain unless acute inflammation arises. Chronic bursitis of the subhyoid bursa is known as *Boyer's cyst*.

Treatment.—Acute bursitis is treated by rest, pressure, and the application of iodine, blue ointment, or ichthyol. If the swelling persists, aspirate and apply pressure, or incise the sac and remove it partly or completely. If pus forms, incise, paint the interior of the sac with pure carbolic acid, and pack with iodoform gauze. Chronic bursitis may be cured by the use of pressure and the application of blue ointment, and with treatment of

Fig. 493.—Diagram from a frozen section. Notice the deltoid and its origin from the edge of the acromion. Notice the subdeltoid or subacromial bursa with its root made to the under surface of the acromion and by the fascia beneath the upper portion of the deltoid. Its base is on the greater tuberosity and the tendon of the supraspinatus, which separates it like an interarticular fibrocartilage from the true joint (Codman).

any causative diathesis, but most cases require incision and packing. A ruptured bursa is treated as an acute bursitis. In bursal tuberculosis the best treatment is excision. If we are dealing with a very deep bursa, the proper treatment is incision, scraping with a sharp spoon, mopping with carbolic acid, and packing with iodoform gauze.

Bursitis of the subacromial bursa has been considered by A. F. Codman ("Boston Med. and Surg. Jour.," Oct. 22 and 29, Nov. 5, 12, 19, and 26, and Dec. 3, 1908), who points out that the deltoid and the subacromial bursa are one and the same thing. When the arm is abducted, the entire bursa is subacromial, when it is adducted, a large portion of the bursa is subdeltoid. Codman describes three types of conditions associated with inflammation of this bursa, first: The acute, or spasmodic type, in which

there is local tenderness on the point of the shoulder, just below the acromion process and outside the bicipital groove. In some cases Dawbarn has shown that the tender point, which is the base of the bursa, disappears under the acromion when the arm is abducted. Codman goes on to show that in attempting abduction about ten degrees of motion can be obtained without moving the scapula. Then the scapula is locked by spasm and moves with the humerus. This spasm may be temporary in mild cases; sometimes pain prevents the patient from voluntarily raising the arm, though it may be raised by passive motion. The pain may run down the outer side of the arm, even into the hand; the patient frequently locates the pain about the insertion of the deltoid, and may be able to note swelling of the bursa.

Codman describes type two, the subacute or adherent type, in which there are adhesions between the roof and floor of the bursa and a definite mechanic hindrance to abduction and external rotation. There may or

FIG. 304.—Showing incision used for demonstration of the bursa (Codman)

may not be local tenderness, but Dawbarn's sign is absent, owing to the presence of the adhesions. Abduction is limited to such a great degree that, as a rule, the tuberosity will not pass beneath the acromion. Any movement in abduction beyond ten degrees causes the scapula to move. The pain is located as in type one, and frequently also passes into the neck. In some cases it is very severe.

Codman's third form is the chronic or non-adherent. In this the full range of motion is retained, but motion is painful. The bursa is thickened and irregular. There may or may not be local tenderness, and if this is present, one will find Dawbarn's sign. Abduction and external rotation are limited little, if at all, but at some point during abduction there is severe tenderness, which disappears as soon as the tuberosity passes beneath the acromion. The scapula does not accompany the motions of the humerus. There is often considerable pain after motion.

Codman points out that the prognosis in type one is very favorable if treatment is correct. In type two the disability, even without treatment,

seldom lasts more than two years. He says that even severe or adhesive cases, if there are no secondary contractures in the forearm muscles, recover in from one to two years. In infective cases the prognosis is

Fig. 495.—Showing the abduction splint in position, the patient standing. It is held by a figure of 8 bandage, which crosses behind the shoulders and by a belt about the waist. The arm is at rest (Codman).

Description of Splint.—The frame of the splint which I use is made of iron wire (diameter 1 inch), stiff enough to maintain its form and to carry the weight of the arm securely. Sufficient cotton wadding to thoroughly pad it is bandaged over it and the whole covered with cotton or linen cloth. The general shape is shown in the photograph. It should be just long enough to extend from the axilla to the seat of the chair on which the patient sits. It is best held in position by a belt around the pelvis and a figure of 8 flannel bandage over the shoulders crossing back of the neck. A pad should be placed in the opposite axilla to prevent excoriation of the skin by the bandage.

During the first twenty-four hours and afterward, if worn at night, the arm should be lightly bandaged to the projecting part of the splint. Additional security is given by the application of a swathe, which may be pinned to the bandage of the axilla.

When properly adjusted it is perfectly comfortable. Unless it is comfortable it is useless. The use of the splint is not essential and is even harmful if not skillfully cared for.

worse than in traumatic cases. In chronic cases, in which the arc of motion is not affected, the prognosis is fairly good.

Treatment.—Acute cases of subacromial bursitis should be treated by keeping the arm abducted. Monks suggests that the patient may sit at a table, the arm being abducted and placed upon a pillow that is on the table.

This relaxes the short rotators and the deltoid, and keeps the base of the bursa from being in contact with the acromion (Codman). At night Codman places the arm on a pillow, with its long axis at right angles with the patient's body as he lies recumbent. If the patient has to get about, he may use a sling most cautiously. He should take the arm out from time to time and rest it on a table. Massage should be used about the bursa, but not directly over it. In the more severe cases with adhesions one may employ massage, passive and active movements, baking, forcible movement and manipulation under an anesthetic, followed by fixation in the position of abduction, or perhaps incision of the bursa with division of the adhesions or excision of the subdeltoid portion of the bursa (Codman). In the cases in which there is irregularity of the surface of the bursa, one should excise and remove the thickened folds or other irregularities.

Housemaids' knee (Fig. 401) is thickening and enlargement of the prepatellar bursa, the result of intermittent pressure. In effusion into the knee-joint the fluid is behind the patella and the bone floats up, in housemaids' knee the fluid is above the bone and the osseous surface can be felt beneath it.

"Miners' elbow" (Fig. 402), which is a condition similar to housemaids' knee, affects the olecranon bursa.

"Weavers' bottom" is enlargement of the bursa over the tuberosity of the ischium. A bursa which is simply thickened and enlarged rarely gives rise to annoyance; but when it inflames, as it is apt to do, it causes the ordinary symptoms of bursitis.

Treatment of Special Forms.—

Some few cases of housemaids' knee may be cured by rest and blistering, but in most cases it is necessary to incise and pack with iodoform gauze. In enlargement of the bursa beneath the ligamentum patellæ, if rest and blistering fail to cure, aspirate or incise. In enlargement of the bursa beneath the tendon of the semimembranosus and also in "weavers' bottom" and in "miners' elbow," incise and pack. In operating for ilio-psoas bursitis I follow Lund's advice and make a vertical incision below Poupart's ligament, and between the anterior crural nerve and the femoral artery. The fibers of the ilio-psoas muscle are separated and the bursa is opened and drained. Some few cases of retrocalcaneal bursitis recover after rest, but most of them require incision and drainage. If osteophytic formations exist, the bony stalactites must be removed by means of the rongeur. Flat-foot, if it exists, is treated by a support (page 750).

Bunion.—A bunion is a bursa due to pressure, and it is most commonly situated above the metatarsophalangeal articulation of the great toe, but is

Fig. 406 — Enlargement of the deep infrapatellar bursa, chronic, and the result of traumatism (Patterson).

occasionally seen over the joint of another toe. When the big toe is pulled toward the other toes by ill-fitting boots, a bunion forms. When a bunion is not inflamed, it may cause but little trouble; but when it inflames, the skin enlarges and the parts become hot, tender, and exceedingly painful. Suppuration may occur and pus may invade the joint, and the bone not only becomes diseased.

Treatment.—In treating a bunion the patient must wear shoes that are not pointed, that have the inner border straight, and that have room for the toes (Jacobson). For a mild case a bunion-plaster gives comfort. It also advises the use of a linen glove over the digits, the phalanges being

Fig. 407.—Bige's apparatus for bunions.

held inward by a piece of elastic webbing, one end of which is fastened to the glove and the other end to a plaster strapping from the heel. A special apparatus may be worn (Fig. 407). In many cases osteotomy of the proximal phalanx or of the first metatarsal bone is required. In some cases excision of the joint is necessary, in others amputation must be performed. Charles May has operated on 65 cases successfully. He removes the distal end of the metatarsal bone and with it two thirds of the bony protuberance on the inner side, and turns the bunion joint area in front of the bone. He sutures this skin in place and now has a synovial membrane for a bursa.

When the bursa is not inflamed, but only thickened, blisters should be applied over it, or there should be applied tincture of iodine, ichthyol, or salicylic ointment. When the bursa inflames, ichthyol ointment is applied. Intermittent heat by foot baths gives relief. Suppuration demands immediate incision and antiseptic dressing. If an ulcerated bunion does not heal by antiseptic dressing, stimulate it with nitrate of silver and dress it with an unguent. hydrarg. nitrat. (1 part to 7 of cosmolin). Jacobson recommends skin-grafting for some cases.

OPERATIONS UPON MUSCLES AND TENDONS.

Tenotomy is the cutting of a tendon. It may be *open* or *subcutaneous*, the open operation being preferred in dangerous regions.

Open Division of the Sternocleidomastoid Muscle for Wry-neck.—Subcutaneous tenotomy for wry-neck has been largely abandoned. It is not only more unsafe than the open operation, but it never completely divides all the contracted band.

The instruments required consist of a scalpel, dissecting forceps, anastomotic forceps, scissors, needles, ligatures, etc. The patient is placed recumbent, the chin being drawn more than is habitual toward the opposite side.

A transverse incision is made over the muscle about one-fourth inch above the clavicle. The superficial parts are divided, the muscle is exposed and sectioned, bleeding is arrested, and the skin is sutured. The anterior jugular vein, which is underneath the muscle, and also the external jugular, which is close to the outer edge of the muscle. Mikulicz advocates the removal of almost the entire muscle, leaving, however, the anterior and posterior portion where the spinal accessory nerve passes. After

ration for wry-neck support the head with sand-bags or a plaster-of Paris dressing until healing occurs, and then inaugurate motions, active and passive.

Subcutaneous Tenotomy of the Tendo Achillis.—This operation is performed for club-foot, in which the heel is raised. The tendon is cut about one inch above its point of insertion. The instrument used for the first puncture is a sharp tenotome. The patient lies upon his back, "with his body rolled a little toward the affected side" (Treves), the foot being placed upon its outer side on a sand-pillow. The surgeon stands to the outer side. The tendon is rendered moderately rigid, and a sharp tenotome, with its blade turned upward, is inserted along the anterior border of the tendon until the surgeon's finger feels the knife approaching the outer side. The sharp pointed instrument is withdrawn and a blunt pointed tenotome is inserted in its place. The tendon is drawn into rigidity, and the surgeon turns the blade of his knife toward the tendon, places his finger over the skin, and saws toward his finger. The tendon gives way with a snap. Treves states that a beginner is apt not to push the knife far enough toward the outside, or he may in the first puncture push the knife through the tendon; in either case the tendon is not completely cut. The little wound, which is covered with a bit of gauze, will be entirely closed in forty-eight hours. In club-foot cases after tenotomy some surgeons at once correct the deformity and immobilize the limb in plaster; some partially correct the deformity and apply plaster for one week, at which time they remove the plaster, correct the deformity further, reapply the plaster, and so on; other surgeons do not attempt correction of the deformity until the cut tendon has begun to unite, when they gradually stretch the new material.

Subcutaneous Tenotomy of the Tendon of the Tibialis Anticus Muscle.—The tendon is divided about one and a half inches above its point of insertion. It can be made tense by extending and abducting the foot. The sharp pointed tenotome is entered upon the outside of the tendon, and is passed well around it. The blunt-pointed tenotome is used to cut the tense tendon.

Subcutaneous Tenotomy of the Tendons of the Peroneus Longus and Brevis Muscles.—These two tendons are cut together back of the external malleolus, and one and a half inches above the tip of the malleolus, so as to avoid the synovial sheath (Treves). The patient lies upon the sound side, the outer aspect of the deformed foot being upward and the inner aspect of the ankle of the deformed side resting upon a sand-pillow. A sharp tenotome is introduced close to the fibula, and is carried around the loose tendons. A blunt-pointed tenotome is now introduced, its edge is turned toward the tendons, and these structures are cut as they are made tense.

Subcutaneous Tenotomy of the Tendon of the Tibialis Posticus Muscle.—This tendon is sectioned above the point where its synovial sheath begins; that is, above the internal annular ligament (Treves). The tendon is made tense and the pointed knife is entered above the base of the inner malleolus. The knife is entered just back of the inner edge of the tibia, and is carried around the muscle and is kept close to the bone. The tendon is sectioned with a blunt knife.

Subcutaneous Fasciotomy of the Plantar Fascia. The contracted bands are discovered by motions which render them tense, and they

are divided just in front of the attachments to the os calcis. The sharp knife passes between the skin and fascia at the inner side of the sole of the foot. The fascia is cut from without inward by the blunt-pointed tenotome. It is usually necessary to section the fascia at more than one point.

Tendon-suture and Tendon-lengthening.—The instruments required in these operations are an Esmarch apparatus; curved needles, and needle-holder; chromicized gut, kangaroo-tendon, or silk for an ordinary case, silver wire for a suppurating wound. In performing tendon-suture make the part aseptic and bloodless. It is wise to apply a rubber bandage on the proximal side, the bandage being applied centrifugally, forcing the proximal end of the tendon into view (Haegler). If searching for the proximal end of a flexor of the finger, flex the injured finger, and hyperextend the adjoining fingers (Filiguet). If this expedient fails, enlarge the incision, or, what is better, make a large flap in the skin. After finding the ends approximate them, being sure the proper ends are brought into contact; stitch them together with a continuous suture or with one of the sutures shown in Fig. 408, 1, 2, and 3. In a suppurating wound suture by silver wire should be tried, though it usually fails. After suturing, remove the Esmarch apparatus, arrest bleeding, close the wound and dress it antiseptically, relax the parts, and place the limb on a splint. If, after suturing, there is much tension, stitch the cut tendon above the sutures to an adjacent tendon, and apply a splint, the finger which was injured being flexed, the others being extended.

Fig. 408.—Tendon-sutures. 1, Of Le Fort; 2, of Le Dentu; 3, of Lejars.

Fig. 409.—Anderson's method of tendon-lengthening.

If only the distal end of the tendon can be found, graft it upon the nearest tendon with a like anatomical course and function. When a tendon has been sutured, begin gentle massage in two weeks. Positive passive motion is begun in three or four weeks. In old injuries, when the ends cannot be brought into apposition, lengthen one end or both ends, either by the method of Anderson (Fig. 409) or by the method of Czerny (Fig. 410). Dr. J. Neely Rhoads ("Med. News," Nov. 28, 1891) suggested that slight lengthening could be accomplished by "cutting half through the tendon at different levels and from opposite sides, leaving some longitudinal fibers to slip on each other, thus gaining slight elongation" (H. Augustus Wilson, in "International Clinics," vol. i, 4th series). Poncet makes several zigzag incisions on each side of the tendon, and when the tendon is pulled upon it elongates decidedly. Hibbs's method is shown in Fig. 412. One of these methods of lengthening may be used if there is deformity from tendon-contraction.

If the tendon cannot be lengthened sufficiently, make a bridge of catgut from one end of it to the other, or graft in another tendon from one of the lower animals, or graft the distal end to a tendon of like function (*tendon-grafting*).

The annular ligament is sutured as shown in Fig. 411.

Tendon-transplantation.—This operation is usually said to have been devised by Nicoladoni in 1882; as a matter of fact, Duplay did the operation in 1876, endeavoring to secure function in an arm rendered powerless by an injury (Eltzings, in "Albany Med. Annals," April, 1902).

The first American surgeon to do the operation was Parrish, of New York, who in 1892 transplanted tendons in a case of club-foot. In some cases in

Fig. 410.—Caerny's method of tendon-lengthening.

Fig. 411.—Method of suturing the annular ligament of the wrist.

which a muscle has been paralyzed surgeons have divided the tendon of the paralyzed muscle and have united its distal end with the tendon of a normal muscle, the normal tendon being split to receive it. It has also been stated that when a muscle or the tendon of a muscle is sutured to a paralyzed antagonistic muscle, the transplanted structure will actually execute the functions of the paralyzed muscle. For instance, a flexor, when so transplanted, may become an extensor and act under the mental impulse of extension; a pronator may become a supinator (H. A. Wilson in "American Med.," April 8, 1905). These principles have been utilized when some or many of the muscles of a limb have been paralyzed, the tendon of an unparalyzed muscle or the tendons of an unparalyzed group of muscles being fastened to the tendons of the paralyzed muscle. It has been shown that the success of this procedure depends upon the accuracy of diagnosis, the division of secondary contractures, the correction of existing deformities, and careful after-treatment. (See the article

Fig. 412.—Hibbs's method of tendon-lengthening.

by Dr. J. Hilton Waterman, in "Med. News," July 12, 1902.) In a paralysis of the lower extremity, as Goldthwait points out, the sartorius usually retains power, and it may be advisable in such a case to divide the sartorius and suture its upper end to the quadriceps above the patella. A strip of the tendo Achillis may be grafted upon the peronei in certain cases. An artificial tendon may be made of silk, the silk being passed from the sound to the paralyzed

tendon (Lange); the silk eventually becomes surrounded by fibrous tissue. Strands of silkworm gut may be used for the same purpose (Kummell). The operation of tendon-transplantation is occasionally of distinct benefit, but I agree with Ridlon, and am not usually sanguine of results. Ridlon wisely reminds us that in such cases much good may perhaps result from the proper use of braces, tenotomy, and hand stretching, followed by prolonged retention in plaster, the patient using his limb actively.

Ridlon points out that most brace treatment is not curative because it only aims to prevent deformity developing, and tenotomy and stretching fail because they only seek to remove existing deformity. The object should be some restoration of function. This is often obtained by following Thomas's direction and "posturing" the limb so as to permit structural shortening of the paralyzed muscles and then fixing them for months.

XXI. ORTHOPEDIC SURGERY.

THIS branch of surgery formerly dealt only with the treatment of deformities by means of mechanical appliances, but of recent years its domain has been enlarged to include the treatment, surgical and mechanical, of deformities, contractures, and many joint-diseases.

Torticollis (wry-neck) is a condition in which contraction of certain of the neck-muscles causes an alteration in the position of the head. The disease is one-sided; the sternocleidomastoid is the muscle chiefly involved, though the trapezius, the splenius, and other muscles sometimes suffer. Acute torticollis, which is rare, is a temporary condition, and results from cold or from injury (see Myalgia). Chronic torticollis may be congenital (due to injury before birth or during birth), may be due to nerve-irritation, to an assumed attitude because of eye-defect, to polio-encephalitis (Golding Bird), to inflammation of the glands or to disease of the vertebrae, and it may be intermittent, but is usually persistent. The muscle stands out in bold outline, the head is turned to the opposite side, the ear of the disordered side is turned toward the shoulder, the chin is thrown forward, and spinal curvature may arise. The corresponding side of the face atrophies. There is no pain. In many cases the head may be restored to its normal position by passive movement or by voluntary effort, but it at once returns to its habitual position. Mikulicz asserts that torticollis is a chronic fibrous myositis, due often to compression during labor. He further says that the lesion known as hematoma of the sternomastoid, which occasionally follows labor, is not hematoma, but thickening due to myositis. D'Arcy Power reported the autopsy on a child one month of age. The sternomastoid muscle contained a fibrous mass, the result, Power believes, of a hemorrhage into the muscle prior to birth ("Med. Chir. Trans.," vol. lxxvi). Power, Clutton, and Owens have all traced cases of hematoma of the sternomastoid from early infancy to the time when tenotomy was required for torticollis. W. W. Richardson ("Surg. Gynec. and Obstet.," 1906) believes that interstitial myositis is always present, but doubts the causal influence of the lateral position of the head *in utero*. In some cases hereditary influence is evident. One woman gave birth success-

only to seven wry-necked children (Nove-Jusserand and Vianny, in "Revue D'Orthop.," 1906). In spasmodic wry-neck the muscle is thrown repeatedly into clonic contractions. In congenital torticollis the muscle and the cervical fascia are shortened, and the muscle does not relax under the influence of an anesthetic. In torticollis due to rheumatism and reflex causes the tonically contracted muscle relaxes when the patient is anesthetized.

Symptoms.—*Congenital* wry-neck is due to central nervous disease, to spinal deformity, or to injury during birth, and in this form the sternomastoid is shortened, hardened, and atrophied. It may not be noticed for some years because of the short neck of infancy. It is associated with a symmetrical development of the face, and is almost invariably upon the right side. *Spasmodic* wry-neck may present tonic spasm only, intermittent spasm alone, or both may appear alternately. It sometimes arises in those whose occupation demands frequent rotation of the head, but more often no such cause can be discovered. It is probably a disease of the cortical area which presides over rotation of the head. (See article by C. A. Hamann, in "Buffalo Med. Jour.," Dec., 1901.) It is a disease especially of adults; in women it is often linked with hysteria. Pahl ("California State Med. Soc.," 1906) analyzed 68 reported cases. Men and women appeared equally liable, it was most frequent between the ages of twenty and thirty, and the right side was affected in twice as many cases as the left side. The exciting cause may be a cold, a blow, or a mental storm; the predisposing cause is the neurotic temperament. It may be due to enlarged glands, to carious teeth, or to eye-strain. In some rare cases bilateral spasm occurs, the head being pulled backward and the face being turned upward. Clonic spasms may come on unannounced, or they may be preceded by pain and stiffness; the head can be held still for a moment only, there is sometimes pain, always fatigue, but during sleep the contractions cease. The attack will probably pass away, but will almost certainly recur.

Treatment.—*Congenital* wry-neck is treated by myotomomy through an open incision in a line parallel to and just below the clavicle. The flaps are raised, access is free to both origins of the muscle, the muscle is readily divided, the wounds in the skin and fascia are closed. This incision leaves a trivial scar. After operation plaster of Paris is used to secure fixation and fixation is maintained from four to eight weeks. Early operation favors the establishment of muscular co-ordination before the development of permanent bony deformity of the vertebrae. Some surgeons cut the scalene muscles as well as the sternocleidomastoid. Gerdes Rowland lengthens the sternomastoid and carefully sutures it ("Practitioner," Sept., 1908). The old subcutaneous myotomomy should be abandoned, as aseptic incision enables the surgeon to see and to feel all the contracted bands of fascia, muscle, and tendon, and to avoid vital structures (page 748). In spasmodic wry-neck there is a fair chance of recovery. Pahl's table (Ibid.) shows that out of 66 cases, 28 recovered, 17 were improved, and 11 were not improved by treatment. Results in 12 were not stated. Treat the neurotic temperament and remove any obvious irritation (eye-strain, carious teeth, enlarged glands). Drugs usually are practically useless, although Chas. S. Potts reported a cure after the hypodermatic use of atropin. The rest cure is sometimes beneficial.

Tenotomy is not to be employed. In 1890 Mayo Collier suggested ligation of the spinal accessory nerve with silver wire. In persistent cases stretch or divide and excise a part of the spinal accessory nerve (Keen). To reach this nerve, make an incision along the posterior edge of the sternocleidomastoid muscle, find the nerve as it emerges from under the middle of the muscle about one and a half inches below the tip of the mastoid process, retract the muscle at this point, and remove at least one inch of nerve. Neurectomy of the spinal accessory nerve paralyzes the sternocleidomastoid muscle, in spite of the fact that that muscle has also a nerve-supply from the cervical nerves. The paralysis is followed by atrophy, and if the spasm affected the sternocleidomastoid muscle only, the operation will cure the case. Unfortunately, other muscles are usually involved, and cure will only be obtained by performing neurectomy on the nerves which innervate the affected muscles. For the treatment of rheumatic wry-neck, see Myalgia (page 726).

Dupuytren's contraction is a contraction of the palmar fascia, of its digital prolongations, and of the fibers joining the fascia and skin. Fixed contraction of one or more fingers occurs. The ring-finger and the little finger most often suffer, but any finger or the thumb may be involved. The contraction may be symmetrical. It is far more common in men than in women. The disease arises oftenest in men beyond middle age, but is sometimes met with in youths. The cause of this disease is unknown, some refer it to gonorrhea or rheumatism or osteo-arthritis; others to traumatism, syphilis, organic nervous diseases, arteriosclerosis, reflex irritation, or neuritis. In one fourth of the cases heredity seems to be influential. If due to traumatism, the right hand should suffer most frequently; but it occurs in the left hand nearly as often as in the right (P. Jansen, in "Arch. f. klin. Chir.," Bd. lxxvii, H. 4). Jansen examined specimens from 7 cases and found connective-tissue hypertrophy and circulatory disturbance, the contraction being a result of the above-named processes.

Symptoms.—Dupuytren's contraction is indicated by a small hard lump or crease which appears over the palmar surface of the metacarpophalangeal joint. This nodule grows and the corresponding finger is gradually pulled down. In some cases the tip of the finger is forced against the palm. The skin becomes dimpled or puckered.

Treatment.—Fibrolysin, which is a soluble combination of thiosinamide and salicylate of sodium, has been used hypodermatically in Dupuytren's contraction and, it is claimed, with success (Schwallbach). In treating Dupuytren's contraction subcutaneous multiple incisions may be made, the tenar fascia and the fasciocutaneous fibers being cut. The finger is straightened and is placed upon a straight splint, which is worn continuously for a week or ten days and is worn at night for at least a month. A more satisfactory operation is that of Keen. Keen divides the skin by a V-shaped cut, the base of the V being downward, lifts up the flap, and dissects out the contracted tissue. A cure is most certain to be obtained by Lexer's radical operation. This surgeon excises the entire aponeurosis and considerable portions of the palmar skin adherent to the aponeurosis. In order to cover this wound it may be necessary to slide a pedunculated flap into the raw surface.

Syndactylism (webbed fingers) is always congenital, and may persist

through several generations. Simple incision of the web is useless; the operation to be performed is that of Agnew or of Diday (figs. 413, 414).

In Agnew's operation a flap of skin from the dorsum is inserted between the fingers and sutured in place.

In Diday's operation a flap is taken from the dorsal surface and another flap is raised from the palmar surface, and each flap is sutured to the finger from which it springs.

Polydactylism (supernumerary digits) is always congenital, is often hereditary, and is usually symmetrical. There may be an incomplete digit, or there may be an entire and well developed finger or toe with a metacarpal or metatarsal bone. The connection to the metacarpus or metatarsus may be by a fibrous pedicle only. If the digit is complete, with a metacarpal bone, no operation is required, if it is incomplete or is ill-developed, it should be removed.

Trigger-finger or Jerk-finger (Lock-finger, Snapping-finger).

—The patient can usually close the fingers, but on trying to open them one finger remains closed. It can be opened by grasping it with the other hand, but then opens with a snap, like opening a knife (Abbe). In some cases two

Fig. 413—Agnew's operation for webbed fingers (Pye)

Fig. 414—Diday's operation for webbed fingers (Pye)

fingers are involved. In a reported case (Frederick Griffith, "Annals of Surgery," 1904) the ring and middle fingers of the left hand locked at the knuckle joints on attempting flexion. The locking occurred when about one-third the amount of flexion necessary to grasp an object was achieved. By bending the fingers with the other hand unlocking was accomplished and flexion was finished voluntarily. In attempting extension blocking occurred at the same point and unlocking was accomplished in the same manner. In most cases, but not in all, there is pain when locking occurs. The condition is gradual in onset. Trigger finger is often associated with rheumatism (in 12 cases out of 121, according to Necker). It is said by Tubby to be due to entanglement of the flexor tendon, or to contraction of the groove in the transverse ligament in the palm. It may be due to a ganglion, enchondroma, or tenosynovitis. Traumatism or irritation may produce it. The tendon-sheath may be thickened or, according to Marciano, there may be a nodule on the tendon which rubs against the sesamoid bone. It may result from occupation.

Treatment.—If a ganglion, a loose cartilage, or a tendon nodule exists, treat by excision. A sesamoid bone may be excised. If there is inflammation, use massage and counter-irritation. If there is no obvious cause, put a compress over the tunnel in the ligament and apply a splint.

Mallet-finger.—This is called also *drop-finger* and *rupture of extensor tendon*. It is due to a blow in the direction of flexion when the finger is extended. It is supposed to be due partly to stretching and partly to rupture of the extensor tendon at the point at which it is the posterior ligament of the distal interphalangeal joint. Abbe has shown that baseball players are liable to a condition which is the reverse of this, in which the last phalanx is dislocated backward. Drop-finger is treated by incision and suture of the tendon to the periosteum.

Genu valgum (knock-knee) results from an unnatural growth of the internal condyle, causing the shaft of the femur to curve inward and the internal lateral ligament of the knee-joint to stretch, the knees coming together and the feet being widely separated. This deformity is usually noted when the child begins to walk, but it may not appear until years or even long after.

FIG. 415. —Club-hand.

Knock-knee may arise from rickets or from an occupation demanding prolonged standing, as from flat foot. It may be present in one knee or in both.

Treatment. Mild rickety cases of knock-knee remain in slight deformity or may get well from improvement of the general health. In ordinary cases simply treat the rickets. The patient is forbidden to stand or to stoop, and the limb, after being straightened as far as possible, is held on an external splint. A pad is put over the internal condyle. Later in the treatment plaster-of-Paris is applied. Some surgeons prefer to immobilize while the leg is

held at a right angle with the thigh. In a severe case the surgeon can immobilize after forcibly straightening (causing an epiphyseal separation) or the performance of osteotomy (page 699). Osteotomy is preferable to treatment by a mechanical appliance (osteoclasis).

Genu varum (bow-legs) is the opposite of knock-knee. Usually the legs are bowed out, the knees being widely separated, the tibiae and feet, as a rule, being curved, and the feet being turned in. This disease in childhood is due to rickets, the weight of the body producing the deformity. In older people incurable bow-legs may arise from arthritis deformans.

Treatment. Some mild cases of genu varum recover as a result of improvement in the health. Ordinary cases are treated by braces, by plaster-of-Paris bandages, and by attention to the general health. When the bones have hardened in severe deformity, osteotomy is necessary.

Club-hand (Fig. 415).—A congenital deformity in which the hand

ates from the normal relation to the forearm. It is usually associated with *other* deformities. In some cases the radius and possibly some of the carpal bones are absent.

Treatment.—By massage and passive motion, by immobilization, by *tenotomy* or *osteotomy*.

Talipes (club-foot) is a permanent deviation of the foot into deformity. There are several forms. *Talipes equinus* (Fig. 416) is a confirmed extension; *talipes calcaneus* (Fig. 417) is a confirmed flexion; *talipes varus* is a confirmed adduction and inversion; and *talipes valgus* is a confirmed abduction and eversion. Two of these forms may be combined, as in talipes equino-varus (Fig. 418, talipes equino-valgus, talipes calcaneo-varus, and talipes calcaneo-valgus. The causes of talipes are congenital or acquired. The congenital form is due to persistence of the fetal form of the foot. Acquired cases may arise from infantile paralysis, from spastic contractions, from *nutrices*, from traumatism, from arrest of bony growth following upon the inflammation of bone, or from hysterical contractures.

Fig. 416. Talipes equinus (Albert)

Fig. 417. Talipes calcaneus (Albert)

Fig. 418. Double equino-varus (American Text-book of Surgery)

Talipes equinus is rarely congenital. In this condition the patient walks upon the toes and cannot bring the heel to the ground.

Talipes Calcaneus.—The patient walks upon the heel and cannot bring the toes to the ground. The true form is seen in congenital cases, the flexors of the foot being shortened, and the tendo Achillis being lengthened.

Talipes varus is rarely met with without equinus. In this condition the patient walks on the outer edge of the foot.

Talipes valgus is met with in flat foot. The patient walks on the inner edge of the foot.

Talipes equino-varus.—The heel is raised and the patient walks upon the outer edge of the foot. This is the usual congenital form.

Talipes equino-valgus is very rarely congenital. The heel is raised and the patient walks upon the inner side of the foot.

Talipes calcaneo-varus is a combination of calcaneus and varus.

Talipes calcaneo valgus is a combination of calcaneus and valgus.

Treatment.—In congenital cases the condition is usually manifest on both sides, and is nearly always talipes equino-varus. Congenital club-foot should be treated in infancy, and when a restoration to position can be effected by the hands of the surgeon, is treated by plaster-of Paris bandages. If a child has begun to walk, it may still be possible to correct the deformity

eventually by manipulations, by plaster-of-Paris bandages, or by club-foot shoes, but most cases require tenotomy of the tendo Achillis before the application of the shoe or the plaster. The club-foot shoe may do good service, but in many instances it is painful and is not so efficient as plaster-of-Paris. In severe cases, before applying the plaster, the patient is given ether; the surgeon cuts the tendons of the anterior and posterior tibial muscles, the plantar fascia, and the tendo Achillis, in the order named, and forcibly corrects the deformity. In old cases, with alteration in the shape of the bones, cuneiform osteotomy, or the removal of the cuboid or other tarsal bones, may be indicated. In these cases Phelps advises an open transverse division of all rigid plantar soft parts. Buchanan employs subcutaneous division of all resistant structures. Occasionally in relapsed and inveterate cases *astragalectomy* is performed. It is seldom practiced upon young children. (See page 719.) In some cases of talipes calcaneus shortening of the tendo Achillis is advised; but such an operation is only of temporary value, as stretching occurs after two years or more. In talipes due to infantile paral-

ysis the operative treatment is the same, but we should not immobilize in plaster but rather in some apparatus which can easily be removed to permit the use of massage and electricity. In paralytic cases tendon-transplantation is occasionally employed. This consists in dividing the tendon of the paralyzed muscle and attaching its distal end to the adjacent tendon of a healthy muscle. (For full consideration see a work on orthopedic surgery.)

Fig. 419. Print of a normal foot sole (A) and of a flat foot sole (B) (Albert)

Pes planus (flat-foot) is a condition in which there is loss of the arch of the foot, due to muscular paralysis or ligamentous weakness, to prolonged standing, or to trauma. Flat-foot is especially apt to occur in rickets. *Spurious flat-foot*, or *inflammatory flat-foot*, occurs in Pott's fracture and in inflammation of the ankle joint

or of the tendon of the peroneus longus muscle. *Paralytic flat-foot* is seen after infantile paralysis. *Static flat-foot* is due to disproportion between the body weight and the support of that weight. All children are born with pronated feet; the arch usually begins to form soon after birth, but in some individuals it never forms. Flat foot, according to de Vlaceos, is thus produced: If we suppose a straight line prolonged downward from the center of the leg, most of the astragalus and os calcis will be external to it, hence the body weight presses on the inner side of the foot, and tends to flatten the arch and cause outward rotation, tendencies which are antagonized by the flexors of the toes and by the tibialis posterior muscle. The os calcis is pronated and is pushed to the side, the astragalus moves after the os calcis, and the ligaments are stretched ("Rev. de Chir.," Aug., 1901). Pes planus is productive of much pain upon standing or walking; in fact, the individual may be completely crippled. Pain is quickly relieved upon sitting down. Walking upon the toes is not painful. A marked flat foot can at once be recognized by wetting the sole of the patient's foot with a colored fluid and causing him to step firmly upon a piece of paper (Fig. 419, A, B). Beginning flat foot cannot be thus recognized and is frequently overlooked, the patient being treated for gout or rheumatism. Even a slight case can be detected by carefully observing the inner surface of the foot

When weight is placed upon it, it is seen to descend as the arch falls. A more accurate method is measurement, to find the middle of the foot. In flat-foot the extremity is lengthened. Golding Bird points out that the middle of the normal foot is the point of articulation of the inner cuneiform and the metatarsal bone of the great toe. In flat-foot the greatest change is in the posterior half of this line. The extent to which the posterior measurement exceeds the anterior is the degree of flat-foot. The excess may reach three-fourths of an inch.

Treatment.—In *paralytic flat-foot*, which arises from infantile paralysis, employ exercise, electricity, and massage. To maintain a correct position of the ankle and to facilitate normal muscular action, apply suitable braces. In some cases of paralytic flat-foot it is advisable to permanently stiffen the ankle joint by operation. Operation is not indicated before the twelfth year, because during the earlier years of life union will probably fail to occur. Goldthwait removes the cartilage from the articular surfaces of the astragalus, calcaneus, tibia, and malleoli, and seeks to obtain permanent bony ankylosis. In *static flat foot* it has long been customary to advise rest in bed for two weeks, and then exercise for several hours a day to increase the arch. The usually recommended exercise has been to rise upon the toes again and again, the patient resting for a time after each séance of exercise by sitting tailor-fashion with the legs crossed under him. Massage is ordered and a shoe is made containing a piece of steel so arranged as to raise the arch of the foot. The patient's general health is, of course, attended to.

Fig. 420.—X-ray of hammer-toe

Orthopedic surgeons have come to regard this usual treatment as unphilosophical and improper.

In static flat-foot it is essential to understand that a flat-foot may be a fully functioning foot, free from pain and disability, and, therefore, not a subject for treatment. For convenience, flat foot is divided into rigid and flexible. Either form may or may not be painful. The pain of flat-foot is usually the result of excessive use. It must be differentiated from Albert's disease, achilodynia, metatarsalgia, osteophytes on the under surface of the os calcis, and Raynaud's disease. Rigid flat foot can be made flexible by manipulative measures or by the employment of H. Augustus Wilson's flat-foot correction screw (see Fig. 421). This apparatus pulls down on the posterior part of the os calcis and the distal extremities of the metatarsal bones and pushes up beneath the tarsus. The force employed is very great and much care should be exercised when it is used upon a patient under anesthesia. It is preferable to use it without ether, relying upon the patient to state when the pressure becomes unendurable. A flexible flat-foot is capable of restoration of the lost muscular control by applied physical culture. Each toe and then the foot muscles should be developed to the maximum, so that the muscular control of the foot becomes almost as good as the muscular control of the hand.

It was formerly customary to prescribe various forms of steel plates to correct the broken-down arch, but orthopedic surgeons are discouraging their

use, as they destroy the muscular control of the foot, and by weakening the foot render it susceptible to sprains and other injuries. When necessity demands the employment of arch supporters, they should be used exactly like splints for fractures. They should be kept on constantly, day and night, for the shortest possible time and laid aside as quickly as possible. Three weeks is entirely too long for them to be used continuously, as in that time they are capable of causing such muscle wasting that months may be required to obtain muscular re-establishment. In cases of flat-foot that are incapable of muscular reconstruction, H. Augustus Wilson ("Amer. Medicine," May 6, 1905, p. 725) advocates the employment of the method devised by Prof. Dr. I. Muller ("Central. f. Chir.," January 10, 1903, p. 40) for paralytic valgus. It consists of an arthrodesis of the astragaloscaphoid joint, and transplantation of the tendon of the extensor proprius hallucis into a hole drilled free from above downward through the scaphoid. Fixation in plaster of Paris in an overcorrected position for four weeks almost invariably results in full

Fig. 421.—H. Augustus Wilson's flat-foot correction screw.

correction and normal function. The anterior tibial tendon is supplemented in its action by the transplanted tendon. Toe drop does not occur because the lesser extensor of the big toe assumes unusual power in raising the toe.

Gleich shortens the foot and raises the arch by sawing through the os calcis, and fastening the posterior part of this bone at a lower level. Trendelenburg advises supramalleolar osteotomy. This operation permits of adduction and the adducted foot should be put up in an immovable dressing of plaster of Paris. Ogston resects the astragaloscaphoid joint. Golding-Bird and Davy remove the scaphoid bone. Stokes removes a wedge shaped piece from the head and neck of the astragalus.

Pes cavus (hollow foot) is an increase in the arch of the foot, due, possibly, according to Golding Bird, to paralysis of the peronei muscles. When the peronei muscles are paralyzed, the adductors act unopposed and secondary contraction of the plantar fascia occurs. Certain it is that a contracted plantar fascia is the chief obstacle to correction. In many cases the cause is the wearing of shoes which are too short for the feet. The pressure made upon the toes causes spasm of the plantar flexors and this spasm permits the fascia to contract.

Treatment.—A shoe is worn containing a plate of steel in the sole, and pressure is applied over the instep. Tenotomy, division of the plantar fascia, or excision of bone may be required. In paralytic cases apply electricity and massage to the paralyzed muscles.

Hallux valgus, or varus, a displacement of the great toe outward or inward, may occur in the young, but it is most frequent in old persons, especially old women. It arises often from wearing pointed shoes, shoes that are too short, or high heels, but may be due to gout or to rheumatic gout. In many cases an exostosis forms in the inner portion of the distal end of the metatarsal bone. In hallux valgus a *bunion* (bursa) is apt to form over the metatarsophalangeal joint and it may inflame or ulcerate.

Treatment.—An arrangement may be worn to straighten the toe and to protect the bunion (Fig. 407). The prominent and hypertrophied inner portion of the head of the metatarsal bone may be removed by means of a chisel, osteotomy may be performed upon the metatarsal bone, the joint may be excised, or amputation may be required. H. A. Wilson advocates lateral excision. By means of bone-forceps he cuts away that part of the distal extremity beyond the phalanx, and with a chisel removes the remaining sharp line edge. He places the phalanx in normal position and holds it so for two weeks ("Am. Jour. Orthopedic Surgery," Jan., 1906).

Hammer-toe (Figs. 420 and 422) is a condition in which there is flexion of one or more toes at the first interphalangeal joint. Shattuck shows that this condition is due to contraction of "the plantar fibers of the lateral ligaments of the joint."* This disease usually begins in youth and may be congenital. A bunion is apt to form, and the joint may become dislocated.

Treatment.—Terrier's plan of treatment consists in making a dorsal flap, removing a bursa if one is found, dividing the extensor tendon, opening the articulation, removing each articular surface with cutting forceps, suturing the soft parts, and applying a plantar splint for two weeks.† Some surgeons excise the joint. Probably amputation of the toe is the best treatment.

Metatarsalgia (Morton's Disease).—This disease

was first described by Dr. Thomas G. Morton, of Philadelphia, in 1876. It is a painful condition of the foot, due to jamming of a nerve between the heads of the fourth

and fifth metatarsal bones. The head of the fifth metatarsal bone is, by lateral pressure, forced against and below the neck of the fourth metatarsal, and as a result the superficial branch of the external plantar nerve and its two digital branches are squeezed. It is usually associated with flat-foot. Pain is produced by walking, and the suffering may be so severe that the patient is obliged to sit down at once. When the shoe is removed and the foot is rested, the pain soon abates. The pain is felt on the outer and inner sides of the little toe, the outer side of the fourth toe, and about the head of the fifth and the neck of the fourth metatarsal bones. Pain can be developed by grasping the foot in the hand and squeezing it. If flat-foot exists, there is also pain due to this trouble.

Treatment.—Mild cases may be cured occasionally by wearing well-fitting shoes and employing massage. Some cases require a brace. Severe cases demand resection of the fourth metatarsophalangeal joint, or amputa-

Fig. 422.—Hammer-toe.

* American Text-Book of Surgery.

† Rev. de Chir., July, 1895.

tion of the fourth toe, and with it the head of the fourth metatarsal bone. Graham, of Washington, has cured cases by excising a portion of the superficial branch of the external plantar nerve.

Coxa Vara and Coxa Valga.—**Coxa vara** (*incurvation or infraction of the neck of the femur*) is a disease characterized by bending of the neck of the femur, the femoral neck being depressed below its normal obtuse angle with the shaft, the hip-joint being perfectly healthy, and the condition, as a rule, being unilateral, but sometimes bilateral. This condition was described by Muller in 1889. Coxa vara is first noticed, as a rule, between the thirteenth and twentieth years, and the commonly accepted view has been that the deformity is rachitic, but Kredel has reported two congenital cases.* Traumatic coxa vara may follow impacted fracture of the neck of the femur in a child. An individual with coxa vara develops a limp, and grows tired after slight exertion, but there is no swelling, no tenderness, and little or no pain. Shortening after a time becomes apparent, and the great trochanter can be detected above Nélaton's line. The extremity is adducted, and usually rotated outward. Abduction is limited. In some cases in which there is joint irritation all joint motions may be distinctly limited.

In a bilateral case there is lordosis, but shortening may not be detected because both legs are the same length. Each great trochanter, however, is above Nélaton's line.

Coxa valga is a condition in which the angle of the neck to the shaft of the femur is more obtuse than normal. The neck may assume a position in line with the long axis of the shaft. It occurs particularly in children who have had infantile palsy, but it may be congenital, may occur in rickets and osteomalacia, and after a prolonged period of disease of a limb. The patient has pain and a limp, the extremity is lengthened, abducted, and in external rotation there is limitation of adduction and the trochanter is flattened. Coxa valga is usually unilateral, but may be bilateral.

The differential diagnosis in coxa vara and coxa valga is often very difficult and the accompanying table will materially aid in contrasting the conspicuous features of the various conditions with which these two deformities of the neck of the femur may be confounded.

	HIP DYSPLASIA	INFANTILE PARALYSIS	CONGENITAL DEFORMATION	PELVIC ABSCESS	COXA VARA OR VALGA	KNEE DEFORMITY
Age Onset	Four to six	Four to six	Any age at birth	Four to six	Any age	From infancy
Pain	Involution Referred to knee.	None	None	Involution Referred to pelvis.	Continual None	Intermittent Referred to knee
History	T.B.	Infantile paralysis disease.	Limp from birth	T.B.	Limp	T.B.
Posture	Flexion abduction external rotation	Uncontracted	Shortening	Flexion abduction external rotation	Great flexion abduction	Knee flexed
Muscular rigidity	Present, not inflexible	Absent	Absent	In some lines	None	Absent
Leg projection	1 degree up	Normal	Normal	1 degree in spine.	Normal	1 degree in spine
Local tenderness	Present	Absent	Absent	Present	Absent	Present
Systemic disease	Yes	No	No	Yes	No	No
X-ray	Displaced femoral head	Atrophy	Alteration in joint	Normal hip	Alteration in neck angle	Normal joint

* Centralbl. f. Chir. Oct. 17, 1896

The x-rays show the deformed bone in either coxa vara or coxa valga.

Treatment.—In coxa vara, as long as bending is progressing, employ rest. When the bone hardens, it may be necessary to perform osteotomy below the trochanters. In coxa valga Galeazzi performs osteotomy through the neck of the femur and allows the trochanter to ascend.

Flail-joints.—After an attack of infantile paralysis involving the entire lower extremity of each side the limbs become limp and swing flail-like when the extremity is made to move, and the joints are much relaxed. In such cases the psoas and iliacus muscles are never completely paralyzed, and the aim of the surgeon is to utilize these muscles in enabling the patient to walk. In many cases the application of apparatus is sufficient. In others ankylosis may be established in the ankles and knees by operation. If ankylosis is established in these joints, the psoas and iliacus muscles become able to move the legs.

XXII. DISEASES AND INJURIES OF NERVES.

DISEASES OF NERVES.

Neuritis, or inflammation of a nerve, may be limited or be widely distributed (*multiple neuritis*). The first-mentioned form will here be considered. The causes of neuritis are traumatism, wounds, overaction of muscles, gout, rheumatism, syphilis, fevers, and alcoholism.

Symptoms. The symptoms of neuritis are as follows: excessive pain, usually intermittent, in the area of nerve-distribution. The pain is worse at night, is aggravated by motion and pressure, and occasionally diffuses to adjacent nerve areas or awakens sympathetic pains in the opposite side of the body. The nerve is very tender. The area of nerve-distribution feels numb and is often swollen. Early in the case the skin is hyperesthetic; later it may become anesthetic. The muscles atrophy and present the reactions of degeneration; that is, the muscles first cease to respond to a *rapidly* interrupted, and next to a *slowly* interrupted, faradic current; faradic excitability diminishes, but galvanic excitability increases. When, in neuritis, faradism produced no contraction, a slowly interrupted galvanic current which is so weak that it would produce no movement in the healthy muscle causes marked response in the degenerated muscle. In health the most vigorous contraction is obtained by closing with the — pole; in degenerated muscles the most vigorous contraction is obtained by closing with the + pole. When voluntary power returns, galvanic excitability declines; but power is often nearly restored before faradic excitability becomes manifest (Buzzard).

Treatment.—The treatment of neuritis consists of rest upon splints and the use of an ice bag early in the case and a hot water bag later. Blisters over the course of the nerve are of value, especially in traumatic neuritis. Massage and electricity must be used to antagonize degeneration. A descending galvanic current allays pain to some extent. Deep injections of chloroform or cocaine may allay pain. Treat the patient's general health, especially any constitutional disease or causative diathesis. The salicylate of ammonium or phenacetin may be given internally. In some cases nerve-stretching is advisable.

Neuralgia is manifested by violent paroxysmal pain in the trajectory of a nerve. This disease, unless it is exceedingly severe and persistent, is treated, as a rule, by the physician. Injections of alcohol or osmic acid into the nerve may secure relief or cure. If neuralgia is due to adhesions about the nerve

or to the pressure of scar or callus, these conditions should be amended surgically. There is some evidence that neuralgia arises, at least occasionally, from dilatation of the vessels of the sheath and subsequent edema and exudation. If this be the case cure may follow opening the sheath and separating adhesions between the sheath and nerve (Robert M. Simon, in "Brit Med Jour," April 10, 1909). Neuralgia of stumps and scars is a surgical condition, and is due to neuromata, or entanglement of nerve filaments in a cicatrix. *Tic douloureux* and other intractable neuralgias require careful removal of any cause of reflex irritation. Causal reflex irritation may arise from disease of the stomach, eyes, teeth, uterus, nose, throat, etc. *Tic douloureux* has been treated by removal of the Gasserian ganglion, intracranial neurectomy of the second and third divisions, division of the sensory root, removal of Meissner's ganglion, ligation of the common carotid artery; neurectomy of terminal

branches of the fifth nerve; division of motor nerves, injections of osmic acid (page 779); injections of alcohol, massive doses of strychnin (Dana) and purgatives (Esmarch). The distribution of the fifth nerve, the seat of pain in *tic douloureux*, is shown in Fig. 423.

Treatment of Neuralgia of Stumps.—Excise the scar, find the bulbous end of the nerve and cut it off. Senn tells us to section the nerve by V-shaped cuts, the apex of the V being toward the body, and to suture the flaps together. Senn's method will prevent recurrence. In some cases reamputation is performed. In entanglement of a nerve in a scar remove a portion of the nerve above the scar and also the neuroma in the scar.

WOUNDS AND INJURIES OF NERVES.

Section of Nerves (as from an incised wound).—After nerve-section sensation and motor power are lost at once. The entire peripheral portion of the nerve degenerates and ceases structurally to be a nerve in a few weeks, but after many months, or even years, the nerve may regenerate. The proximal end degenerates only in the portion immediately adjacent to the section.

it rapidly regenerates, and if it does not adhere to the peripheral segment a bulb or enlargement composed of fibrous tissue and small nerve-fibers forms just above the line of section; this bulb adheres to the perineural tissues. The entire distal end degenerates, but new axis cylinders form in this segment by proliferation of the nuclei on the sheath of Schwann. Union of a divided nerve is brought about by the projection of axis cylinders from the proximal end or from each end and the fusion of these cylinders. The nearer the two ends are to each other, the better the chance of union. When a nerve has been divided and has not been sutured, abolition of function may be permanent or restoration may occur. Sensation may return in from six weeks to several months. Motor power may never return. If it does return it will do so long after sensory restoration. Restoration of motor power requires from twelve weeks to three and one-half years. It is seldom noted before six months. The return is always slow (John B. Murphy, in "Surg. Gynec. and Obstet.," April, 1907). Failure of return means that the ends are separated by a wide interval or that fascia is interfused between them. In some recorded cases motion and sensation have returned with great rapidity, due, some have said, to anastomoses with adjacent nerves. Murphy shows that when restoration begins trophic energy returns even before sensation, and when trophic energy returns the blueness and coldness of the limb lessen.

The nerve fibers which convey impressions of cutaneous pain and of extreme heat and cold regenerate far more rapidly than those which subserve sensations of light touch and slight degrees of heat and cold.

The investigations of Head and others show that restoration does not begin at the normal area and spread from there over the anesthetic area, but that the reverse is the case. It begins from the confines of the anesthetic area and spreads toward the normal part.

General Symptoms.—Immediately after nerve-section vasomotor paralysis comes on, and for a few days the paralyzed part presents a temperature higher than normal. It then becomes blue and cold. Pronounced changes occur in the trajectory of a divided nerve. The muscles degenerate, atrophy, and shorten, and develop the reactions of degeneration. When union of the nerve occurs, the muscles are restored to a normal condition. If the nerve contains sensory fibers, complete anesthesia (to touch, pain, and temperature) usually follows its division; but if a part is supplied by another nerve as well as by the divided one, anesthesia will not be complete. Trophic changes arise in the paralyzed parts. Among these changes are muscular atrophy; glossy skin; cutaneous eruptions; ulcers, dry gangrene; painless felons; falling of the hair; brittleness, furrowing, or casting off of the nails; joint-inflammations; and ankylosis. The diagnosis as to which nerve is cut depends upon a study of the distribution of motor and sensory paralysis.*

A curious fact that was pointed out by Letiévant is that after division of a nerve blunt pressure may be appreciated over the entire analgesic area. This phenomena was long thought to be due to nerve anastomoses, the sensory areas from different nerves overlapping. The explanation now given is founded on Sherrington's demonstration that the motor branches of a mixed nerve carry sensory fibers through muscles and tendons, and Head's proof that certain adherent fibers convey impressions of deep sensibility as produced by pressure

* See Bowlby on "Injuries of Nerves."

The Symptoms of Division of Nerves.—*Brachial Plexus*—If one or more cords of the brachial plexus are divided, motor paralysis and anesthesia appear in the limb, the extent of the paralysis and the area of the anesthesia depending upon the cord or cords involved. It should be remembered that the inner cord of the brachial plexus gives origin to the ulnar nerve; the inner and outer cords give branches which fuse to form the median nerve. The posterior cord gives origin to the subscapular, the circumflex, and the musculospiral nerves. The outer cord gives origin to the external anterior thoracic and the musculo-cutaneous, as well as to the outer trunk of origin of the median.

Evulsion of the brachial plexus is sometimes effected by an injury, when the arm is not lost. Algernon T. Bristow ("Annals of Surgery," Sept., 1902) reports 3 cases of this rare injury, and has collected 24 undoubted instances. One of his own cases was operated upon the third day after the accident. In this case there was complete paralysis of the upper extremity, with the exception of the sensory area of the intercostohumeral and the circumflex nerves. The accident had been inflicted by the patient's forearm becoming entangled in a rope, which was pulled upon by a steam winch. On reaching the hospital he felt severe pain, referred to the arm. There was much swelling in the inner portion of the subclavian triangle, the left pupil was contracted, and it seemed likely that the nerves had been evulsed close to the intervertebral foramina. From the fact that sensation was preserved in the skin of the convexity of the shoulder down to the insertion of the deltoid, Bristow concluded that some fibers of the posterior cord of the plexus had escaped division; but when the operation was performed, this conclusion was found to be erroneous. An incision was made, and it was found that the plexus had given way at the point where the four cervical nerves and the last dorsal unite to form the three trunks. In order to reach the lower ends, it was necessary to saw the clavicle and divide the two pectoral muscles, and the torn ends of the nerve-trunks were found underneath the clavicle. Suturing was performed. The ends of the sawn clavicle were sutured together, the wound was closed and dressed, and the arm was put up in Sayre's dressing.

This article of Bristow's is of extreme interest. He discusses the injury to the sympathetic and the reason that sensation was preserved over the area usually supplied by the circumflex. After the performance of this operation sensation over the entire upper arm returned. We agree with Bristow that after such an injury early operation is the only thing that offers any prospect of the return of function. It may be necessary to perform nerve anastomosis, uniting the end of the distal segment of a divided trunk with an undivided trunk. I myself once operated upon a patient that had developed paralysis, motor and sensory, after violent stretching of the arm. In the light of Bristow's case I assumed that evulsion of the plexus had probably taken place. Incision disclosed the fact that the plexus was intact, but was surrounded with dense scar-tissue. This tissue was removed, so as to loosen the nerves, but I have lost track of the patient, and do not know the result. My patient was operated upon many months after the injury. It is well to bear in mind that in an injury of the supraclavicular division of the brachial plexus there will probably be palsy of the great serratus muscle.

Murphy points out that an injury above the clavicle will involve the cir

curved and musculospiral—that as the great pectoral is supplied from both the external and internal cords of the plexus, complete paralysis of the great pectoral proves that both cords are involved and that unimpaired movements of the diaphragm on the side of the lesion (observed with the fluoroscope) show that the cords of the plexus are not divided within the foramina, but well outside of them (John B. Murphy, in "Surg., Gynec., and Obstet.," April, 1904).

Brachial Birth Palsy.—It has been pointed out by Clark, Taylor, and Prout ("Am. Jour. Med. Sciences," Oct., 1905) that brachial birth palsy results from tension on the nerve-trunks by overstretching during delivery, the nerve-sheath first rupturing and then the nerve-fibers. When the sheath ruptures hemorrhage occurs, fibrous tissue forms, and the scar presses on the intact, slightly stretched, or actually lacerated nerve and prevents repair. The authors tell us that the fifth cervical root first gives way, then the sixth, and so on down the plexus if there is sufficient force. In the mild cases the fifth root alone suffers. They call it brachial birth palsy, or *laceration palsy*, and sum up the symptoms in a severe case as follows: The arm hangs powerless; abduction at the shoulder is impossible because of deltoid and supraspinatus palsy; the forearm is extended and flexion is impossible because of biceps, brachialis anticus, and supinator longus palsy; palsy of supinator brevis and biceps causes pronation of hand; there is inward rotation of the humerus because of palsy of the supraspinatus, infraspinatus, and teres minor.

Brachial birth palsy is manifest soon after its infliction by evidences of pain on handling the extremity, the pain being due to neuritis (authors above quoted). Medical treatment is relied on for one year, and then, if improvement is not manifest, operation is indicated (page 786).

Posterior (Long) Thoracic Nerve.—Division of this nerve causes paralysis of the serratus magnus muscle, which is made evident by eversion from the thorax and rotation of the scapula when the arm is taken forward (*wing-like scapula*). In paralysis of this muscle the arm cannot be raised above the horizontal.

Suprascapular Nerve.—Division of this nerve produces some anesthesia over the scapula and paralysis of the supraspinatus and the infraspinatus muscles. The supraspinatus is but an adjuvant to the deltoid and palsy of it is not manifestly disabling. Palsy of the infraspinatus renders external rotation of the humerus impossible, and writing becomes most difficult because the pen cannot be moved along the paper. Sewing, too, is greatly interfered with.

Circumflex Nerve.—Division of the circumflex nerve produces paralysis of the deltoid muscle, so that it becomes impossible to lift the arm to a right angle with the body. There is some slight retention of power in the anterior fibers, which are supplied by the anterior thoracic nerve. The skin over the lower part of the muscle is usually anesthetic.

Musculocutaneous Nerve.—Division of this nerve produces paralysis of the biceps and of the brachialis anticus muscles (paralysis of the forearm flexors). This palsy becomes especially evident when the forearm is supinated, because in this position the supinator longus can no longer act as a flexor of the elbow. There is anesthesia of the radial side of the forearm anteriorly and posteriorly.

The Musculospiral or Radial Nerve.—Division of this nerve high up near the plexus causes paralysis of the extensor muscles of the elbow and the wrist, of the supinators, and of the long extensors of the thumb and fingers. When divided near the middle of the humerus, the triceps usually, but not invariably, escapes. If the injury is below the branch going to the supinator longus, that muscle will escape; otherwise it will become paralyzed. The extensor palsy causes wrist-drop and loss of the power of extending the first phalanges of the fingers and thumb; and, as Gowers has pointed out, flexion is reduced to one-third of the normal, the flexors having lost power "from the loss of antergic support." As a rule, in musculospiral palsy there is loss of supination. Sensibility is sometimes greatly affected, and sometimes very slightly. If the injury is above the level of the musculospiral groove there will be anesthesia in the area supplied by the sensory fibers of the nerve

FIG. 424.—Paralysis of musculospiral nerve after fracture of the humerus ("wrist-drop"); but when fingers have been flexed into palm, *a*, they can be extended. *b*, at first interphalangeal joints by lumbricals and interossei, which are supplied by the ulnar and median nerves (Erichsen).

FIG. 425.—Distribution of sensory nerves on the backs of the fingers: *T*, Musculospiral or radial nerve; *M*, ulnar nerve; *U*, median nerve (Krause).

(Fig. 429). If the nerve is injured in the musculospiral groove there are seldom sensory disturbances. Anesthesia rarely occurs in the upper arm in any case, and even after an injury in the groove the hand sensation may be normal or nearly so. Fig. 424 shows the position of the parts in musculospiral palsy and Figs. 425 and 429 the sensory distribution of the nerve.

The Median Nerve.—After division of the median nerve there is paralysis of the pronators; the flexor carpi radialis; the finger flexors, except the ulnar portion of the deep flexor; the abductors, and the flexors of the thumb; and the two radial lumbricals. The forearm can be placed in a position midway between pronation and supination; but further pronation cannot be voluntarily effected. In executing flexion of the wrist a strong deviation toward the ulnar side takes place. The thumb is in a position of extension and abduction, and cannot be brought into apposition with the finger-tips. The second phalanges of the fingers cannot be flexed on the first, and the distal phalanges of the first and second fingers cannot be voluntarily flexed. The corresponding phalanges of the third and fourth fingers can be flexed, this being accomplished by the unparalyzed ulnar half of the deep flexor. Flexion of the first phalanges is still possible, as it is accomplished by means of the interossei. The

extensor action of the interossei muscle upon the middle and distal phalanges, being unopposed, may eventually cause subluxation. The sensory distribution of the median nerve is shown in Figs. 425, 426, 427, and 429. It is the sensory nerve of the radial side of the palm, the front of the thumb, the first and second fingers and half of the third finger, and the back of the last

Fig. 425.—Section of median nerve; areas of anesthesia (heavy shading) and of dysesthesia (light shading) on palmar surface of hand (Bowlby).

Fig. 427.—Section of median nerve; regions of anesthesia and dysesthesia on dorsal surface of hand (Bowlby).

phalanx of the index and the middle finger (Gowers). The sensory changes after median paralysis are quite variable—sometimes wide-spread and complete, at other times trivial, and occasionally absent. Gowers says that if there is anesthesia it is usually of the palmar surface, and may also occur on the dorsal aspect of the ends of the first two fingers.

Fig. 424.—Division of ulnar nerve.

The Ulnar Nerve.—When the ulnar nerve is divided, there is paralysis of the flexor carpi ulnaris, of the ulnar portion of the deep flexor, of the muscles of the little finger, of the abductor pollicis, and of the inner end of the flexor brevis pollicis (Gowers). It becomes impossible to adduct the thumb, and the majority of the movements of the little finger are abolished. Flexion of the fingers is impossible at the first joints, and extension is impossible at the

other joints; but, as Gowers points out, the loss is slighter in the first fingers than in the others, because the lumbricales of the first two fingers — supplied by the median nerve. Interosseal flexion is impossible, and opponents of the interossei, acting without normal antagonism, contract and p

Fig 429.—Distribution of the cutaneous nerves to the shoulder, arm, and hand. The region of the N. radialis is represented by the unbroken hatched line, that of the N. ulnaris by the broken hatched lines: *a*, Anterior, *b*, posterior surface; *sc*, Nn. supraclavicular (plexus cervicalis); *as*, chief branch of N. axillaris; *epi*, *epi*, Nn. cutanei post. sup. and inf. duce what is known as *claw-hand* (Figs 428 and 430), a condition in which the first phalanges are overextended and the others are flexed. The sensory loss in ulnar paralysis is extremely variable. The sensory distribution is to the ulnar side of the hand, both back and front, involving the little finger, the ring-finger, and the ulnar half of the middle finger (Figs. 425, 429, and 431),

Lumbar Plexus.—The lumbar plexus supplies the cutaneous surface of the lower portion of the abdomen, of the front and the sides of the thigh, and of the inner portion of the leg and foot (Fig. 432). It innervates the flexors and adductors of the hip-joint, the extensors of the knee, and the cremaster muscle. The branches sent to the leg are the obturator and the anterior crural nerves.

Sacral Plexus.—The sacral plexus supplies the extensors and rotators of the hip, the knee-flexors, and all the muscles of the foot; also the skin of the gluteal region, the back of the thigh, the outer portion and the posterior part

Fig. 430.—Paralysis of ulnar nerve from wound at A; contracture of common extensor with posterior luxation of first phalanges; R, head of metacarpal bone (Duchenne).

Fig. 431.—Showing sensory loss and ordinary position in injuries of the ulnar nerve (Bowly).

of the lower leg, and most of the foot (Gowers) (Fig. 432). Its chief branches are those to the external rotators of the hip—the gluteal nerve, the small sciatic, and the great sciatic.

The Anterior Crural Nerve.—When this nerve is divided, the extensor muscles of the knee are paralyzed. The psoas muscle is not affected, even if the nerve is divided within the abdomen; but high division may produce paralysis of the iliacus muscle. In anterior crural palsy the skin is anesthetic over almost the entire thigh, the inner surface of the leg and foot, and the inner sides of the first and second toes (Fig. 432).

(Gowers). The anesthesia is manifest on the outer portion of the anterior surface of the leg, and also on the dorsum of the foot (Fig. 432).

The Internal Popliteal Nerve.—Damage to this nerve paralyzes the posterior tibial muscle, the flexor longus digitorum, the muscle of the calf, the popliteus muscle, and the muscles of the plantar surface of the foot. The toes become flexed at the two distal joints, and extended at the proximal joints. Walking is greatly interfered with. There is loss of the power of rotating the flexed leg inward, if the damage is above the branch to the popliteus muscle, and extension of the ankle-joint is lost. As the consequence, talipes calcaneus develops (Gowers). The anesthesia is variable, but usually involves the sole of the foot and the outer surface and lower portion of the back of the leg (Fig. 432).

The Plantar Nerves.—Division of the internal plantar nerve paralyzes the short-toe flexor, the two inner lumbricales, and the plantar muscles of the great toe, except the adductor (Gowers). There is anesthesia of the inner portion of the sole of the foot and of the plantar surface of the three inner toes and of half of the fourth toe (Fig. 432).

Division of the external plantar nerve causes paralysis of the muscles of the little toe, of the adductor of the great toe, of all the interossei, of the two outer lumbricales, and of the flexor accessorius (Gowers). There is anesthesia of the skin of the outer half of the sole of the foot, of the little toe, and of half of the fourth toe (Fig. 432).

The Facial Nerve.—The nerve may be divided during the mastoid operation or may be lacerated by a fracture of the petrous portion of the temporal bone and a peripheral palsy results. The face is asymmetrical and is drawn to the sound side. Asymmetry becomes more marked on attempting to smile or to show the teeth. Whistling and frowning are impossible. Sense of taste may be less acute or lost on the anterior two-thirds of the tongue. There is relaxation of the palate and deviation of the uvula. Reactions of degeneration can be demonstrated in the palsied muscles. In some cases there are sensory disturbances (hyperesthesia or anesthesia) and in some there are vasomotor perturbations on the palsied side. On the paralyzed side the muscles are relaxed, the nasolabial fold is to a great extent gone, the nostril cannot be dilated. The brow wrinkles have been smoothed out, the eyelids cannot be closed; on attempting to close the eye the globe tilts upward and outward, the cornea and conjunctiva inflame, the lower lid droops, and tears run down the cheek.

Treatment.—In all recent cases of nerve section, try, if possible, to suture the ends of the divided nerve. Primary suture means suture within twenty-four hours of the accident. In 123 reported cases of *primary suture*, 110 were cured in from one day to one year (Willard). The return of sensation may be rapid or may be slow, muscular power returns more slowly than sensation. If the patient is not seen until long after the accident, incise and apply *secondary sutures*; if the nerve cannot be found, extend the incision, and the trunk above and trace it down, and find the trunk below and follow it. In 130 reported cases of *secondary suture* 80 per cent. were more or less cured (Willard). Even after primary suture, loss of function is bound to last for a time. After secondary suture, sensation may return in a few days, but it may not return until after a much longer period; in any case

muscular function is not restored for months. After partial section of a nerve the ends should be sutured. In performing secondary suture it may be necessary to effect "lengthening" in order to approximate the ends. *Transplantation* of a portion of nerve is sometimes practised (*implantation* or *anastomosis*). *Nerve grafting* is bridging the gap by means of a portion of nerve from one of the lower animals or from a recently amputated human limb. Nerve transplantation may fail utterly; it may be followed by great improvement, but absolute and perfect restoration of function cannot be obtained. R. Peterson* has made a study of the 20 recorded cases of nerve grafting: 8 of the operations were primary and 12 were secondary. The periods after the injury at which operation was performed varied from forty-eight hours to a year and a quarter, 4 of the 8 primary cases improved, 8 of the 12 cases of secondary operation showed improvement in motion or sensation. The distance between the nerves did not seem to affect the results. No case recovered completely, but in one case sensation returned completely and only the abductors of the thumb remained weak. In most of the cases that were benefited sensation returned by the tenth day and motion within two and a half months. In one of the successful cases, that of A. W. May-Robson,† the spinal cord of a rabbit was used. A facial nerve divided in the aqueduct of Fallopius may perhaps be sutured at the site of the injury. This should be attempted as soon as the palsy is observed, as was suggested, I believe, by Frederick Sydenham ("Brit. Med. Jour.," May 8, 1909). If the ends of the divided nerve cannot be approximated, *suture à distance* may be practised, as was done successfully by Sydenham (ibid.). If suture at the site of injury is impossible the end of the peripheral segment of the divided nerve may be anastomosed to the hypoglossal, glossopharyngeal, or spinal accessory nerve (page 776).

Pressure upon nerves may arise from callus, scars, a dislocated bone, a tumor, or an external body.

The **symptoms** may be anesthetic, paralytic, or trophic.

The **treatment** is as follows: Remove the cause (reduce a dislocated bone, chisel away callus, excise a scar, etc.); then employ massage, douches, exercise, and electricity.

Dislocation of the Ulnar Nerve at the Elbow.—This condition is very rare. It may occur as a complication of a fracture or a dislocation, or as an uncomplicated condition. It may be produced by violence or by muscular effort, which ruptures the fascia, the function of which is to retain the nerve back of the inner condyle of the humerus. In some cases the symptoms are slight and transitory, the nerve functioning well in its new situation. As a rule, there are pain, numbness, or anesthesia of the ulnar trajectory, some stiffness of the elbow, and stiffness of the little finger and ring finger. The nerve can be felt in front of the inner condyle of the humerus. In some cases neuritis follows, with trophic changes.

Treatment.—Expose the nerve by an incision, incise the fibrous tissue back of the inner condyle, and press the nerve into the bed prepared for it and hold it in place by sutures of kangaroo-tendon passing through the triceps

* Amer. Jour. of Med. Sciences, April, 1896.

† Ib. 1.

tendon. Wharton advises suturing also "the margin of the fascial expansion of the triceps tendon superficial to the nerve."*

Contusion of Nerves.—The symptoms of contusion of nerves may be identical with those of section. Sensation or motion, or both, may be lost. The case may recover in a short time, or the nerve may degenerate as after section.

The treatment at first is rest, and later electricity, massage, frictions, and douches.

Punctured Wounds of Nerves.—The symptoms of punctured wounds of nerves may be partly irritative (hyperesthesia, acute pain, and muscular spasm) and partly paralytic (anesthesia, muscular wasting, and paralysis).

The treatment after the puncture has healed is the same as that for contusion.

OPERATIONS UPON NERVES.

Neurorrhaphy, or Nerve-suture.—When a nerve is completely or partially divided by accident, it should be sutured at the first possible moment. The instruments required are an Esmarch apparatus, a scalpel, blunt hooks, dissecting forceps, hemostatic forceps, curved round intestinal needles or sewing needles, a needle-holder, and fine catgut, silk, or kangaroo-tendon. In primary suture render the part bloodless and aseptic. Enlarge the incision if necessary. If the ends can readily be approximated, pass two or three sutures through both the nerve and its sheath and tie them (Figs. 433 and 434). If the ends cannot be approximated, stretch each end and then suture. The sutures do not traverse the nerve, but go through the perineum and adjacent connective tissue. Remove the Esmarch band, arrest bleeding, suture the wound, dress antiseptically, and put the part in a relaxed position on a splint. After union of the wound remove the splint and use massage, friction, electricity, and the douche. The operation in some instances fails, but in many cases succeeds. In some few cases sensation returns in a few days, but in most cases does not return for many weeks or months. Sensation is restored before motor power. After successful suturing of a divided median nerve sensations of skin pain and of extreme heat and cold appeared in fifty six days and were restored in two hundred and seven days. Sensations of light touch and slight degrees of heat and cold appeared in two hundred and sixty days and were not completely restored for one year (Kenneth A. J. Mackenzie, in "Annals of Surg.," July, 1909). Secondary suture is performed upon cases long after division of a nerve. If operation is not done for three years or more after division it is very improbable that complete regeneration will ever occur, and yet it is always worth trying, for muscular control has been regained after suturing in one case twenty-nine years subsequent to nerve division (Alfred S. Taylor, in "Jour. of Orthopedic Surg.," Nov., 1908). The part is rendered aseptic and bloodless, an incision is made, the bulbous proximal end is easily found and loosened from its adhesions; the shrunken distal end is sought for and loosened (it may be necessary to expose the nerve below the wound and

* A report of 13 cases of dislocation of the ulnar nerve at the elbow, by H. R. Wharton, Amer. Jour. of Med. Sciences, Oct., 1895.

Nerve-grafting is practised by some. A. W. Mayo Robson used the spinal cord of a rabbit to fill a gap between the ends of the divided median nerve of a man. The restoration of function was almost complete. Some surgeons have grafted in bits of nerve obtained from a recently amputated limb. It makes no difference whether the grafted nerve was motor or sensory or mixed. The results of grafting are seldom good. Chas. A. Powers ("Transactions of the American Surgical Assoc.," 1904) collected 22 cases from literature, 20 from Peterson's paper, 1 case of Durante's, and 1 of his own. In this series there were 3 good results and 3 "fair" results. The bit of nerve grafted does not participate in repair—it is a mere bridge, and acts as does the suture à distance.

Neurectasy, Neurotomy, and Neurectomy.—*Neurectasy*, or nerve-stretching, may be applied to motor, sensory, or mixed nerves. A nerve can be stretched about one-twentieth of its length. Neurectasy has been employed for neuralgia, neuritis, muscular spasm, hyperesthesia, anesthesia, painful ulcer, perforating ulcer, the pains of locomotor ataxia, and many other conditions. The operation, which was once the fashion, seems to benefit some cases, but it is not now thought so highly of as formerly. The incision for neurectasy is identical with the incision for neurectomy or neurotomy of the same nerve. *Neurotomy*, or section of a nerve, is performed only upon small and purely sensory nerves. It is performed chiefly for peripheral neuralgia or for some other painful malady. It is useless, because sensation, as a rule, soon returns. Paget saw complete return of sensation in four weeks after division of the median nerve. Corning endeavors to prevent this regeneration by inserting oil between the ends. He uses oil of theobroma containing enough paraffin to make the melting-point 105° F. The oil is melted, is injected around the nerve, and cold is applied. The nerve is now sectioned with a canaliculated knife, the ends are separated widely, more oil is injected, and cold is again applied. The theory is that this oil, which is solid at the temperature of the body, devitalizes the nerve at the point of section and acts as a barrier to the passage of regenerating fibers. This method has been applied especially in cervicobrachial neuralgia.* *Neurectomy*, or excision of a portion of a nerve trunk, is applicable only to sensory nerves and to painful affections.

Sympathectomy.—*Jonnesco's Operation*.—It has long been known that division of the sympathetic nerve in the neck may produce important changes in the eye and in the cerebral circulation. In 1893 Jaboulay divided the sympathetic on each side, for the purpose of treating epilepsy. The removal of the ganglia of the sympathetic was proposed by Baracz; and the operation was first performed by Jonnesco, in 1896, for epilepsy. The operation is performed by some surgeons for epilepsy, for exophthalmic goiter, and for glaucoma and for trifacial neuralgia. In operating for glaucoma the superior cervical ganglion on each side is removed, as it is from this that the sympathetic fibers that pass to the eye are derived. If the operation is done at all, it should be a bilateral one.

Fig. 435.—Suture of a nerve by splitting the ends (Beauch).

* Medical Record, Dec. 5, 1896.

The operation is used in epilepsy on the theory that there is an anemic condition of the brain in this disease which is corrected by producing a hyperemia, and that the hyperemia improves cerebral nutrition. The operation in epilepsy is largely theoretical, although Jonnesco claims 12 per cent of cures in a large number of operations. In exophthalmic goiter there seems to be some distinct evidence that the operation may be beneficial, but Curtis shows that the mortality is high. Personally, I have not employed it in epilepsy, and at the present time I should not be inclined to do so. In exophthalmic goiter, if any operation is necessary, I should perform partial thyroidectomy; but in progressive glaucoma, which is always so absolutely hopeless, the operation is a justifiable procedure and occasionally seems to have a distinct influence in retarding the development of the disease.

The incision should be made along the posterior margin of the sternocleidomastoid muscle. I have become convinced, in performing two operations of this kind and through studies made upon the dead body, that the ganglion may be more easily reached from behind the sternocleidomastoid than from in front of it. The internal jugular vein and the carotid artery are lifted upward and forward; and the superior ganglion will usually adhere to the under portion of the carotid sheath, and be lifted up with it. Theoretically, it is not necessary to open the carotid sheath in this operation, but, practically, this had better be done, so that one may, without any possibility of doubt, distinguish between the pneumogastric and the sympathetic nerve. The moment the nerve is cut, the pupil on that side will contract.

Stretching of the Sciatic Nerve.—Some surgeons stretch the sciatic nerve by anesthetizing the patient and holding the leg and thigh in line, strong flexion being made upon the hip, the entire lower extremity being used as a lever (Keen). This method, which has caused death, inflicts needless damage, and stretching after an incision has been made is safer and better. The instruments required are a scalpel, hemostatic forceps, dissecting forceps, a dissector, retractors, and a scale with a handle and a hook. The patient lies prone, the thigh and legs being extended. An incision four inches in length is made a little external to the middle of the thigh, and going at once through the deep fascia; the biceps muscle is found and is drawn outward; the nerve is discovered between the retracted biceps on the outside and the semitendinosus on the inside, resting upon the adductor magnus muscle. The nerve, which is caught up by the finger, is first pulled down from the spine and then up from the periphery, and finally the hook of the scale is inserted beneath the trunk and the nerve is stretched to the extent of forty pounds. Very rarely is even a single ligature needed. The wound is sutured and dressed. If the incision is made at a higher level below the gluteofemoral crease, the sciatic nerve will be found just by the outer border of the biceps.

Neurectomy of the Infra-orbital Nerve. This operation was first performed by Abernethy in 1793. The instruments required in this operation are a scalpel, dissecting forceps, aneurysm needle, hemostatic forceps, blunt hooks, a dissector, and metal retractors. The patient lies upon his back, the head being a little raised by pillows. The surgeon stands to the outside of and faces the patient. A curved incision one and a half inches long is made below the lower border of the orbit. The nerve lies in a line dropped from the supra-orbital notch to between the two lower blephar-

teeth. The nerve is found upon the levator labii superioris muscle. A piece of silk is passed under the nerve by an aneurysm needle and firmly fastened. The upper border of the incision is drawn upward; the periosteum of the floor of the orbit is elevated and held by a retractor; the roof of the infra-orbital canal is broken through; the nerve is picked up far back with the blunt hook and is divided with scissors, and the entire nerve is drawn out by making traction upon the silk. The bleeding in the orbit is checked by pressure. The wound is stitched without drainage.

Neurectomy of the Supra-orbital Nerve.—Before sterilizing the parts shave off the eyebrow. The instruments required and the position of the patient are as for the operation upon the infra-orbital nerve. A curved incision one inch long discloses the nerve as it emerges from the supra-orbital notch or foramen at the junction of the inner and middle thirds of the eyebrow. The nerve is pulled forward and cut off above and below.

Neurectomy of the Inferior Dental Nerve.—The instruments are the same as for any other neurectomy, and in addition a chisel, a mallet, and a rongeur forceps. Make a curved incision around the angle of the jaw. Lift the supramaxillary branch of the facial nerve downward (Kocher). Separate the masseter muscle with a periosteum-elevator and slight touches with the knife. Chisel an opening in the center of the ascending ramus (Velpéau's rule). This opening exposes the beginning of the dental canal. If necessary, the opening may be enlarged with a rongeur. Pull the nerve out with a hook and remove a piece from it.

Extracranial Operation for Neuralgia of the Fifth Nerve.—

The operation for removal of the Gasserian ganglion is difficult, bloody, and dangerous. Removal of portions of the pain-haunted nerve-trunks sometimes cures the condition and often ameliorates it for a considerable time. The injection of osmic acid into the peripheral nerves may actually cure or secure prolonged relief. The serious operation of removing the ganglion may be performed if peripheral operations fail or in violent and intractable cases of long standing in which pain is felt in more than one branch. Removal of nerves by ordinary neurectomy often gives comfort for a few months, but rarely gives prolonged relief. If we seek striking benefit by an extracranial operation, it must be thoroughly done.

Injection of Osmic Acid.—This method was suggested by Bennett, of London, in 1897. Osmic acid had been used for many years in a sort of haphazard way, being thrown into tissues about the nerves by means of a hypodermatic syringe. Bennett suggested exposure of the nerve and the injection of 5 to 10 minims of a 1 per cent. solution. Acid when so used actually destroys nerve-fibers, and a considerable amount of fibrous tissue forms which intercepts regenerating fibers. It is probable that secondary degenerative changes occur in the nerve-trunks, and it is possible that they occur in the ganglion. Murphy warmly advocates the method. It certainly produces immediate relief by causing immediate anesthesia, but whether such relief is permanent is as yet too early to say. I have used it in several cases with satisfaction. In the case in which I exposed the ganglion I injected that structure and the result seems to be the same as if I had removed the ganglion. In neuralgia of the fifth nerve the painful nerve or nerves should be exposed, and from 5 to 10 minims of a 2 per cent. solution of osmic acid injected into several

and temporarily stitched to the side of the nose. The zygoma is exposed by a transverse incision. At the root of the zygoma two holes are drilled one-fourth of an inch apart, and two more holes one-fourth of an inch apart are drilled through the zygomatic process of the malar bone. The zygoma is then divided by a saw (Fig. 437). The posterior saw line runs between the two drill-holes at the root of the zygoma. The anterior cut passes between the two anterior drill-holes. The direction of the first cut is directly downward. The direction of the second cut is downward and forward from above. The arch is lifted and detached downward and backward. The exposed tendon of the temporal muscle is retracted backward. The removal of a little fat exposes the pterygomaxillary fossa. The internal maxillary artery is exposed, two clamps are applied, and the vessel is divided between them. The finger loops for the sphenomaxillary and pterygomaxillary fissures. The external pterygoid muscle is separated from the greater wing of the sphenoid and from the root of the external pterygoid process. On the edge of the greater wing of the sphenoid a long prominence is usually detectable. It overhangs the sphenomaxillary fossa and should be cut away by the use of a chisel. The superior maxillary nerve is lifted with a blunt hook, is grasped with forceps, and is twisted off as near the sphenoid as possible (Fig. 438). The distal end is drawn upon, and the nerve, having been previously loosened, is drawn back through the infra-orbital canal. The zygomatic arch is wired in place, the temporal fascia is sutured with buried sutures, and the skin wound is closed. If the pain involved only the second division, but also the third division, the operation previously described should be performed first, and the third division should be reached a few weeks later. The third division is reached by removing the sphenoid process. The inferior dental and lingual nerves are found, and are twisted off close to the ganglion, and the distal portions are removed.

Fig. 438.—a, The zygomatic arch, turned down after sawing; b, tendon of the temporal muscle retracted; c, superior maxillary nerve and Meckel's ganglion; d, infra-orbital nerve emerging from canal; e, internal maxillary artery.

Removal of the Gasserian Ganglion.—This formidable procedure was first suggested by J. Ewing Mears in 1884 and was first performed by Wm. Mearns in 1890. This operation is often bloody and difficult, and is only undertaken in very severe cases of tic douloureux, in which the first division is involved, or in cases upon which less grave procedures have failed. Jaboulay and Cavaillon ("Lyon. Med.," May 17, 1908) speak of it as a grave operation and difficult technic which should be left as a final resort. Many operators say that there is a large mortality after gasserectomy and claim that it is only about 5 per cent. Some operators report a mortality of from 10 to 17 per

cent. The greater the experience of the surgeon in this operation, the smaller will be the mortality. Knowledge of the region and parts, dexterity from frequent repetition, and special training count for much. The operation usually cures the pain if the patient recovers from the actual procedure. It is claimed that the pain may recur even after complete removal of the ganglion. I have never seen this occur and am disposed to think that recurring pain is apt to mean that there was a partial removal. Carson collected 100 cases, Murphy and Neff 42 cases. The mortality in this group of 142 cases was 15 per cent. Most of the cases reported by Murphy and Neff were operated upon during or after 1899, and in this group the mortality was 10 per cent. ("Progressive Medicine," March, 1903). In Lexer's series of 201 cases, referred to below, the mortality was 17 per cent. In many cases a perfect cure is obtained. In some few the pain returns upon the side operated upon. Occasionally it arises on the side not operated upon. In some cases ulceration of the cornea follows operation. Such ulceration may be trivial, may result in opacity, or may destroy the eye.

Fig. 439.—Hartley's osteoplastic flap in removal of Gasserian ganglion (Tiffany).

Fig. 440.—Removal of Gasserian ganglion. a, Middle meningeal artery; b, ophthalmic division; c, submaxillary division; G, ganglion (Krause).

Paralysis of the abducens occurs in some cases. The hemorrhage may be so profuse as to require packing of the wound and suspension of the operation for a few days. The bleeding may come from the meningeal artery, from the sinus, or from the veins of Santorini. Lexer ("Arch. f. klin. Chir.," Bd. lxx, H. 4) gives a table of 201 cases. Of the survivors, 93.4 per cent. were apparently cured. In two-thirds of the cases the trouble was right-sided. In 10 the operation was temporarily abandoned because of hemorrhage. The experience of surgeons in general is that after the removal of the ganglion there is apt to be some atrophy of the tongue and the eye usually becomes insensitive and watery. The masseter muscle will be paralyzed.

The Hartley Operation for Removal of the Gasserian Ganglion.—

This operation was first performed by Hartley in 1891, five months before Krause performed it. The surgeon is provided with the instruments for osteoplastic resection of the skull. Special retractors, various hooks, scalpels, a dry dissector, dissecting and hemostatic forceps, and an electric forehead-light are required. Long strips of gauze must be ready for packing in case of hemorrhage. The patient is placed recumbent, with head turned to the opposite side. The application of a provisional ligature or clamp to the external carotid artery is advocated by some, but this step did not control the venous bleeding, which is the most harassing hemorrhage encountered. Many operators form a large osteoplastic flap in front of the ear (Fig. 439) and break it out. I do not believe that an osteoplastic flap is necessary. The temporal fascia is so thick and tense that when the wound in it is carefully sutured protection is perfect and safety is secured. Hemorrhage is arrested. It may be found that the meningeal artery has been ruptured. If this accident has happened and the vessel lies in a bony canal, plug with Horsley's wax. If the vessel is bleeding upon the dura, ligate by passing suture-ligatures around it. If it is torn off at the foramen spinosum, pack the foramen with iodoform gauze, and postpone the conclusion of the operation for forty-eight hours. It may be necessary at any stage of this operation to pack the wound and postpone completion for two days. Some surgeons (Krause, Bergmann) ligate the meningeal artery as a routine procedure but this operation may be difficult and require much time. If the unligated vessel is divided, the hemorrhage can be arrested by gauze packing or by plugging the foramen spinosum with a bit of sterile wood, but it is best to ligate the vessel. The head and body of the patient should now be elevated. This allows the brain to drop posteriorly and renders forcible retraction unnecessary, and, further, it lessens venous bleeding (Lexer). The next step is to lift up the dura and with it the brain (Fig. 440). Find the inferior maxillary nerve and clamp it with hemostatic forceps. Find the superior maxillary nerve and clamp it. Uncover the ganglion. Loosen the nerves from their beds with a dry dissector and divide each one at its foramen of exit. Twist the clamp forceps so as to reel up the nerves. This pulls out the ganglion intact with the motor root and the root of origin, as far back as the pons (Krause's method). Arrest bleeding, close the flap; sew the lids of the affected side together, and cover the eye with a watch-crystal.

Cushing has modified the Hartley operation so as to permit of extradural manipulation below the arch made by the middle meningeal artery and thus lessen the danger of laceration of the artery (*Jour. Amer. Med. Assoc.*, April 28, 1900). The anterior arm of the incision of the soft parts is so placed that it does not cut the nerve to the occipitofrontalis muscle. Thus deepening of the lid and obliteration of brow wrinkles on that side are avoided. He trephines the wall of the temporal fossa very low down, opens into the skull below the arch of the meningeal vessels, and thus avoids the meningeal at the foramen spinosum of the sphenoid bone and the sulcus arteriosus of the parietal bone.

Horsley's Intradural Method.—An opening is made into the middle fossa of the skull, the dura is opened, and the ganglion is found and removed. This operation is easier than the extradural method, but is believed to be more dangerous.

The Frazier-Spiller Operation of Intracranial Neurotomy of the Sensory Root of the Trigemini. If experience shows that after division of the sensory root the nerve does not regenerate, and it seems probable that it does not, the operation must be regarded as a valuable addition to our resources. This operation is by many surgeons preferred to removal of the ganglion. In this operation the zygoma is temporarily resected. The temporal fossa is exposed, the bony wall is trephined, and the trephine opening is enlarged by the use of a rongeur. The dura is separated and the ganglion and its sensory root exposed. The dural envelope of the ganglion is opened, is separated, and the sensory root is exposed. The sensory root is then picked up on a blunt hook and divided. It is frequently possible, Frazier tells us, to separate the sensory root from the motor root. In this operation we avoid the venous hemorrhage from the foramen ovale and foramen rotundum which is apt to be encountered when removing the ganglion.

Abbe's Operation of Intracranial Neurectomy of the Second and Third Divisions. This operation is preferred by Charles A. Ballance, who opposes exposure of the ganglion or division of the sensory root unless the first division of the nerve is the seat of pain. He advocates this in spite of knowing full well that the pain may return in a few years. He advocates it because of its safety, its simplicity, its freedom from serious hemorrhage, its avoidance of opening the intradural space and of all danger of corneal anesthesia, and also because if pain returns the operation can be repeated. The operation is performed as follows: Ligate the external carotid artery of the diseased side, make a vertical incision over the middle of the zygoma down to the bone. An opening into the skull is made by a mallet and gouge, and this opening is enlarged by a rongeur until it is one and one-half inches in diameter. The dura is lifted from the middle fossa and the nerves are exposed. Each nerve-trunk is clamped, is divided near its foramen of exit, and is separated from the ganglion by cutting or by twisting with the forceps. A strip of sterile rubber tissue, one and one-half inches in length and three-fourths of an inch in width, is laid over the round foramen and the oval foramen and is pressed into place by gauze. In a few moments the gauze is withdrawn and the ganglion is allowed to descend upon the rubber tissue. The wound is then closed. (See Robt. Abbe, in "Annals of Surgery," Jan., 1903.) The rubber tissue is used to block the foramina of exit and prevent future emergence of regenerating nerves. Mayo Robson blocks the foramen with a thin plate of lead or silver, a knob of the plate entering the oval foramen to prevent displacement.

Division of the Auditory Nerve for Tinnitus Aurium.—Ballance has performed this operation on the right side with success in a most distressing case of painful tinnitus.

When the cerebellar hemispheres were displaced by marine sponges the nerves of the posterior fossa were brought into view. He divided the eighth nerve, but made no attempt to preserve the nerve of Wrisberg. Five months after operation the patient was well except for deafness and deviation of the tongue to the left. (See Ballance, in "Lancet," 1908, vol. ii.) Frazier has divided the auditory nerve for vertigo.

Operation for Facial Paralysis of Extracerebral Origin (Facio-accessory Anastomosis and Faciohypoglossal Anastomosis).—Operation for this condition was first performed in 1895. (See "Remarks on the

Operative Treatment of Facial Palsy of Peripheral Origin," by Chas. A. Ballance, Hamilton A. Ballance, and Purves Stewart, "Brit. Med. Jour.," May 2, 1903; and also the "Surgical Treatment of Facial Paralysis by Nerve Anastomosis," by Harvey Cushing, "Annals of Surgery," May, 1903.) In 1898 Furet suggested to Faure that he should anastomose the peripheral end of a divided facial nerve to that portion of the spinal accessory nerve which goes to the trapezius muscle. Faure did this, but the operation failed. Robert Kennedy, of Glasgow, did the first successful operation. He divided the facial for the relief of spasm and at once anastomosed a partially divided spinal accessory. The procedure first employed by Ballance was, after noting by galvanism that muscular fiber still remained, to expose the facial nerve at its point of exit from the stylomastoid foramen, to cut the nerve trunk across as high up as possible, to expose the spinal accessory, and to suture the distal end of the facial into the trunk of the spinal accessory. The spinal accessory was cut half through to make a bed for the end of the facial. The paper of the Ballances and Stewart above referred to recommends end-to-side anastomosis between the divided facial and the hypoglossal. The authors have operated five times for facial palsy. Cushing, Keen, Hackenbruch, Korte, Currie, Beck, Vidal, Girard, Lund, Alt, Frazier, and others have done similar operations. Marked improvement may follow operation even if a palsy has lasted for a considerable time. Improvement followed operation in Carne's case, although the palsy was nearly a year old. The period when improvement should be expected is uncertain. Signs of improvement may not be evident for six months or longer. In Cushing's cases they begun in thirteen days. In Kennedy's case in seven days. In most cases operation restores facial symmetry when at rest and in many cases volitional movements. The patient will often become able to close the eye and raise the angle of the mouth. Curious associated movements may occur. In Currie's case when the patient lifted his shoulder there was contraction of the occipitofrontalis muscle ("South African Med. Record," 1907).

Facio-accessory anastomosis does not restore emotional movements, but faciohypoglossal anastomosis may restore them. Kuster reports a case which confirms this.

Operation is indicated when a complete facial palsy is of such duration that recovery is not to be hoped for by longer delay. The Ballances and Stewart believe that when a palsy has lasted six months without sign of recovery, operation is indicated. A paralysis due to traumatism gives a much better prognosis after operation than does a paralysis due to a septic process (Chas. A. Ballance, Hamilton Ballance, and Purves Stewart, in "Brit. Med. Jour.," May 2, 1903). Murphy has collected 33 cases of anastomosis of the facial nerve with the spinal accessory, hypoglossal, or glossopharyngeal, and Joseph Beck has added 5 cases of his own in which he performed faciohypoglossal anastomosis.

The hypoglossal is preferred to the accessory. Its trunk is larger and its cortical center is adjacent to the facial cortical area. After such an operation associated movements are not observed when the mouth is kept closed and, if Howers is correct, the fibers of the facial, which supply the muscles closing the mouth, may take origin from the hypoglossal nucleus (John B. Murphy, in "Surg., Gynec., and Obstet.," April, 1907). Murphy points out that an

anastomosis may be end to end, implantation of the facial into a slit in the other nerve, implantation of the facial into a partial transverse division of the other nerve or end to side (*Ibid.*).

Operation for Brachial Birth Palsy. (See article by L. P. Clark, A. S. Taylor, and T. P. Prout, in "Am. Jour. Med. Sciences," Oct., 1905.) These authors report 8 cases of operation with some notable improvements and with 2 deaths. In these cases they found great thickening of the fascia and in some cases fibrous tissue almost completely obscured the remains of lacerated trunks or roots. They advise that the patient be placed recumbent, with a sand-pillow beneath the shoulders and with the head extended and bent toward the opposite shoulder. An incision is made at the posterior border of the sternocleidomastoid and the plexus is exposed and explored. If the lesion is above the clavicle, it is at once attacked; if below that bone, the incision is carried down, and the bone is sawed in two. The scar tissue with the lacerated nerves is removed and the nerves or nerve-roots are sutured. The wound is closed, the clavicle being wired if it was divided. After dressings are applied the head is bent toward the shoulder of the damaged side and fixed with plaster-of-Paris.

I operated on a case of Dr. Charles S. Potts's in the Phila. Hospital. The roots were not torn, but were found imbedded in a thin layer of scar which it was possible to remove. The result was good. Nerve anastomosis may be necessary if excision of scar leaves an unbridgable gap or if nerve roots were divided with foramina.

XXIII. DISEASES AND INJURIES OF THE HEAD.

DISEASES OF THE HEAD.

In approaching a case of brain disorder, first endeavor to locate the seat of the trouble; next, ascertain the nature of the lesion; and, finally, determine the best plan of treatment, operative or otherwise. In all operations upon the brain the surgeon must be able to determine accurately the situations of certain fissures and convolutions, the finding of the situations of these convolutions and fissures comprising the science of *craniocerebral topography*.

Fig. 441. The meningeal artery exposed by trephining (after Esmarch).

The regional terms used in craniocerebral topography are derived from Broca (Fig. 442). The middle meningeal artery is found at the *pterion*, one and one-quarter inches posterior to the external angular process, on a level with the roof of the orbit (Fig. 441). The fissures and convolutions of the brain are shown in Figs. 443-445). The *fissure of Bichat* is marked by a line on each side drawn from the *inion* to the external auditory process.

A line from the *glabella* to the *inion* overlies the median fissure and the superior longitudinal sinus. The *fissure of Rolando* is very important, as marking the pos-

terior limit of the motor region of the brain. It begins near the median line, half an inch posterior to the middle of the distance between theinion and glabella (Hane). This fissure runs downward and forward at an angle of 67.5°

Fig. 442.—Skull, showing the points named by Boscaw. *A*, Astion (junction of the occipital, parietal and temporal bones); *B*, bregma (middle of anterior wall of foramen magnum); *C*, cephalon (junction of the sagittal and coronal sutures); *D*, diploë (on a level with the superior border of the eyebrows and corresponding nearly to the glabella, the smooth swelling between the eyebrows); *E*, external angle of the lower jaw; *F*, fontanelle (external occipital protuberance); *G*, glabella (junction of nasal and lambdoid sutures); *H*, helicis (junction of the nasal and frontal); *I*, inion (the angle between the parietal foramina); *J*, junction (point of junction of great wing of sphenoid and occipital parietal and squamous bones. This may be H shaped or K shaped or "retrourné" in which the frontal and temporal just touch); *K*, keystone (or better, the superior stephanion, intersection ridge for temporal fascia and coronal suture); *L*, lambdoid (intersection of ridge for temporal muscle and coronal suture); *M*, mastoid (intersection of ridge for temporal muscle and coronal suture); *N*, nasal (intersection of ridge for temporal muscle and coronal suture); *O*, obelion (intersection of ridge for temporal muscle and coronal suture); *P*, pterion (intersection of ridge for temporal muscle and coronal suture); *Q*, quadratus (intersection of ridge for temporal muscle and coronal suture); *R*, ridge (intersection of ridge for temporal muscle and coronal suture); *S*, superior stephanion (intersection of ridge for temporal muscle and coronal suture); *S'*, inferior stephanion (intersection of ridge for temporal muscle and coronal suture).

for a distance of three and three-eighth inches. Chiene finds the fissure of Rolando by the following method: He takes a square piece of paper and folds it into a triangle (Fig. 446, 1); the angle BAC of this triangle is 45° ; the edge DA is folded back on the dotted line AE ; the angle DAE equals half of 45° , or 22.5° , and the angle CAE equals the same (Fig. 446, 2); unfold the paper in the line CV ; in the figure thus formed $BAC = 45^{\circ}$ and $EAC = 22.5^{\circ}$; $EAB = 67.5^{\circ}$, which is the angle desired. Place the point A in the mid-line of the head, over the point of origin of the Rolandic fissure; the side AB is laid along the middle line of the head, and the line AE corresponds to the fissure of Rolando.* Horsley determines the situation of the Rolandic fissure by the use of his metal cyrtometer (Fig. 447). He places the point marked *ao* over the inion and midway between theinion and the glabella. To find the fissure of Sylvius (Fig. 444, *S*, *S'*, *S''*), draw a line from

Fig. 443.—View of the brain from above (Ficker)

* "American Text-Book of Surgery."

the external angular process to the occipital protuberance. The fissure of

Fig. 444.—Outer surface of the left hemisphere of the brain (Ecker)

Sylvius begins on this line one and one-eighth inches behind the external angular process, the main branch of the fissure runs toward the parietal eminence; the ascending branch of the fissure corresponds to the squamosphenoidal suture, and continues upward in the same line half an inch above the suture. The *pre-central sulcus* (Fig. 444. F) limits anteriorly the ascending frontal convolution; it runs parallel with and just behind the coronal suture, and a finger's breadth in front of the fissure of Rolando. The *intra-occipital fissure* (Figs. 443, 444. *i*) limits the ascending parietal convolution posteriorly. It begins oppo-

Fig. 445.—Inner surface of the right hemisphere of the brain (Ecker).

Fig. 446.—Chiene's method of fixing position of Rolandic fissure ("American Text-book of Surgery").

site the junction of the lower and middle thirds of the fissure of Rolando, passing

upward in a line parallel with the longitudinal fissure and midway between the Rolandic fissure and the parietal eminence, passes by the parieto-occipital fissure, and downward and backward into the occipital lobe. The motor areas, which on

Fig. 447. Horsley & cytometer.

the outer surface are adjacent to the fissure of Rolando, are shown in Figs. 443 and 444.* The superior longitudinal sinus is overlaid by a line from theinion to the glabella. The lateral sinus is indicated by a line running from the occipital protuberance horizontally outward to a point one inch posteriorly to the external auditory meatus, and from this point by a second line dropped to the mastoid process. The *supra-mastoid triangle* of Macewen is bounded by the posterior root of the zygoma, the posterior bony wall of the auditory meatus, and a line joining the two. The mastoid antrum is opened through *Macewen's triangle* to avoid injury to the lateral sinus. *Barker's point*, the proper spot to apply the trephine in absence of the temporo-sphenoidal lobe, is one and one-fourth inches above and one and one-fourth inches behind the middle of the external auditory meatus. Fig. 448 shows clearly the main points of craniocerebral topography, obtained by methods approved by many scientists.

Krönlein's method of localizing certain points is the most generally serviceable. (See Fig. 449.) A line, known as the base line, $z\kappa$, is carried horizontally backward from the lower border of the orbit through the upper border of the external auditory meatus. Another horizontal line, $\kappa\kappa'$, is drawn parallel with this, on a level with the supra orbital ridge. A line $z\kappa$ is erected from the middle of the zygoma to the supra orbital line. A vertical line is drawn from the articulation of the lower jaw, A, and is prolonged to K. A vertical line is

Fig. 448.—Head, skull, and cerebral fissures; BC, corresponds to Broca's convolution; EAP, external angular process; FR, fissure of Rolando; IF, inferior frontal sulcus; IIF, intraparietal sulcus; MMA, middle meningeal artery; OPr, occipital protuberance; PE, parietal eminence; POF, parieto-occipital fissure; SP, Sylvian fissure; A, its ascending limb; TS, temporo-sphenoidal lobe. The pterion (to the left of B) is the region where three sutures meet, viz those bounding the great wing of the sphenoid where it joins the frontal, parietal, and temporal bones (adapted from Marshall by Hare).

* Recent studies indicate that the motor region is entirely in front of the Rolandic fissure.

drawn from the posterior border of the mastoid base ($M K'$) and is taken as the middle line of the skull. A line is drawn from K to P , and between points R and P' it overlies the fissure of Rolando. The angle of $P K K$ bisected by the line $K S$, which corresponds to the fissure of Sylvius from point of bifurcation to its posterior termination. K marks the bifurcation the fissure of Sylvius. To reach the anterior branch of the middle meningeal artery trephine at K ; to reach the posterior branch, trephine at K' .

Fig. 449.—Krönlein's method of locating the fissures of Rolando (RP) and Sylvius (KS); Krönlein's point of trephining for hemorrhage from the middle meningeal (KA'), and von Bergmann's region for trephining for abscess of the temporo-sphenoidal lobes ($AaA'M$) ("American Text-book of Surgery").

Head Injuries During Labor.—Caput Succedaneum.—This condition is edema of the scalp due to prolonged pressure. The edema is circular and circumscribed and occupies the part not subjected to continued pressure during the uterine contractions of labor. The ring of tissues which are impressed around project like a cup into the birth canal. The veins become congested and edema results. The parts subjected to pressure may appear normal or may exhibit ecchymoses or even excoriations. The pressure is

usually made by the os, and its situation varies with the presentation, but because the most frequent presentation is left occipito-anterior, the common position of the caput is over the superior and posterior portion of the right parietal bone. In a face presentation great disfigurement may occur. It is seldom that a double caput is encountered. It always means that the presentation has shifted. The worst cases of caput follow prolonged labor. The edematous swelling contains bloody serum, pits on pressure, does not fluctuate, is not limited to the outline of one bone, and the skin above it is usually discolored by ecchymoses. No treatment is necessary, as the condition will disappear in from a few hours to three days.

Cephalhematomata.—By this term we mean extravasations of blood beneath the untorn pericranium. It is supposed by many to be always due to pressure and venous congestion, as is a caput succedaneum. As Cushing points out, the condition cannot result only from the venous stasis of prolonged pressure. If it did it would always exhibit above it a caput succedaneum, and this is far from our actual experience" (Harvey Cushing, in "Keen's Surgery," vol. iii). It is certainly due in some cases to bending or breaking of a cranial bone. The condition is said to occur in 1 labor out of 200. In most cases there is but one cephalhematoma, but there may be two, three, or even four. The commonest situation is over the right parietal bone (the common seat of caput succedaneum) and caput succedaneum may be associated with a cephalhematoma. The blood begins to flow beneath the pericranium during labor and the swelling increases during the first few days after birth; in fact, it is frequently not noticed for a day or two. The swelling is tense and smooth with a convex outline. It may cover but a small portion of a bone or an entire bone, but never extends beyond the bounding sutures. This limitation is due to the fact that the pericranium is adherent to the sutures. In the course of a couple of weeks the tumor may become surrounded by a hard ring due to the formation of new bone, and a shell of bone may eventually surround and cover over the clot, an area of permanent bony thickening remaining. In other cases no bone forms, but the clot gradually disappears. An extradural and even a subdural cephalhematoma may be associated with a subpericranial cephalhematoma.

Cephalhematomata unassociated with cerebral symptoms usually disappear without operation. If there is no sign of subsidence after two weeks, follow Cushing's rule, evacuate by a puncture-like incision and apply pressure. If suppuration occurs, incision is necessary. Suppuration may occur if the scalp was excoriated.

Diseases of the Scalp. The scalp is composed of skin, subcutaneous fat, and the occipitofrontalis muscle and aponeurosis. The scalp is liable to inflammation from various causes, and also to other diseases—namely, tumors, cysts, warts, moles (local cutaneous hypertrophies), cirroid aneurysm (page 432), nevi, and lupus. *Abscesses of the scalp* are common. If an abscess forms beneath the pericranium, the pus diffuses over the area of one bone, being limited by the attachment of the pericranium in the sutures. If an abscess forms in the tissue between the occipitofrontalis and the pericranium, it is widely diffused. Treves calls this subaponeurotic connective tissue "the dangerous area." Abscess of the subcutaneous tissue is apt to be limited because of the great amount of fibrous tissue. Abscess is treated by instant incision at the most dependent part, and drainage.

Diseases and Malformations of the Bones of the Skull.—The bones of the skull are liable to caries, necrosis, osteitis, periostitis, atrophy, hypertrophy, tumors, etc. (see Diseases of Bones).

Cranial Pneumatocele.—This rare condition is a result of perforation of a bone which permits air to collect beneath the periosteum. It may occur in the mastoid or occipital region or over the frontal region. These protrusions vary greatly in size; and as their shape depends upon the periosteal attachment to sutures in the neighborhood, they vary in shape. The overlying tissues are natural in appearance. The protrusion is tense, but may lessen or disappear on pressure. McArthur points out ("Jour. Am. Med. Assoc.," May 6, 1905) that if diminished by pressure, the patient may hear a sound like rushing air or water in the ear if the protrusion is occipital or mastoid; and in the nose, if it is frontal. An elevated ridge of bone surrounds a pneumatocele. The protrusion is tympanitic on percussion. The condition is due to perforation of the bony wall of an air sinus by disease or injury or rupture. McArthur points out that in half of the reported cases the rupture was not preceded by any history of inflammation or injury. The condition is not dangerous.

Treatment.—Incision, finding the opening, enlarging it, removing osteophytes; bringing the walls of the cavity together and applying pressure.

Microcephalus.—By microcephalus is meant unnatural smallness of the head due to imperfect development. Marked microcephalus is not a common condition, but it is an occasional cause or associate of idiocy. A child may be born with a skull completely ossified even at the fontanelles, or the ossification may become complete soon after birth, but in many cases of microcephalus ossification takes place late or not at all. In microcephalus the face is usually fairly well developed; the jaws are prominent; the forehead is flat; the cranium and brain are small; the convolutions of the brain are simpler than is natural; there is apt to be marked asymmetry of the two sides of the brain; internal hydrocephalus may exist; areas of sclerosis and atrophy are common; porencephaly is not unusual. Some patients have perfect motor power; others are slow and incoordinate. Epilepsy, chorea, and athetosis frequently complicate the case. Idiots of this type often present deformities such as cleft palate, strabismus, distorted ears, hypertrophied tongue, deformed genitals or extremities, ill-shaped and irregularly developed teeth. They exhibit irregular muscular movements, are frequently paralyzed in childhood (infantile paraplegia or hemiplegia), and suffer from subsequent contractures. They are active, destructive, excitable, and are liable to be violent and almost demoniacal. As Clouston says, they look impish and unearthly.

Treatment.—Skilled training in a school for the feeble minded or in an institution for idiots is necessary in treating microcephalic idiocy. Idiots have but little power of attention, and sensory impressions give rise to but few concepts, and these are feeble and fleeting. In order to educate the idiot it is highly desirable that speech be acquired, and "the more strongly the attention can be aroused, the more perfect does speech become" (Kirchhoff). The principle of the education of idiots is to stimulate, coordinate, and guide sight, hearing, and feeling.

Lannelongue, of Paris, has suggested an operation in cases of idiocy

with premature ossification (see *Linear Craniotomy*, page 846). In this procedure the author has no confidence. Idiocy is a general disorder and not a local brain disease. Soft parts mould bone, and bone does not control soft parts. There is no evidence that the brain is being compressed; in fact, the simplicity of the convolutions suggests the contrary. In many typical cases of microcephalic idiocy there is no synostosis even years after birth. The operation has been much abused. It is sometimes fatal, and, although a fatality may gratify the family, a surgeon is not a legal executioner. The remarkable improvement which has been reported in some cases is wrongly supposed to be due to the operation. As a matter of fact, the new surroundings, the strange faces, the firm discipline, the effect of the anesthetic, and the shock of the operation attract the feeble attention and rouse the sluggish senses. Many cases are brought for operation because they are for the time being unusually intractable and excitable, and the return to the usual level of conduct after operation is regarded as a permanent gain, when it is often but a temporary alleviation. We believe that scientific training is the proper treatment, and that the efficiency of training is not increased by the previous performance of craniotomy, and we follow the precept of Agnew, that a surgeon might as well cut a piece out of a turtle's back to make a turtle grow as to cut a piece out of the skull to make the brain grow.

Diseases and Malformations Involving the Brain.—Cephaloceles.—A cephalocoele is a congenital protrusion of intracerebral contents through a defect in the skull. These protrusions are covered with skin. The defect through which the protrusion occurs is always in the median line, although in some cases (as at inner angle of the orbit) the visible protrusion may be at the side. Nearly all such protrusions are either frontal or occipital, although now and then one presents in the pharynx, having emerged from the skull between the body of the sphenoid and the ethmoid.

Frontal cephaloceles are divided into:

1. Nasofrontal—those which are in the region of the glabella.
2. Naso-orbital—those at the inner angle of the orbit.
3. Nasoethmoidal—those below a nasal bone.

Each one of the above forms passes through the horizontal plate of the ethmoid.

Occipital cephaloceles are divided into:

1. Superior—those above the external occipital protuberance. In these the bony gap may join the posterior fontanel.
2. Inferior—those below the external occipital protuberance. In these the bony gap may join the foramen magnum.

The above regional classification is that advocated in von Bergmann's "System of Practical Surgery" (translated and edited by Wm. T. Bull and Walton Martin).

The commonest form is hydrencephalocoele, and all other forms result from retrograde changes in this.

Hydrencephalocoele.—This is by far the commonest and is also the most dangerous form encountered. The protrusion consists of arachnoid, a layer of brain tissue, and a cavity containing ventricular cerebrospinal fluid and connected with the lateral ventricle. It is in reality a protrusion of the lateral ventricle. It is covered with skin—natural skin, unless the protrusion

is very large, in which case the skin is more or less atrophied. Beneath the skin is fascia and beneath this, arachnoid. The pericranium and dura do not cover it, but each has a gap in it and these two tissues join each other around the bone margins.

Encephalocele.—Results from retrograde changes in a hydrancephalocele. The protrusion of the ventricle has become reduced and the hernia consists of a portion of brain covered by arachnoid. Encephalocele is only seen in the nasofrontal region. If there is any fluid in this protrusion, it is not in its interior, but on its surface, and results from a cyst of the arachnoid.

Meningocele.—We formerly understood by a meningocele a protrusion of the membranes alone; we now regard it as a condition resulting from retrograde changes in a hydrancephalocele. The brain tissue of the latter disappears; beneath the arachnoid is a layer of cells identical with those which line the ventricles; the connection with the ventricle is entirely or almost completely cut off; a cyst forms in the subarachnoid tissue, and thickened pia surrounds the cyst. (See "System of Practical Surgery," by E. von Bergmann, vol. i, translated and edited by Wm. T. Bull and Walton Martin.) The above condition is called by von Bergmann encephalocysto-meningocele.

Diagnosis.—The congenital origin and situation make certain that the condition is cephalocele. The bony gap can usually be felt; whether it can or cannot, an x-ray picture should be taken. Such a picture may indicate that the mass contains brain matter. The protrusions vary greatly in size and shape. Some are rounded, some are flattened, some are stalked. The skin covering them may be natural, atrophied, filled with vessels, scarred, or ulcerated. Sometimes the cephalocele is very tense; sometimes it is loose. In naturally hairy regions the skin over the summit of the protrusion is bald, but that around the base is hairy. If there is connection between the interior of the protrusion and the ventricle, the mass can be diminished in size by compression. If it shrinks rapidly from compression, the opening into the ventricle is large. In such cases compression of the mass quickly causes signs of cerebral pressure. Lumbar puncture may cause the protrusion to diminish in size; crying may cause it to increase in size. Large cephaloceles fluctuate and perhaps pulsate. Meningocele feels and looks like a cyst (is translucent and fluctuates); it does not usually pulsate, it has a small base, it becomes tense on forcible expiration, and some cases can be very slowly diminished by compression.

Encephalocele is small, opaque, does not fluctuate, has a broad base, does pulsate, becomes tense on forced expiration, and attempts at reduction fail and cause pressure symptoms.

Hydrancephalocele is larger than a meningocele, is translucent, fluctuates, rarely pulsates, is pedunculated, is rendered a little tense on forced expiration, and can be lessened in size by compression but cannot be reduced.

Treatment.—In von Bergmann's "System of Practical Surgery" we find the wise caution to attempt no operation for an occipital protrusion beneath the protuberance, when the cleft enters the foramen magnum and is associated with cleft of the cervical vertebra—for a condition in which the soft parts are defective and the brain is exposed (*cranioschisis*)—on a case complicated with hydrocephalus or on a case complicated by some other condition which is of necessity fatal. We no longer refuse to operate because the mass contains some brain matter or because it communicates with the ventricle,

although if it does so, the prognosis is much worse. For a large hydran- cephalocele nothing can be done and early death is inevitable. In rare instances an encephalocele is converted into a meningocele, and the bony aperture closes, thus bringing about a cure. Among the expedients for treating meningocele are electrolysis, injection of Morton's fluid (gr. x of iodine, gr. xxx of iodide of potassium, 3j of glycerin), pressure, and excision. In cases of cephalocele, when portions of the nerve-centers are not contained in the sac, A. W. Mayo Robson advises the performance of a plastic operation. He ligates the neck of the sac, excises the sac, sutures the skin-flaps separately, and leaves the stump outside the line of superficial sutures. It is usually possible to tell by palpation if nerve-centers are in the sac, but if in doubt, make an exploratory incision, and sweep the finger around inside of the sac.* Meningoceles should be operated upon by Robson's plan.

Spurious Meningocele.—It occasionally happens, after a fracture of a child's skull, that cerebrospinal fluid gathers beneath the pericranium and bulges the pericranium and scalp. This condition is called spurious meningocele. When a spurious meningocele forms, the bone must have been broken and the dura and arachnoid ruptured. This protrusion fluctuates, pulsates, and is influenced by respiration. In some cases there is communication with the ventricles of the brain. The parietal and frontal regions are the most usual seats of the trouble. The opening in the skull may close; it may remain stationary; it may actually enlarge by bone-absorption. In some cases the spurious meningocele undergoes spontaneous cure; in some cases rupture occurs, in other cases death takes place as a result of the cerebral injury. (See Joseph Sailer on "Spurious Meningocele," "University Med. Magazine," Sept., 1900.)

Treatment.—Close the opening by a plastic operation.

Hydrocephalus.—In *external* hydrocephalus the fluid is on the surface of the brain; in *internal* hydrocephalus the fluid is in the ventricles. Hydrocephalus may be *acute* or *chronic*, *congenital* or *acquired*.

Acute hydrocephalus is usually internal, but may be external. It results from meningitis—usually tuberculous meningitis of the base. The symptoms are headache, elevated temperature, delirium, stupor, convulsions, paralysis, and choked disc.

Treatment of acute hydrocephalus by medical means is of no avail. Tapping of the ventricles may be tried.

Chronic internal hydrocephalus is usually congenital, but may arise after birth in children under seven. In congenital hydrocephalus the condition may be due to circulatory disturbances in the brain of the embryo resulting from uterine disease or injury during pregnancy. Syphilis and alcoholism in parents seem sometimes to be responsible. Chronic acquired hydrocephalus results from inflammation, especially tuberculous inflammation. A tumor pressing on the veins of Galen may cause it. In chronic acquired internal hydrocephalus there is overproduction or underabsorption of cerebrospinal fluid and perhaps both conditions may exist. The usually causative condition is an inflammation of the interior of the ventricles, particularly of the choroid plexuses, and as a consequence venous return is obstructed and oversecretion occurs. One or both foramina of

* "Amer. Jour. Med. Sciences," Sept., 1895.

Monro may be closed, and if only one is closed, unilateral hydrocephalus may arise (Alfred S. Taylor, in "Am. Jour. of Med. Sciences," August, 1904). The aqueduct of Sylvius, the foramen of Magendie, and the central canal of the cord may be occluded. The cranium enlarges enormously and the bones of the skull are widely separated. The brain is distended and thinned and the sulci are obliterated. The broad forehead overhangs the eyes; the fontanelles are elevated. The child is mentally weak or is an idiot, and very often does not learn to walk or to talk. Convulsions, palsies, and contractures are common, and blindness is frequent. Such children usually die young.

The *treatment* of chronic hydrocephalus is rarely of much avail. Pressure by strapping with adhesive plaster has been tried. Tappings through a fontanelle may be performed by means of a trocar (only $\frac{3}{16}$ or $\frac{3}{32}$ of fluid being withdrawn at a time). If much fluid is allowed to flow out, the head must be strapped with adhesive plaster afterward. If the skull ossifies, the lateral ventricles may be tapped after trephining. It has been proposed to drain by tapping the theca of the spinal cord (Quinke). This last operation is called *lumbar puncture* (pp. 878, 879). It will, of course, fail if the foramina in the floor of the fourth ventricle or the aqueduct of Sylvius are blocked. Even if they are open, it is of little service. The operation which promises most was devised by Sutherland and Cheyne, and is known as *intracranial drainage* ("Brit. Med. Jour.," Oct. 15, 1898). Their theory is that in hydrocephalus fluid distends the ventricles because the channels of communication between the ventricles and the subarachnoid spaces are closed. The subarachnoid spaces communicate directly with veins, hence fluid cannot collect under pressure in these spaces. Intracerebral drainage establishes a communication between the subarachnoid space and one ventricle. It is not necessary to operate on both sides in bilateral hydrocephalus, because the lateral ventricles communicate. A small opening is made in the skull. The dura is incised. A number of strands of catgut, which are tied together, are pushed through the brain so that one end of the catgut mass lies in a ventricle and the other end beneath the dura. The dura and scalp are then sutured. Brewer makes an osteoplastic occipital flap, makes a dural flap, lifts the cerebral lobe, and pushes a drain of rubber tissue into a lateral ventricle.

The elder Senn passed a rubber tube into the ventricle and put the outer end of the tube beneath the skin of the scalp.

Alfred S. Taylor ("Am. Jour. Med. Sciences," August, 1904) makes an osteoplastic flap with its base over the right mastoid, cuts a dural flap, passes a slender aspirating needle through the second temporo-sphenoidal convolution into the lateral ventricle, draws off a *little* fluid, and measures the thickness of the brain. He then takes 6 strands of No. 2 forty-day catgut, each strand half an inch longer than the thickness of the brain. The strands are tied together with a spiral of catgut, $1\frac{1}{2}$ inches of the loop being left free. Three layers of Cargile membrane are wrapped about the shaft, but the tip remains free. It is carried into the ventricle along the needle track by thumb forceps, and the loops are slipped here and there, but chiefly downward, under the dura. Cargile membrane is placed between the loops and dura and the dura and skin are sutured. Taylor operated on 6 cases and 2 recovered, with relief of all signs of pressure.

Cushing, after determining by lumbar puncture that the ventricles can be emptied, obtains retroperitoneal drainage by a combined laparotomy and craniectomy.

INJURIES OF THE HEAD.

Caput Succedaneum.—(See page 790.)

Scalp-wounds.—Scalp-wounds bleed profusely because the scalp is very vascular, because many of the blood-vessels are in fibrous tissue and cannot contract and retract, and because even blunt force splits the scalp almost like an incision. Scalp-wounds are treated as are other wounds. Even a large piece of scalp with only a narrow pedicle may not slough; hence try to save any piece that has an attachment. Always shave a wide area and disinfect the shaven area and the wound. Arrest hemorrhage, and exercise great care in cleansing the wound and the parts about it. Stitch the wound with silkworm-gut. Very few sutures are needed if the wound is longitudinal, but many are required if it is transverse. The permanent arrest of hemorrhage is rarely effected by ligatures, but rather by sutures judiciously placed. If drainage is required, use a few strands of silkworm-gut; but drainage is rarely used unless we know the wound is grossly infected. Wet antiseptic dressings are used for the first few days and moderate pressure is applied by wet gauze bandages. Avulsion of the scalp is discussed on page 275.

Contusions of the Head.—Scalp-swelling from hemorrhage is usually considerable. The patient may be stunned or dazed. The swelling of hematoma must not be mistaken for *fracture* with depression. In hematoma there is a central depression; hard pressure on the center finds bone on a level with the general contour of the bone, and the margin of a hematoma is circular, is not quite hard, and is elevated above the general contour. In depressed fracture the edge is on a level with or below the level of the general bony contour, and the margin is sharp and irregular. The treatment is by bandage-pressure. If suppuration arises, at once incise.

Concussion, Contusion, and Laceration of the Brain.—For many years it was customary to regard concussion as a condition produced by molecular vibrations in the nervous substance of the brain. Duret's classical observations profoundly modified surgical thought, and led to the opinion that in concussion of the brain there is injury to the brain itself, a rupture of cerebral vessels brought about by the advance and recession of a wave of cerebro-spinal fluid. This wave, it is thought, first flows in the direction of the force. Keen says that there may be slight brain injuries which can properly be called "concussions," but it is better to consider concussion as synonymous with laceration of the brain. Kocher considers concussion as identical with *contusion of the brain*. It seems, however, highly improbable that slight cases of concussion are accompanied by vascular rupture or organic mischief; the symptoms are too transitory, and reaction too rapid and complete to permit of any such view. Experiments on animals show we can develop concussion without laceration or contusion. Autopsies have been carefully made in some cases of death from concussion, and no organic lesion has been discovered. It is quite true that the same force which causes the concussion may cause contusion or multiple lacerations, and a severe force is apt to do so. But we are not then justified in assuming that concussion is contu-

sion or laceration we should rather conclude that the individual had both concussion and a demonstrable injury. Both conditions arise from violence, but the two conditions are not identical. I believe with von Bergmann that there is such a condition as concussion, which may be pure concussion or may be associated with organic damage, and even if a man dies and is found to have an organic injury, the concussion may have caused, or, at least, have hastened, the fatal result. I believe with von Bergmann that it is not repeated waves of force from the blow but the concussion of the blow itself that does the harm. The brain is momentarily displaced by the blow. The blow acts on the entire brain; the centers are first stimulated and then depressed, and in fatal cases are not only depressed but are paralyzed. The cause of concussion is violent force either direct (as a blow upon the head) or indirect (as a fall upon the buttocks). This force shakes, oscillates, jars, or displaces the brain, giving rise to stimulation and then to exhaustion of the nerve-centers, and perhaps to rupture of vascular twigs, large vessels, or even the membranes. In the less severe cases concussion only exists; in the more severe cases there is also contusion or laceration or compression soon arises.

As von Bergmann points out, the entire cortex in concussion is momentarily stimulated and then depressed. The momentary stimulation exists when a man "sees stars" as a result of a blow. The depression or exhaustion is manifested by heaviness, dulness, stupor, perhaps by unconsciousness. The stimulation of the medullary centers, von Bergmann points out, lasts longer, as a rule, than the stimulation of the cortex, and is manifested particularly by a slow pulse. If the pulse grows rapid and weaker, the pneumogastric center is becoming exhausted and the patient is in danger of death. In slight cases of concussion only the cortex may be involved, the medullary center escaping. In rapidly fatal cases of concussion the medullary centers are quickly paralyzed.

Symptoms. — In very trivial cases the patient is slightly and momentarily dazed and the pulse is temporarily slow and weak, but he is otherwise unaffected. In a rather slight case of brain concussion the patient may or may not fall, his face is pale, he feels weak, giddy, nauseated, and confused, but he soon reacts, and often vomits. The pulse is weak and is slow for a time and then becomes normal. In a severe case he lies in a state of complete muscular relaxation. The extremities are cold; the skin is pale and cold; the pulse is small, soft, slow, and weak, because of stimulation of the pneumogastric center, the respiration varies, being sometimes deep, sometimes superficial, sometimes rapid, and sometimes irregular. He seems unconscious, but can usually be roused to monosyllabic response by shouting, pinching, or holding a bright light near his face. Occasionally, however, there is complete unconsciousness. The urine and feces are often passed involuntarily. The pupils may be unaltered, may be dilated or contracted, may be equal or unequal, but in any case they will react to light. Paralysis rarely exists, but if there is paralysis, it is temporary. The temperature at first is subnormal. In a very severe concussion in which there is great danger of death the pulse is very rapid, small, weak, and probably irregular because of exhaustion of the medullary center, and the patient is absolutely unconscious because of depression of the cortex. In a severe cortical laceration there will be twitchings or even general convulsions, or the patient will lie curled up with limbs flexed and

eyes is shut, and will resist all attempts to open his eyes or mouth or to move his limbs (A. Pearce Gould). Erichsen called this condition "cerebral irritability." If a patient with very severe concussion and very rapid pulse is going to get better, the pulse will become slower. If a patient with severe concussion and a slow pulse is improving, the pulse will become normally rapid and stronger; if he is getting worse, it will become abnormally rapid and weaker. How long may concussion last? As von Bergmann well says: Concussion is transient in its manifestations. It is a matter of a few minutes or at most a few hours, and any prolongation of severe symptoms beyond this time, especially if they are intensifying as time goes on, indicates an associated injury. When the patient reacts from concussion, he will most probably vomit. Within twenty-four hours he usually improves, but is feverish and complains of headache and lassitude, sometimes becomes delirious, and in rare cases develops mania. After concussion recovery may be complete, but, on the contrary, a person's whole nature may change: he may develop hysteria, insanity, or epilepsy, and in many cases there is complaint for a long time of headache, insomnia, low spirits, and lassitude. Concussion may pervert or wipe out all memory of the causative accident and also, strange to say, of a varying period preceding the accident. The loss of memory of the accident is permanent; the amnesia for a period preceding the accident may be permanent, but may only be temporary. Statements made regarding an accident by those who have had concussion must be received with many grains of salt. If the patient in concussion recedes from, instead of advancing toward, recovery, coma will set in or inflammation will develop. The prognosis is always uncertain. Any concussion producing more than very temporary unconsciousness is almost surely a serious injury, because considerable laceration has probably occurred.

Treatment.—In treating brain concussion bring about reaction by the administration of aromatic spirits of ammonia (no alcohol, as this agent excites the brain), by pouring a few drops of ammonia on a handkerchief and holding it near the nose, by surrounding the patient (who lies in bed with a pillow) with hot bottles, by hot irrigation of the head, by the application of mustard over the heart, and by the administration of enemata of hot coffee or hot saline fluid. Do not pour fluid into the patient's mouth until he becomes able to swallow easily. If he cannot easily swallow, rely on hot enemata and hypodermatic injections of strychnin. Place the patient in bed in a quiet room and watch him. If reaction is inordinate, apply cold to the head, give arterial sedatives and diuretics, and purge. For some days or for some weeks, according to the case, insist on an easy life. For many weeks after a grave concussion a patient must be kept away from business and be watched, because of the possibility of an abscess of the brain arising, and because of the liability of such patients to develop hysteria, neurasthenia, or insanity. Give a plain diet containing a minimum of meat, administer an occasional purgative, and secure sleep. Sleep can often be obtained by some simple expedient, such as the administration of warm milk, placing a hot-water bag to the abdomen or feet, or applying a mustard plaster for a short time to the back of the neck. In cases where obstinate wakefulness exists, it becomes necessary to give bromid, chloral, sulphonal, trional, or some other hypnotic. Morphin is avoided be-

cause it is thought to increase venous congestion of the brain, but the elder Gross often used it, especially in cerebral irritation. If signs of compression arise, it is best to trephine, as the compressing agent may be a clot (see page 804). If inflammation arises, some surgeons will not trephine; but it is wise and proper, especially if the damage seems to be localized, to incise the scalp and inspect the bone. If a fracture is discovered and the symptoms are serious, perform an exploratory trephining, open the dura, and secure drainage for inflammatory products.

In any severe concussion of the brain with contusion of the scalp the surgeon should at once incise the scalp and inspect the bone.

Compression of the Brain.—The combination of symptoms indicative of cerebral compression may be present in a number of different conditions. We find these symptoms in abscess of the brain, tumor of the brain, intracranial hemorrhage, foreign bodies, inflammatory exudate, and fracture of the skull with marked depression. The symptoms of compression are expressive of impairment of the functions of the entire brain by insufficient and imperfect circulation of blood, this impairment of circulation being the result of a lessening in capacity of the cavity containing the brain, its membranes, the blood-vessels, and the cerebrospinal fluid (von Bergmann). If a brain tumor, or abscess, or blood-clot, or portion of depressed bone occupies space previously given to brain matter, vessels, etc., there is less room within the skull to contain the special structures; they are squeezed and the circulation is greatly impeded. This condition is compression. The circulation is slowed, and because of slow circulation the activity of the centers is finally inhibited. It is stated by Cushing that the rise which occurs in the blood pressure is conservative and is expressive of nature's effort to maintain the circulation in the compressed medullary centers. The cortex is temporarily stimulated and then depressed, because of impairment of nutrition. The medullary centers are first stimulated. The respiratory center is stimulated by retention of CO_2 in the blood, then the vasomotor center is stimulated, then the vagus, and finally, perhaps, the convulsive center (von Bergmann's "System of Practical Surgery"). The stimulation of the cerebral centers is followed after a time by weakening or actual paralysis. The centers are said to suffer in regular order, viz., the cortex, the corona radiata, the gray matter of the cord, and, finally, the medulla (Huguemin). As von Bergmann points out, by the time the convulsive center becomes stimulated, the cortex is usually exhausted and the patient is unconscious. In compression the sensitive cortex first feels the effect and feels it most gravely, and the cortical impairment may last long after other trouble has passed. In some cases the cortex alone seems to be distinctly involved. When the vagus center is stimulated, the pulse becomes slow, later, as the center becomes exhausted, it becomes rapid and weak, and this change has the same unfavorable significance as in concussion. If death occurs it results from paralysis of respiration and not of circulation.

Symptoms.—The symptoms, known as *pressure symptoms*, are divided into those occurring during the period of stimulation and those occurring during the period of increasing exhaustion. The symptoms of the first stage are headache, vomiting, flushing of the face, contraction of the pupils, choked

disc, mental excitement, elevation of blood-pressure, restlessness, and slowing of the pulse. The pulse becomes slow, regular, and strong. The symptoms of the second stage are heaviness, dulness, drowsiness, passing into stupor, and finally into coma. The respirations are stertorous and after a time become Cheyne-Stokes. The pulse is weak, intermittent, compressible, and increasingly rapid. There are involuntary evacuations of feces and urine, and finally paralysis of respiration which causes death, the heart beating for a time after respiration has ceased (von Bergmann's "System of Practical Surgery").

The *headache* usually present in the first stage of compression is intense, persistent, sometimes general and sometimes more or less localized, and often aggravated by percussion of the cranium. It persists even in delirium, and the patient ceases to appreciate it only when unconsciousness begins. The *vomiting* is usually without nausea and is due to stimulation of the medullary center. At first vomiting may arise from taking food, but it soon continues independent of food. The tongue is probably clean. Cerebral vomiting is usually associated with severe headache. *Restlessness* is a pressure symptom in the stage of stimulation, and the patient rolls his head, tosses his body, and groans with pain. The *heart* does not begin to slow until the patient begins to be dull and drowsy, or until stupor arises, when the pulse slows and the tension rises. Finally it becomes very slow—perhaps less than 40 in a minute. If the condition grows worse, the pulse after a time suddenly becomes rapid and of low tension instead of slow and of high tension, a most unfavorable sign, indicating exhaustion and approaching paralysis of the vagus. In the stage of stimulation the patient is excited, unstable, irritable, and the condition of delirium gradually gives way to drowsiness, stupor and coma. In some cases of compression there is distinct protrusion of the eyeballs. Before the patient is unconscious the pupils are contracted. When the patient is comatose, they are usually dilated, but may be contracted and respond slowly to light or not at all. If the conjunctival reflex is gone, they will not respond at all (Gowers). In a lesion making unilateral compression toward the base, the pupil on the side of the compressing cause is apt to be much dilated and even immobile. *Choked disc* begins in the stage of stimulation and continues to the end. That choked disc is due to intracranial pressure seems demonstrated by numerous operation reports, especially by Cushing, of Johns Hopkins Hospital, in which relief of pressure obviates choked disc (see page 828). The existence of choked disc is determined by the use of the ophthalmoscope. The respirations become stertorous or stertorous as coma develops because of the vibrations of the relaxed palate in the air current, and the cheeks flap during expiration. As the activity of the respiratory center fails from increasing anemia, the respirations become slow and infrequent, or, perhaps, of the Cheyne Stokes type. Gowers calls Cheyne Stokes breathing as "alternating periods of decreasing and increasing depth of breathing, separated by a pause" (Lectures on Diseases of the Brain). The *unconsciousness* of compression may be sudden or gradual, may be partial or complete. Apoplexy and many traumatisms cause immediate unconsciousness. A meningeal hemorrhage causes a gradually increasing unconsciousness. A brain tumor may cause heaviness, dulness, stupor, or,

perhaps, after a long time, even coma. If compression comes on gradually, the brain more or less accommodates itself, and unconsciousness, if it occurs at all, is considerably deferred. A sudden increase of pressure may produce immediate unconsciousness. *Stupor* is partial unconsciousness, a condition in which a person lies as though asleep, though he rouses partially and temporarily when positively spoken to. In profound coma the limb reflexes are diminished or lost, the muscles are flaccid, and swallowing is impossible. In coma there is incontinence of feces and either incontinence or retention of urine. There may be the incontinence or retention. The *temperature* of a patient suffering from compression varies. In traumatic cases it may be at first subnormal and later normal or elevated. In inflammatory conditions it is elevated, except in abscess of the brain, in which it is subnormal in half the cases. After an apoplexy it is for a time subnormal, but as shock passes away it becomes somewhat elevated. Any sudden compression causes shock and temporarily subnormal temperature. Lesions of the pons and medulla cause elevation—perhaps remarkable elevation of temperature. In great or sudden brain compression complete coma always exists without voluntary movement. In cerebral compression *paralysis* may exist, which may be very limited (monoplegia), may be of one side (hemiplegia), or may be general. In hemorrhage into the interior of the brain the unconsciousness is immediate or nearly so. In bleeding from the middle meningeal artery a period of consciousness intervenes between the injury and the coma, in which period blood collects and the coma comes on gradually. In compression from depressed fracture or from a foreign

FIG. 450.—Fracture of skull with depressed fragments. Compression of brain by bone (Scudder).

body the symptoms usually come on at once, but they may be deferred for some hours. Compression from inflammation or pus begins gradually after a considerable time has elapsed. The symptoms described as pressure symptoms are those of pure compression. When traumatism causes the condition, the compression symptoms are mingled with those of concussion, or perhaps of contusion or hemorrhage. The brain adjacent to any lesion causing compression suffers more than the brain distant from it. The blood supply of the entire brain is affected, but the adjacent brain has its capillaries particularly and directly compressed. Hence the paralysis sometimes produced by certain lesions. The course of compression depends on the nature and persistence of the cause. Great temporary pressure may produce no permanent harm. Moderately severe pressure may be recovered from, even after weeks of stupor. Great pressure, sufficient to induce coma, if not relieved quickly, will cause death. Persistent cerebral symptoms after a head injury, when no obvious lesion can be made out, are probably due to edema of the brain.

Determination of the Cause of Coma in a Patient.—A diagnosis must be made between coma due to brain injury and the comatose condition

of apoplexy, uremia, epilepsy, hysteria, diabetes, opium-poisoning, and alcoholic intoxication. In hospital practice cases of unconsciousness without a known history are frequent. In attempting to diagnosticate, examine carefully for any evidence of traumatism, and inquire as to how and where the patient was found, if any fit occurred, and if a bottle or a pill-box was found near by or in the pockets. The surgeon should himself examine the pockets. Smell the breath to notice alcohol or opium, but always remember that a victim of Bright's disease is liable to apoplexy, that a man may be stricken with apoplexy while he is drunk, and may fracture his skull by falling when under the influence of opium or of alcohol. The odor of acetone (violets) on the breath or in the urine indicates the existence of diabetes. Draw the urine with the catheter if any water is in the bladder. Examine the urine for albumin, acetone, and sugar, and take the specific gravity. In doubtful cases of coma have an ophthalmologist use the ophthalmoscope. He might find optic atrophy indicative of Bright's disease or choked disc indicating compression. The cerebrospinal fluid obtained by lumbar puncture will contain blood if

hemorrhage has taken place beneath the cerebral dura or in a ventricle of the brain. This test is valuable in fracture of the base of the skull, for in this condition cerebrospinal fluid is usually bloody. In *post-epileptic*

Fig 451.—Frontal section of skull. Middle meningeal hemorrhage. The dura bulges outward toward the skull cavity (diagram) (Scudder).

Fig 452.—A case of rupture of middle meningeal artery. Preparation of dura. In the Warren Museum. The specimen is viewed from the outer side (Scudder).

coma the temperature is never below normal, there are no unilateral symptoms, the condition resembles sleep, and the patient can be aroused. *Hysterical coma* occurs in boys and women, there are no objective symptoms, and the patient, though swallowing what is put into his mouth, cannot be roused. In *uremia*, besides the condition of the urine (and always remember that a person with albuminuria is apt to develop apoplexy), there is a persistent subnormal temperature, and convulsions are prone to occur. There is perhaps edema of the legs, and paralysis and stertor are absent. In *apoplexy* hemiplegia exists, and the initial temperature is for a short time subnormal. A single convulsion may have ushered in the case. *Alcoholic unconsciousness* is often diagnosticated when apoplexy really exists. A man will smell of alcohol who has had one drink, but one drink will not produce coma; hence the smell of

alcohol is not conclusive. In any case of doubt some hours of watching will clear up the diagnosis. Regard a doubtful case as serious until the truth is clear. In *opium poisoning* the pupils are contracted to a pin-point, the respirations are usually slow, shallow, and quiet, and may be stertorous, but there is no paralysis. Always remember that hemorrhage into the pons will produce pin point pupils, but it also causes paralysis (crossed paralysis if in the lower half of the pons) and high temperature with sweating. In *opium poisoning* the temperature is subnormal. In *diabetic coma* the pupils will react to a very bright light, the temperature is subnormal, and the breath and the urine smell of acetone.

Treatment of Brain Compression.—The treatment of brain-compression depends on the cause. Hemorrhage (extradural or subdural) requires trephining and arrest of bleeding; coma from depressed fracture demands trephining and elevation; foreign bodies must be removed; abscesses must be evacuated; some tumors are to be removed. In many tumor cases the growth is not removed, but a decompression operation is performed (page 840). In cerebral compression, if death is threatened by respiratory failure, make artificial respiration and at once trephine over the supposed region of compression. Horsley has shown that irrigation of the head with hot water is of great value in bringing about reaction from shock in cases of brain injury.

Intracranial hemorrhage may be either *spontaneous* or *traumatic*. In the vast majority of instances spontaneous hemorrhage comes from the lenticulostriate artery (Charcot's artery of cerebral hemorrhage), and produces apoplexy, a disease belonging to the physician, except in some intractable cases, for which ligation of the common carotid on the same side as the rupture may be indicated. In adults traumatism is almost always the cause of a meningeal hemorrhage. The blood may flow from a sinus, from the middle meningeal artery or one of its branches, or from vessels of the pia. Traumatism during delivery is an occasional cause of hemorrhage from the middle meningeal artery (Richardière) and a not unusual cause of hemorrhage from cortical veins. Violent paroxysms of coughing in whooping cough occasionally produce extradural hemorrhage or subdural hemorrhage. Geo. S. Brown reports such a case. He diagnosticated the condition and operated successfully ("New York Med. Jour.," April 25, 1903).

Traumatic Meningeal Hemorrhage. Hemorrhage may take place—(1) between the bone and the dura (*extradural*); (2) between the dura and the brain (*subdural*); and (3) in the brain substance (*cerebral*).

1. **Extradural hemorrhage** arises usually from the middle meningeal artery or from one of its branches. A spicule of bone may penetrate a venous sinus and produce extradural hemorrhage, or a sinus may rupture. Rupture of the meningeal artery or one of its branches is usually, but not always, accompanied by fracture (Fig. 453). In fact, in some cases not even a bruise can be found (Fig. 452). The ruptured vessel may be upon the opposite side to that on which the force was applied, hence the evidence of scalp injury is not a certain sign of the side of the skull involved. The accident may or may not cause temporary unconsciousness; but even if it does, from the unconsciousness the patient almost always reacts, and there is a *distinct period*

of consciousness between the accident and the lasting coma, the coma being due to pressure from a continually increasing mass of extravasated blood (Fig. 451).

If the main trunk or a large branch is ruptured, the period of consciousness is short; if a small branch is ruptured, the period of consciousness is prolonged for hours or perhaps for days. As the clot forms and enlarges the patient becomes heavy, dull, stupid, and sleepy; he sleeps so soundly he can scarcely be aroused, and snores loudly, and finally passes into stupor and then into coma. The other signs of this condition are paralysis of the side opposite the blood-clot (not necessarily of the side opposite the point of application of the force, for the artery may rupture from contre-coup on the uninjured side); this paralysis is apt at first to be localized, but it gradually and progressively widens its domain. If the clot extends toward the base, the pupil on the same side as the clot ceases to react to light, becomes immobile and dilates widely, and, if the clot be on the left side, aphasia may be noted. As the clot enlarges adjacent centers become involved. The face becomes paralyzed, then the arm, and finally the leg. Not unusually epileptiform attacks occur, starting in discharges from the centers which are irritated by the advancing clot before their function is abolished by pressure.

The pulse becomes full, strong, usually slow, but occasionally frequent, the breathing becomes stertorous; the temperature rises, that of the paralyzed side exceeding that of the sound side. In a compound fracture the pressure of escaping blood may force brain matter out of the wound. In extradural hemorrhage from a sinus the symptoms cannot be differentiated from those produced by arterial rupture.

Treatment—In treating extradural hemorrhage localize the clot, not by the seat of the wound or contusion, but entirely by the symptoms. In a doubtful case endeavor to bring about reaction; but if the state of shock deepens or does not improve and if pressure-symptoms increase, operate at once. To reach the middle meningeal artery or its anterior branch trephine one and one-fourth inches back of the external angular process, at the level of the upper border of the orbit (Figs. 441 and 449). If this incision does not expose the clot, trephine again at the level of the upper border of the orbit and just below the parietal eminence (Fig. 449). The first incision gives access to the main trunk and to the anterior branch; the second incision exposes the posterior branch. If signs indicate that the clot is traveling to the base, the trephine should be used half an inch lower than the point first directed. Arrest bleeding by a suture ligature or by packing (page 453), and always open the dura and inspect the brain. By this procedure a subdural hemorrhage may be discovered which, without it, would have been missed. Drainage must be employed.

Subdural hemorrhage is usually due to depressed fracture and rupture of the middle cerebral artery or of a number of small vessels. The symptoms are identical with those of extradural bleeding, but are usually very rapid in

Fig. 453.—Fracture of skull with middle meningeal hemorrhage. Compression of brain by blood (Scudder).

onset and are accompanied by a more distinct drop in temperature, graver depression. The cerebrospinal fluid obtained by lumbar puncture is bloody.

The *treatment* is trephining at the first point named in the previous paragraph, enlarging the opening upward and backward with a rongeur, opening the dura, turning out the clot, ligating the bleeding point or packing, elevating the depression of bone, draining, and stitching the dura with catgut. Hemorrhage from internal pachymeningitis requires the same treatment.

3. **Cerebral Hemorrhage.**—The symptoms of cerebral hemorrhage are identical with those of apoplexy. The *treatment* is the same as that for apoplexy, except in intractable cases, when the common carotid on the same side as the clot may be ligated.

Rupture of a sinus may arise without a bone injury, but is usually associated with a compound fracture. A sinus may be wounded during a brain operation. The *treatment*, if the rupture happens from fracture, is trephining, enlarging the bone opening by the rongeur, pack with one large piece of iodo-

Fig. 454.—Section of outer and inner tables, with two parallel lines (after Agnew).

Fig. 455.—Tearing or tearing of the table that is on the outer after the application of the trephine (after Agnew).

gauze, or catch the rent with hemostatic forceps, leaving them in place three or four days, or apply a lateral ligature or a suture ligature. If the depressed bone is not depressed, it may be left in place. If during an operation a sinus should be wounded, control hemorrhage by a suture ligature, or control hemorrhage by packing.

Intracranial Hemorrhage in the Newborn.—Certain most common cases of birth palsy seen in children are the result of subdural and subarachnoid hemorrhage at birth and damage of the cortical motor area. In these conditions there is spastic paralysis of the hemiparesis type, or of both sides. In some cases there is plastic diplegia and usually mental retardation. ("Am. Jour. Med. Sciences," Oct., 1905.) It has not been the custom to operate for hemorrhage in the newborn, most of the cases do not die, but remain for life weakened and paralyzed, or epileptic or idiotic.

The hemorrhage, in cases of birth palsy, is, as Cushing remarks, "venous and due to 'rupture of some of the delicate and deeply situated venous radicles of the cerebral cortex'" ("Am. Jour. Med. Sciences," Oct., 1905). It may result from traumatism due to bone overlapping or laceration during parturition, or may arise during asphyxia after birth. Cushing, in covering in examining still-born infants and infants that died soon after birth, found that many of them died with cortical hemorrhage. In some the extravasations were very large—in fact, completely covering a cerebral hemisphere. In some they were much smaller. In one the life was lost in the delivery.

The vessels usually torn are on one side and are the cortical or subcortical radicles which enter the longitudinal sinus near the superior sagittal sinus.

Fractures of the Skull

is the cortical area most apt to be gravely damaged. If the vessels of both sides are torn, a bilateral cortical lesion results.

Symptoms of Hemorrhage.—In Cushing's masterly paper ("Am. Jour. Med. Sciences," Oct., 1905) the symptoms of recent hemorrhage are set forth. There is the history of a long and difficult labor, forceps perhaps having been used, or a history of postpartum asphyxiation. The fontanelle bulges and perhaps does not pulsate. The fluid obtained by lumbar puncture contains blood-corpuscles. There is usually twitching and, as a rule, convulsions occur. They may occur soon after birth or not for several days. When they occur soon, they may be general; when they occur later, they may be unilateral. Paralysis is rare in the early days after birth. There may be alterations in the circulation and respiration. Pupillary alteration and ocular palsy seldom occur. If the child is not operated upon it may die or it may apparently recover. If it apparently recovers after a considerable hemorrhage, several months may pass before ominous symptoms are recognized. The late manifestations of the disease may be "spastic pabies, or blindness, or deafness, or feeble-mindedness, or, in severe cases, even complete amentia" (Cushing). Epilepsy may be a result.

Treatment.—Osteoplastic craniotomy in the parietal region, on one side or both, according to the unilateral or bilateral nature of the hemorrhage, opening of the dura; washing out and turning out the clot; suturing the dura and closing the scalp without drainage. Cushing reports 4 cases, in one of which operation was done on both sides. He says chloroform should be given and that the parietal bone can be cut with blunt, curved scissors.

Fractures of the skull may be *simple, compound, depressed, non-depressed, or punctured*. A fracture of the skull may be produced by a *bending force*, by a *bursting force*, or by an *explosive force* (see Gun-shot-wounds).

A bending force is usually applied by the forcible impact of a body of small area. It produces a fracture and seldom causes distant injuries. The fracture may be of the inner table only, or of both tables. If both tables are fractured the broken bone is displaced and remains so.

In fracture by bursting, lines of fracture run to distant points from the seat of application of the force. Such an injury is inflicted by the impact of a flat surface of considerable area. In some cases we have a force which first is bending in character, but causes bursting to also occur, because there is no rebound.

Falls of large heavy objects or falls on the head, blows from large flat objects on the head, crushes in railroad accidents, etc., may burst the skull. In bursting fracture there is often widespread injury.

Fractures are divided into fractures of the *vault*, usually due to direct force, and fractures of the *base*, due to extension of fractures of the vault, to indirect violence (a fall upon the feet, the buttocks, or the vault), to forcing of the condyles of the lower jaw against or through the base, or to foreign bodies breaking through the orbit, vault of the pharynx, the ear, or the roof of the nostrils. *Fracture by contre-coup*, which occurs on the side opposite the point of application of the violence, is very rare. Fractures of the skull are uncommon in early youth, but they are much more frequent in the aged. Usually the entire thickness of the bone is fractured, but either the outer or the inner table (Fig. 456) may be broken alone. In complete fractures the inner table is broken more extensively than is the outer table, because the

inner table is the more brittle, because the force diffuses, and also, as Agnew taught, because the inner table is part of a smaller curve than is the outer table, and violence forces bone-elements together at the outer table, but tears them asunder at the inner table (Figs. 454, 455).

Fractures of the Vault.—A fracture of the vault of the skull may be simple and undepressed, or it may be depressed (Figs. 450 and 456), compound, or comminuted. A mere crack may exist in a bone, and if a rent

Fig. 456.—Fracture of the vault with extensive depression of the inner table ("American Text-book of Surgery").

exists in the soft parts, a bit of dirt or a hair may be caught in the crack. Fractures of the vault arise from direct force. A fissure may escape recognition, although in some cases percussion gives a "cracked pot" sound. Any considerable depression can be detected. In a simple fracture occasionally the cerebrospinal fluid collects under the scalp and forms a tumor which pulsates and becomes tense on forcible expiration (spurious meningocele, page 795). Compound

fracture can be readily recognized, but do not mistake a suture, a Wormian bone, or a tear in the pericranium for a fracture. A fissured fracture is marked by a dark line of blood which *sponging will not remove*. Fracture of the inner table alone can only be suspected. The prognosis of fracture of the vault depends upon the extent of brain injury rather than upon the extent of bone injury. Simple fractures unite by bone; compound fractures with loss of bone unite only by fibrous tissue. The dangers may be *immediate* (hemorrhage, brain injury, and septic inflammation) or be *distant* (epilepsy, insanity and persistent headache).

Treatment.—The mortality of fracture of the skull was formerly much greater than at present. Before the days of antiseptics it was 51 per cent. (Harte). Trephining is performed much oftener than was once the custom, and is vastly safer. Out of 26 trephined cases, 3 died (Harte). In any case of fracture of the skull endeavor to bring about reaction before operating, unless the signs of pressure continually increase or the evidences of shock remain unimproved or become graver. A *simple fracture without depression and without brain symptoms* is treated expectantly (by rest, quiet, low diet, purgation, moderate elevation of and cold to the head, and arterial sedatives). A *simple fracture with moderate depression and without cerebral symptoms* is treated expectantly, and so also is a *simple fracture in which symptoms existed but are abating*. *Simple fracture with marked depression* requires immediate trephining, even when brain symptoms are absent. Some surgeons make an exception in young children, and wait a while before trephining, in the expectation that the expansile brain will lift the depressed but elastic

bone up to the level. Trephining in cases where no symptoms exist, although there is marked depression, often prevents disastrous consequences arising in the future, and is known as "*preventive trephining*" (Agnew, Keen,

Fig. 457.—Extensive fracture of the base of the skull ("American Text-book of Surgery").

Horsley, Macewen, von Bergmann, and others). In all *compound fractures* shave and asepticize the entire scalp, enlarge the incision, and explore the bone. If a fissure exists, it must be asepticized, and if a hair or other foreign body is found in it, in order to effect removal and secure asepsis the outer table of the skull must be cut away with a chisel, the fissure being thus converted into a broad groove. In a *compound fracture with much depression* trephine, elevate, and irrigate. In any fracture trephine if distinct symptoms exist. In punctured wounds of the brain (*punctured fractures*) always trephine, open the dura, and disinfect (Keen). In any case of fracture of the vault where trephining has been performed it is wise to open the dura and examine the brain.

Fractures of the Base.—A fracture of the base of the skull may exist in only one of the three fossae, in two of them, or it may involve all. Fig. 457 shows an extensive fracture of the base of the skull. The middle fossa is oftenest involved. Fracture of the posterior fossa is the most fatal. These fractures may be due to direct violence, to indirect force, and to extension of a fracture of the vault. Extension from the vault is always by the shortest route. Fracture by direct violence may arise from the penetration of the nasal roof, the orbital roof, or the pharyngeal roof by a foreign body. The posterior fossa may suffer from a fracture by direct violence applied to the neck. Fractures by indirect force may arise from blows upon the frontal bone (the orbital portion of the frontal or the cribriform process of the ethmoid breaking), from falls upon the chin (the condyle of the jaw breaking the

middle fossa), or from falls upon the buttocks, the knees, or the feet (fracture occurring in the posterior fossa). The base is very rarely broken by contre-coup (Treves).

Symptoms.—Fractures of the base of the skull are apt to be compound. A solution of continuity in the pharynx, roof of the nares, orbit, or ear permits access of air to the seat of fracture and allows blood and cerebrospinal fluid to flow externally. In *fracture of the anterior fossa* the fracture may be compound, because of laceration of the mucous membrane of the nares or of the conjunctiva. Blood may run from the nose, its source being the vessels of the mucous membrane or the dura, the fracture being compound. Epistaxis does not prove the fracture to be compound, but only suggests it; but if the epistaxis is prolonged, the probability is greatly increased; and if the flow of blood is succeeded by a flow of cerebrospinal fluid, the diagnosis of compound fracture is positive. Cerebrospinal fluid appears only when the mucous membrane, the dura, and the arachnoid are each lacerated (Treves). In *fracture of the anterior fossa* blood is apt to flow into the orbit, producing *subconjunctival reehymosis*, and some blood is often swallowed and vomited. In *fractures of the middle fossa* blood may flow from the ear through a tear in the tympanum, its source being the vessels of the tympanum, the meningeal vessels, or a sinus. Blood may flow through the Eustachian tube and come from the nose, may be spit up, or may be swallowed and vomited. In some cases a quantity of cerebrospinal fluid flows from the ear, the discharge being increased by expiratory effort and a position which favors gravity. The cerebrospinal fluid must not be confused with either blood-serum or liquor Cotunnii. The cerebrospinal fluid is always present in large amount; the liquor Cotunnii can be present only in minute amount. Blood serum is highly albuminous; cerebrospinal fluid is a serous fluid of very low specific gravity, never shows more than a trace of albumin, and contains considerable chlorid of sodium and in some instances sugar, which, when present, reacts to Trommer's and to Moore's tests, but does not refract polarized light nor ferment with yeast (Keeley, from Collins). Treves states* that cerebrospinal fluid cannot flow from the ear in fractures of the middle fossa—(1) unless the line of fracture crosses the internal meatus, (2) unless the prolongation of the membranes into the meatus is torn; (3) unless a communication exists between the internal ear and tympanum; and (4) unless the drum-membrane is torn. Miles, of Edinburgh,† claims that bleeding from the ear followed by a flow of cerebrospinal fluid is not pathognomonic of fracture of the middle fossa of the base. He maintains that when the drum is ruptured, we may have these signs; when bone is not broken, the chief source of the blood being the vessels of the pia and temporo-sphenoidal lobe, the blood and cerebrospinal fluid flowing inside the sheath of the auditory nerve, passing into the vestibule through the lamina cribrosa, and from the vestibule into the middle ear finding exits from this space by way of the Eustachian tube and also through the rent in the drum membrane. Profuse serous discharge may flow from the ear after an injury without fracture when the drum is ruptured, the fluid coming from the cells of the mastoid. It must be understood that fracture of the base may exist when there is no flow of blood or of serous fluid. A fracture of the middle fossa is usually compound, made so, even when the

* "Applied Anatomy."

† Edinburgh Med. Jour., Nov., 1895.

drum is not ruptured, by the Eustachian tube, and there is often paralysis of the seventh or eighth nerve or of both of them. In *fracture of the posterior fossa* there is usually respiratory derangement and blood accumulates beneath the deep fascia and produces discoloration in the line of the posterior auricular artery (*Bottle's sign*), the discoloration first appearing near the tip of the mastoid. The discoloration appears in the line of nerves and vessels which emerge from the deep fascia, the vessels passing through openings and the extravasated blood emerging from the same openings. Fractures of the posterior fossa are apt to be compound through the pharynx, and in such cases the patient spits or vomits blood. Fractures of the posterior fossa are more fatal than fractures in either of the other fossae because of the adjacency of vital centers. Fractures of the base are apt to be associated with *paralysis of cranial nerves*. Optic neuritis often arises after the first week. In fractures of the base the temperature is subnormal during the shock, rises to 100° to 101° , falls again to about normal, and remains normal or subnormal unless there be inflammation or sepsis. Lumbar puncture may obtain bloody fluid. Such a finding means subarachnoid bleeding and indicates fracture. Harte ("Annals of Surgery," Oct., 1901) has collected 46 positive cases of fracture of the base of the skull from the records of the Pennsylvania Hospital; 35.5 per cent recovered.

Treatment.—In fracture of the base I now always do a subtemporal decompression usually on both sides as Cushing advocates. This is, first of all, exploratory and may disclose a bleeding meningeal artery. After the dura is opened it enables us to evacuate fluid causing pressure and in which bacteria could multiply, and to prevent recurrence of pressure after the wound has been closed. If there is bleeding under the dura the brain should be lifted to let the blood out, and a drain of rubber tissue should be inserted. If there is only brain edema no drain is required.

In addition to performing decompression I always give urotropin, as advised by surgeons in Johns Hopkins. (S. J. Crowe, in "The Johns Hopkins Hospital Bulletin," April, 1909). This drug renders the cerebrospinal fluid bactericidal. Other methods of treatment are secondary to the above. My experience is that this plan saves many cases which would otherwise perish. Until lately the methods were as follows. In treating a compound fracture of the base of the skull collect any serous discharge and analyze it, and disinfect any cavity involved. In fractures of the middle fossa with ruptured drum clean the ear mechanically, wash it out with a stream of warm corrosive sublimate solution of a strength of 1:2000 (turn the head toward the affected side while washing, so that the mercurial solution will not run down the Eustachian tube), wash with normal salt solution, insufflate iodoform, insert a piece of iodoform gauze, and apply an antiseptic dressing. Several times daily the ear is to be irrigated, and insufflated with iodoform. The nasopharynx must be frequently irrigated with normal salt solution or boric-acid solution, and insufflated with iodoform. The conjunctival sac is frequently irrigated with boric-acid solution. If after a head injury blood accumulates back of the drum, this membrane should be incised to permit of drainage and disinfection. In fractures of both the middle and anterior fossae and in fractures of the posterior fossa communicating with the pharynx the nasopharynx must always be cleaned. The exact method depends on the choice of the surgeon. We may wash out

these cavities frequently with hot water, next with peroxid of hydrogen, and finally with boric-acid solution, or can simply use normal salt solution. After washing, insufflate the nasopharynx with iodoform. Repeat the cleansing at regular intervals and also cleanse the conjunctival sac frequently. In some cases drainage has been obtained from the anterior fossa by breaking through the cribriform plate and introducing a tube by way of the nostril (Allis), and from the middle fossa by trephining above and behind the external auditory meatus. In a compound fracture of the orbit disinfect and drain. It may be necessary to trephine the roof of the orbit to secure drainage. In fracture of the posterior fossa examine to see if the fracture is compound, into the

Fig. 458.—Extensively comminuted gunshot-fracture of the skull (after von Bergmann).

Fig. 459.—Gunshot fracture of internal table of the skull (after von Bergmann).

pharynx, and if it is, cleanse with great care the nasopharynx and mouth, as previously directed. In a very extensive fracture of the base, besides use of the methods set forth above, the entire head should be shaved and a plaster-of-Paris cap be applied. A patient with fracture of the base must be put into a quiet and darkened room and be kept upon a low diet, sleep being secured, and the bowels and bladder being attended to. If we are uncertain as to whether a fracture exists or not, keep the patient quiet and in a darkened room and on a low diet. Attend to the bladder, keep the bowels loose, examine the nasopharynx with mirrors and the ear-drum through a speculum, and make a lumbar puncture.

Wounds of the brain are produced by violence and by foreign bodies (knives, bullets, etc.). Except when

due to penetration of a fontanelle in a child or of a parietal foramen in adults, wounds of the brain are accompanied by fracture of the skull. These wounds are very dangerous; foreign bodies (bone, hair, clothing, etc.) are often lodged in the brain, hemorrhage is usually severe, and sepsis is almost inevitable without proper treatment. Such cases are very fatal, though some astonishing recoveries are on record. Figs. 458 and 459 show gunshot-fractures of the skull.

The symptoms of brain wounds may be slight and long-deferred or may be immediate and overwhelming; they depend upon the site and extent of the injury. Localizing symptoms may exist, and encephalitis with coma is apt to arise. Abscess not unusually follows.

In treating wounds of the brain always shave the entire scalp and examine the weapon, if possible, to see if a piece were broken off. Asepticize, enlarge the wound, trephine, arrest bleeding, elevate any depression, remove foreign bodies, irrigate the wound, drain with gauze, suture the dura, and dress.

Wounds in War.—When the bullet of a military rifle, fired at very close range, crosses the brain it may blow the skull into fragments, but often it does not, and produces fracture of the skull and wound of the brain. The "explosive effect" is far less marked on the head of a living man than on the head of a corpse and may even be absent when the range was only 100 yards. At moderate range, at the point of initial contact of the bullet with the skull a fracture is produced, the opening is slightly larger than the bullet, and short fissures commonly radiate from it. Fragments from the internal table are usually displaced and driven into the brain. The wound of exit is more irregular and is apt to exhibit more and longer fissures than the wound of entrance. When a bullet strikes a glancing blow it may fracture the outer table alone, it may produce a "gutter-fracture" (two scalp openings, and "a gutter ploughed" through both tables of a portion of the skull, as O'Reilly expresses it), very seldom a fracture of the inner table only, penetration of the skull, and lodgment of the bullet, and perforation of the skull, the bullet passing through the head and emerging. Nearly half the cases are instances of perforating wound.

In all of these injuries there is great shock, but concussion symptoms may be absent. The patient may die at once or almost at once, but if he is alive a few hours after the injury he has still to face the danger of infection and resulting inflammation. The danger depends on the brain injury and the amount of infection and not on the extent of the bone damage. The symptoms vary according to the part of the brain injured and the extent of the damage.

In practically all cases bone fragments are driven into the brain, and as the scalp is a dirty region, the wound is more or less infected.

The mortality from these injuries is very large. In the American Civil War it was 61.2 per cent. In the Franco-Prussian War it was 51.3 per cent. In the Boer War, among the British it was only 33.1 per cent., a very notable improvement. (See *Military Surgery*, by Surgeon General Robert N. O'Reilly, U. S. A., in "Keen's Surgery," vol. iv.) In the Russo-Japanese War the mortality seems to have been something over 37 per cent.

In estimating mortality those killed outright and those dying before reaching the hospital are not counted. Much brain matter may ooze out from such a wound. Cerebral hernia is common after these injuries, especially if much bone was destroyed by the injury or removed by the surgeon.

Treatment of Wounds in War.—At the first aid station antiseptic dressings are applied. On reaching the field hospital the wound is explored, if time, situation, and military necessities permit. Every wound of this sort is regarded as being complicated by infection and by depression or wide dispersion of bone fragments. The patient is reacted from shock and a flap of scalp is turned down to permit of exploration. Depressed fragments of bone are elevated or removed and loose pieces are removed. Treatment is the same as for wounds from revolver bullets (see below).

Wounds from Revolver Bullets.—The bullet may strike the skull and glance (if fired at an angle) with or without the production of a fracture. A small bullet (No. 22) may strike perpendicularly and fail to enter, sometimes causing a fracture and sometimes not doing so. Even a No. 22 may enter the skull, and I recently removed a bullet of this size which had entered and crossed the skull and lodged beneath the cortex on the opposite side of the brain. A bullet may cause a "gutter-fracture"—may enter the cranium and lodge—or may cause a complete perforation. A revolver bullet is much more apt to lodge than a military bullet.

The wound of entrance is small, the wound of exit is larger. At the wound of entrance the inner table is more extensively fractured than the outer table, at the wound of exit the outer table is more widely broken than the inner table. In these cases there is always great shock and concussion, and concussion symptoms exist even when the bullet has entered the brain. In moderate concussion the action of the heart is retarded, in severe concussion it is accelerated (page 797). A bullet may be lodged within the cranium when merely a fracture without a bullet hole can be detected. In these cases the bullet produced a fracture and entered the cranium, and then the depressed bone flew back into place (v. Bergmann). In such cases, if complete perforation occurs, the one existing opening is the opening of exit. A bullet may lodge in the bone, between the dura and the bone, between the dura and brain in the brain, between the dura and bone of the opposite side, or in the bone of the opposite side, in the nasal fossa, maxillary antrum, or orbit. Always examine the side of the head opposite to the wound of entrance to determine if there is any bulging or fracture. A bullet may pass across the brain and be deflected from the inner surface of the skull. Ruth does not believe the bullet can rebound from the opposite wall.* If certain regions are injured localizing symptoms may arise. Much brain matter may ooze out from the wound. Sometimes this causes great impairment of function, sometimes little or none. The secondary symptoms of gunshot-wounds of the head are varied and uncertain, and may not be observed at all before death. Fowler wisely points out that a patient with a gunshot wound of the head may have also received other injuries, and the other injuries may be in part, at least, responsible for cerebral symptoms.

Treatment of Wounds from Revolver Bullets.—Endeavor to bring about reaction (see Concussion). In severe cases apply heat to the head and make artificial respiration. It will sometimes be necessary to operate while artificial respiration is being made. In treating gunshot wounds of the head shave and asepticize the whole scalp, disinfect the entire track of the ball, and arrest hemorrhage at the wounds of entrance and exit, using the rongeur to expose the bleeding points if the bullet be large, employing the trephine if it be

* See the instructive article by Fowler, in *Annals of Surgery*, Nov., 1895.

small. If the bullet has emerged and has been picked up, examine it to see if it is entire. The bullet, if retained, is to be sought for. The x-rays are invaluable in locating the missile. Place the head in such a position that the track of the ball will be vertical, then introduce Fluhner's aluminum probe or Senn's probe, and let it find its way by gravity. The probe may find the ball near the wound of entrance, in which case extract the ball with forceps, or the probe may find the ball near the opposite side of the head, in which case make a counter-opening through the bone at a point the probe would touch if it were pushed entirely across. Take a new and *clean* rubber catheter (No. 9, French), insert a stylet, and carry the catheter through the wound (Keen). Knowing the depth of the ball, search for it around the catheter-tube as an axis, and when found, extract it. After extraction drain the wound by means of a tube. When a counter-opening exists, drain through and through. If the ball cannot be detected, drain by a tube carried to the depths of the wound. After dressing always place the head in a position favorable to drainage. Fluhner tells us that when a counter-opening fails to disclose the bullet, use the new opening as a doorway through which to search for the ball. He believes the bullet is not unusually deflected. The angle of deflection is somewhat greater than the angle of incidence, and the bullet is apt to fall a little toward the base. Splinters of bone are often driven into the brain by a bullet, and these should be removed whether the ball is found or not. Several varieties of probes have been commended. Fluhner uses a large-sized aluminum probe. Senn uses

Fig. 460.—Senn's bullet-probe.

an instrument shaped like the Nélaton probe, but of the same diameter as the bullet (Fig. 460). (Of course, the porcelain probe will not show a black mark from contact with a hard-jacketed bullet.) Fowler uses a graduated pressure probe; so long as the pressure is within the limits of the spring, as shown by the scale, the probe is in the bullet-track. Girdner's telephonic probe is a valuable aid to diagnosis. Bullets are now located by the Röntgen rays. There can be no doubt that many gunshot-wounds have been recovered from without operation, and it is beyond question that many deaths follow operation (about 33½ per cent., according to Hahn). Von Bergmann is so impressed with these facts that he does not operate when cerebral symptoms are absent.

Prolapse of the Brain and Hernia of the Brain.—In a compound fracture, especially a gunshot-fracture, with torn dura and pia, brain-matter may emerge from the wound. In fracture of the base brain-matter may enter the orbit, the nose, or the ear. A flow of brain-matter may continue from a wound for many hours. A week or more after an injury a portion of the brain may protrude or prolapse. To this condition the term *prolapse* should be applied. In many instances the protrusion is covered with pia, but if the pia were torn or cut, it will not be a covering. This protrusion emerges from the opening in the skull, mounts up, growing larger and larger, until it may

become the size of a fist. It usually pulsates. When bare it is soft, lobulated, of a dirty white color, pulsating, painless to the touch, often bleeding, and sometimes discharging cerebrospinal fluid. Death may soon follow such protrusion, but the protruding mass may become necrotic and be sloughed off, a granulating surface remaining, which heals.

Fig. 461.—Hernia cerebri under scalp after operation for brain tumor (W. W. Keen).

Hernia cerebri (Fig. 461) sometimes follows operations upon the brain or injuries of the skull and dura, when large pieces of bone have been removed or when the dura has been widely cut or torn and has not been carefully sutured. The condition is due to increased cerebral pressure. Hernia of the brain is protrusion through the dura but not through the scalp, the scalp wound being healed above the protrusion. In a decompression operation we deliberately create a hernia of the brain.

Prolapse of the brain is treated by antiseptic dressings and perhaps by craniotomy to relieve pressure. Skin-grafting benefits some cases. Pressure is dangerous. Excision by the knife or cautery seldom does any good. Hernia in some cases can be treated by repeated lumbar punctures, in some other by craniotomy of the opposite side of the skull.

Fungus Cerebri (Fig. 462). When the brain is exposed, a granuloma may grow from the meninges and fungate through the skull. This condition is fungus cerebri and is not composed of brain-matter. It is due to infection of the brain, and is most frequent when a bit of bone or some other foreign body is retained. A fungus is soft to the touch, is livid in hue, bleeds easily,

Fig. 462.—Fungus cerebri (W. W. Keen).

frequently contains multiple foci of suppuration, and pulsates. It often attains the size of a small orange. It is treated by removing the granulations and any foreign body, and applying, with moderate pressure, aseptic dressing soaked in alcohol. After healing, a depression marks the site of the fungus.

Traumatic inflammation of the brain and its membranes is divided into *encephalitis* or *cerebritis*, inflammation of the cerebrum; *cerebellitis*, inflammation of the cerebellum; *meningitis*, inflammation of the meninges; *arachnitis*, inflammation of the arachnoid; *pachymeningitis*, inflammation of the dura; and *leptomeningitis*, inflammation of the arachnoid and pia.

Pachymeningitis Externa.—Inflammation of the external layer of the dura is called *pachymeningitis externa*. It may arise from tumor, caries, necrosis, middle-ear disease, sunstroke, or traumatism. Syphilis is a not unusual cause. The other membranes may become involved. Suppuration may arise, having extended by contiguity from neighboring parts. The symptoms of *pachymeningitis externa* are uncertain. They resemble often those of *leptomeningitis* (page 818). Pressure-symptoms may arise. Headache is always present. Paralysis may or may not exist. If pus forms, the ordinary constitutional symptoms of suppuration are evident (high temperature and sweats), not the symptoms of abscess in the brain. In a severe case the other membranes become involved.

The treatment consists in removing the cause (carious bone, pus, middle-ear disease). In *pachymeningitis* from traumatism it is sometimes advisable to trephine in order to drain inflammatory products; in a case with localizing symptoms always trephine; in an ordinary case, without pus and with no evidences of traumatism, use wet cups back of the mastoid processes, apply an ice bag to the head, and purge by means of calomel. Administer iodid of potassium in most cases. If sunstroke is the cause, treat according to ordinary medical rules.

Pachymeningitis Interna.—This term means inflammation of the inner layer of the dura. Inflammation may extend from the pia, or from the outer layer of the dura. The disease is most often met with in infants and in the chronic insane, but may occur in those not insane in late middle age or beginning old age. The form known as *hematoma* of the dura mater, or *pachymeningitis interna hemorrhagica*, may arise during infectious disease (typhoid fever and rheumatism), in persons of the hemorrhagic diathesis, in diseases causing atrophy of the brain, in chronic diseases of the heart and kidneys, and in syphilitics. Among the exciting causes are traumatism, inflammation in adjacent parts, and, especially, the abuse of alcohol. In this disease blood is extravasated on the inner surface of the dura. Many observers do not class hemorrhagic *pachymeningitis* as inflammation, but regard the hemorrhage as primary.

The symptoms of internal *pachymeningitis* are very chronic, come on gradually, are not characteristic, and may be absent. They consist usually of mental irritability or excitement, followed perhaps by hebetude and persistent headache; and apoplecticiform attacks, with contraction of the pupil, slow pulse, and vomiting; there may also be muscular rigidity and spasm of the extremities. Choked disc is not infrequent; localizing symptoms may be made out, and coma is apt to arise. Cranial nerves are seldom affected.

The treatment is operation. This is unpromising, but Munro saved a case out of 5 ("Chicago Med. Recorder," Dec., 1902).

Acute leptomeningitis is a purulent inflammation of the soft membranes of the brain. The pathological changes can be noted in the pia and in

the brain-substance. The brain is edematous, the pia purulent, the convolutions are flattened, the ventricles are distended with fluid, and hemorrhages occur into the brain-substance. Pus may be localized upon the pia, but it is usually diffused over one hemisphere or over both. Various organisms may be found, especially streptococci, staphylococci, and diplococci. In some cases we find the bacillus pyocyaneus or the bacillus pyocyaneus fortidus, which is identical with the colon bacillus and with the bacillus meningitis purulenta (Park). Saprophytic organisms are occasionally present. This disease may be acute or chronic, and a severe case is spoken of as *encephalitis*. *Secondary leptomeningitis* is apt to affect the convexity, *primary leptomeningitis* is apt to affect the base.

The **causes** of leptomeningitis are epidemic cerebrospinal fever, tuberculosis, acute general disease (pneumonia, typhoid, erysipelas, and rheumatism), bone-diseases, traumatism, middle-ear disease, syphilis, and sun-stroke. The tissues of the pia and the cerebrospinal fluid contain diplococci identical with pneumococci. Infection may take place by various avenues. It may pass from the nose by way of the Eustachian tube to the ear, or from the nose to the frontal sinus or ethmoid sinuses (Hirt), and from these situations to the brain. It may pass from the middle ear or mastoid to the membranes of the brain. In fractures at the base the organisms enter by way of the pharynx and the Eustachian tube, or the ear. The **symptoms** of acute leptomeningitis are violent headache persisting during delirium, flushing of the face, rigidity of the neck, cerebral vomiting, a slow pulse, elevated temperature, photophobia, contraction of the pupils, intolerance of sound, hyperesthesia of the skin and muscles, and delirium passing into stupor and coma. A chill or a succession of chills may occur. Choked disc, strabismus, and nystagmus are not unusual. Convulsions or paralyses may occur. Death is the rule within one week. The **treatment** usually consists of the administration of urotropin (this drug rapidly enters the cerebrospinal fluid, see page 811); purgation with calomel; cold to the head; warm baths with cold affusions to the head; iodid of potassium, bromid of potassium, or morphin for vomiting and headache. Lumbar puncture is usually performed, but for diagnostic rather than therapeutic reasons. A patient in this condition should be trephined in order to relieve pressure and to give exit to inflammatory products. It gives some hope of recovery, and the usually adopted medical treatment is practically useless. After trephining, the administration of urotropin should be continued. Should the patient recover, he must be guarded for a long time from physical exertion, mental excitement, worry, irritation, constipation, and insomnia.

Chronic Leptomeningitis (or Chronic Encephalitis).—The causes of chronic leptomeningitis are the same as those of the acute form. If traumatism is the cause, the inflammation arises at a later period than it would in acute encephalitis. The **symptoms** of concussion follow a head-injury. Days, or even weeks, after the accident, a series of symptoms occur—namely, localized pain at the seat of injury, often accentuated by tapping; listlessness, irritability, apathy regarding business affairs and home obligations, or profound depression and hypochondria with inability to attend to business. Choked disc may exist. In any case acute encephalitis may arise, with or without a chill. The **treatment** of this disease is symptomatic unless local symptoms exist. Always operate if localizing symptoms are found. Intense local pain justifies trephining.

Tuberculous Meningitis (Acute Hydrocephalus; Water on the Brain).—This inflammatory condition is due to the bacilli of tuberculosis. In a child affected with tuberculous meningitis there is often a record of a fall, the injury acting as an exciting cause by establishing an area of least resistance. Prodromal symptoms are common (restlessness, irritability, anorexia, change of character). The disease begins with a convulsion or with headache, fever, and vomiting, the child cries out from pain (*the hydrocephalic cry*), and the bowels are constipated. The pulse is rapid in the beginning, but later becomes slow and irregular. The pupils are contracted, there is muscular twitching, and the sleep is impaired. The temperature is about 103° . In the second period of the disease the vomiting ceases, constipation becomes more marked, the belly retracts, headache is not so violent, and the patient lies in a soporose condition interspersed with episodes of delirium. In this stage the pupils dilate and are often unequal, the head is retracted, convulsions occur or limited rigidity is noted, the respirations are sighing, and if a finger nail is drawn along the skin, a red line develops (*the ligne cerebrale*, due to vasomotor paresis). Squint and consequent double vision are usual. In the last stage coma becomes absolute and general convulsions or limited spasms are apt to occur. Optic neuritis exists, and the child passes to death along a road identical with that of typhoid collapse. In some cases the examination of cerebrospinal fluid withdrawn by lumbar puncture throws light upon the diagnosis. In children the base of the brain is usually involved, and the disease is apt to last from two to four weeks; in adults the convexity is usually involved, and death is apt to occur in a few days.

The **treatment** is like that for traumatic meningitis. Operation seldom offers any chance of improvement, and never does unless the process is limited in area and confined to the convexity. Lumbar puncture is usually performed but for diagnostic rather than for therapeutic reasons.

Abscess of the brain is a localized collection of pus. The organisms found are noted upon page 818 (Acute Leptomeningitis). The **causes** are suppurative otitis media (in half of all the cases), fracture of the skull, osteomyelitis of the cranial bones, abscess of the lung, gangrene of the lung, empyema, and concussion or wound of the brain, and general diseases. As Ballance points out, abscess of the brain complicating head injury is not really an abscess of the brain unless the wounding material entered into the brain substance. In most cases the abscess is "a local meningeal suppuration with participation of the adjacent brain cortex, a meningocortical abscess rather than a brain abscess proper" ("Some Points in the Surgery of the Brain," by Chas. A. Ballance). General infections may cause abscess (pyemia, tuberculosis, and specific fevers). A tuberculous mass may caseate (tuberculous abscess). The abscess may be between the dura and skull (extradural), adhesions forming and preventing a general leptomeningitis, between the dura and brain (subdural), or in the brain substance (cerebral or cerebellar). Leptomeningitis may arise because no adhesions are created, because septic clots form in veins or sinuses, or because infected blood regurgitates into the sinuses (Park). A traumatic abscess is generally beneath the area to which the traumatism was applied, but it may be on the opposite side. Source of infection may be the nose, the orbit, or the middle ear (page 820). Roswell Park says infection may pass along blood-vessels, lymph-vessels, nerve-sheaths, or the prolonga-

tions of the membranes which extend outside of the skull. An acute inflammation of the middle ear rarely causes abscess, because an acute inflammation in sound tissue causes the formation of granulation tissue, which acts as a barrier to infection. Chronic inflammation of the middle ear is the most frequent cause of abscess. Park tells us that if the roof of the tympanum is involved, it may perforate and abscess of the middle fossa may form, if the tympanum is perforated toward the mastoid antrum, the abscess arises in the temporo-sphenoidal lobe, if the perforation is toward the sigmoid groove, the abscess forms in the cerebellum.*

Chronic bone disease is seldom followed by spreading meningitis, often by abscess. When infection reaches the brain by direct extension from a suppurating bone it must pass through the membranes, but it is usually limited by adhesions. The cortex is very vascular, and strongly resists infection and is seldom extensively destroyed, but the white matter is far less resistant and abscess tends to form in it (Ballance, *Ibid.*). In some cases of abscess of the temporal lobe following ear disease the cortex seems normal, in others the membranes and cortex are fused over a narrow area which constitutes the stalk of an abscess in the white substance of the lobe. This is the "mushroom abscess" of Ballance. An abscess may increase rapidly in size and finally break into a ventricle or through the cortex. It may become encapsuled and latent. A slow growing abscess may push aside nerve fibers as does an encapsulated tumor, but a rapidly growing abscess destroys them.

In the cerebrum multiple abscesses, except in cases of general infection are seldom seen. In the cerebellum they are not uncommon. One or several abscesses may arise from a primary one. If they are adjacent to the primary one they are called satellite abscesses and tend to break into the older parent area.

Ballance, in considering the onset of abscess, adopts the views as to the five types set forth by Brissaud and Souques. These types are as follows ("Some Points on the Surgery of the Brain," by Chas. H. Ballance).

(1) A subacute evolution. In this there is a febrile onset, like the onset of a specific fever, with headache, vomiting, and elevated temperature. After a few days there comes a remission, the period of delusive calm. In this period symptoms are absent or trivial. Though there may be progressive emaciation, there is no elevation of temperature in this period.

Suddenly convulsions occur which are followed by coma, or coma arises without antecedent convulsions. The patient may die in coma or the coma may pass away, "the symptoms indicating a local brain lesion" (Ballance, *Ibid.*). In this stage elevated temperature may appear again.

(2) Evolution with violent general infection, the symptoms of abscess being merged and usually lost in the symptoms of general infection.

(3) Evolution with complete latency. The patient presents no symptoms until a few hours before death or he may die suddenly without a symptom having been observed. In this connection Ballance speaks of the difference between "symptoms not noticed and symptoms not present" (*Ibid.*).

(4) Only when symptoms were not present does he use the term "complete latency" to indicate the condition. Karschhoff has reported the case of a boy in whom an abscess in the frontal lobe was latent for three years and another case in a man due to gunshot injury, which was latent for four and a half

* Park, in Chicago Med. Record, Feb. 1895.

years and in which nearly ten years elapsed between the injury and death ("Annals of Surgery," July, 1909).

5) Onset not to be distinguished from a brain tumor.

6) Onset with headache and fever, or with mental excitement. Then the patient appears to get completely well and remains so for weeks, for months, or for a year, or more. This condition may occur in abscess secondary to influenza (Ibid.).

Symptoms of Abscess of the Cerebral Substance or of the Cerebellum.—The symptoms due to pus-formation are as follows: There is an initial rise of temperature, but (except in extradural abscess) the temperature may quickly become normal or even subnormal. Subnormal temperature is not nearly so common as is usually supposed. It has been present in about one-half of the cases I have seen. Toward the end of the case the temperature may rise and the fever becomes linked with delirium. Surface elevation of temperature over the seat of the abscess is occasionally observed. A chill may occur, but seldom does. Anorexia and vomiting are present. Urinary chlorids are diminished and the phosphates are increased (Somerville). Certain symptoms are due to pressure: Headache begins (which at first is general, then local, and grows worse later in the case, and exists even in delirium, this fact distinguishes it from the headache of fever, which ceases in delirium); pulse is very slow; respiration tends to the Cheyne-Stokes type, drowsiness lapses into stupor and stupor passes into coma; paralysis of the sphincters takes place; convulsions are common; sensation is rarely impaired; and paralysis of the basal nerves may occur (third and sixth especially). The pupil on the same side as the abscess is sometimes dilated and fixed. Choked disk is not invariably found. It may be more marked on the same side as the abscess. Localizing symptoms, spasmodic and paralytic, depend upon the center which is irritated or destroyed. In cerebellar abscess there are vertigo, vomiting, occipital headache, rigidity of the post-cervical muscles, and inco-ordination, but choked disk may be present or absent.

Meningitis arises soon after an accident; an *abscess*, more than a week, and often many weeks, after an accident. Meningitis presents high temperature and the general symptoms before outlined. *Mastoid disease* may occasion cerebral symptoms without abscess, or it may cause abscess. In *sinus-thrombosis* there is septic temperature, the veins of the face and neck are enlarged, and a clot can usually be felt in the jugular. A *tumor* grows slowly, usually presents almost from the start localizing symptoms, and double choked disk is frequently present. In tumor the temperature is apt to be normal.

Treatment. If abscess is due to ear disease with implication of the mastoid cells, at once open and clean out the mastoid (Fig. 476), and after this proceed to trephine the skull in order to reach the abscess. In any case, if symptoms of abscess exist, trephine the skull at once. If localizing symptoms are present, open over the suspected region. If localizing symptoms are not present and the cause is ear disease, trephine at Barker's point (Fig. 476). If no pus is found between the bone and dura, open the membrane. When the dura is opened, if the abscess is subdural, pus will be evacuated; if the abscess is in the brain-substance, the brain will bulge very much and will not be seen to pulsate. A grooved director is plunged into the brain, in the direction of the abscess, for two or two and a half inches (Keen). If pus is not found, withdraw the director and introduce it at another point. When pus

is discovered, incise the brain with a knife, enlarge the opening by inserting a closed pair of forceps and withdrawing the instrument with the blades open. Scrape away the granulation tissue lining the abscess-cavity, irrigate with hot salt solution, and introduce a rubber drainage-tube and suture it to the scalp; stitch the dura, but leave an ample opening for the tube; bring the tube out through a button-hole in the scalp, and after the first two days pull the tube out a little every day and cut off a piece. If the first trephining does not find pus, trephine again at another point. In cerebellar abscess make a flap with the base up, and trephine or gouge away the bone just below the line of the lateral sinus. Puncture the brain as for cerebral abscess.

Brain Disease from Suppurative Ear Disease.—Chronic disease of the middle ear is apt to destroy the bone between the tympanum and the middle fossa of the skull, and thus produce meningitis, thrombosis of the petrosal or lateral sinuses, abscess of the temporo-sphenoidal lobe or of the cerebellum, or extradural abscess. Chronic otitis media also induces inflammation or suppuration of the mastoid cells (*empyema of the mastoid*). Pus in the mastoid may discharge itself into the middle ear, and from this point into the external auditory canal, through a perforation in the drum-membrane (especially in acute cases). In some cases the pus becomes blocked up within the mastoid process. Pus in the mastoid may after a time break into the cavity of the cranium or into the lateral sinus, or may find its way externally and open into the sheaths of muscles arising from the mastoid. It not unusually opens into the sheath of the digastric muscle (*Breid's abscess*). These facts teach the surgeon that chronic ear disease should never be neglected, but should, if possible, receive the closest attention of the specialist. If no perforation exists in the drum, the surgeon must make one. In ordinary cases cleanliness and antiseptics are sufficient, the ear being syringed every day with a warm 2 per cent. solution of common salt. If only a small drum-perforation exists, 10 drops of pure alcohol or of corrosive sublimate solution (1:5000) are dropped into the ear daily; but if a large drum-perforation exists, boric acid and iodoform (7 to 1) are insufflated. Never inject alum. A strong silver solution is not safe; if it is used, wash the ear out afterward with warm salt water. If granulations or polypi exist, they must be removed. Some cases require the removal of the drum-membrane and the ossicles of the ear. Many cases of mastoid necrosis are due to tuberculosis. If headache, vomiting, and mastoid tenderness exist, open the mastoid (see page 848), in order to prevent abscess of the brain. In acute otitis media it is very rarely necessary to open the mastoid. The middle ear is on a lower level than the antrum of the mastoid, and in most acute cases both the middle ear and mastoid cells drain safely through a drum-perforation. Because a man has chronic otitis media it is by no means always necessary to trephine the mastoid. In many cases removal of the ossicles and drum-membrane effects a cure. In chronic otitis media, even if the mastoid is trephined, the ossicles and membrane ought to be removed.

Cerebral abscess from ear disease is almost always in the temporo-sphenoidal lobe, but may arise in the cerebellum. The **symptoms** are a transient rise of temperature, followed in many cases by a normal or subnormal temperature; vomiting; mastoid, frontal, and temporal pain. The mind is dull, and stupor arises which passes into coma; the bowels are constipated; choked disc may be present; and convulsions or spasms or paralyzes may exist.

Trephine and clean out the mastoid, and aseptinize (see Operations upon the Skull and Brain). Also trephine at Barker's point, one and one-fourth inches behind, and the same distance above, the middle of the external auditory meatus, open the dura, and seek for pus. If pus is not found, open the cerebellum.

Extradural Abscess.—The eye-symptoms and pain are the same in this as in cerebral or subdural abscess, but the temperature is different, rising to 103° or 104° F. There is often considerable tenderness above and behind the mastoid. In extradural abscess following disease of the middle ear trephine and clean out the mastoid; follow up a bone-sinus to the abscess, rongeur away the bone, being careful to avoid injuring the lateral sinus; curet, irrigate, and drain.

Infective Sinus-thrombosis.—Any sinus may be attacked. The disease may result from scarlet fever, smallpox, diphtheria, influenza, typhoid, or any acute suppuration. In erysipelas of the scalp, septic clots may form in the veins which pass through the bone and reach the longitudinal sinus. Infective thrombosis of the superior longitudinal sinus is thus produced.

In carbuncle of the lip and orbital suppuration the cavernous sinus may become involved.

In caries of the basilar portion of the occipital bone the circular sinus or the cavernous sinus may suffer. In caries of the petrous portion of the temporal bone, and in suppuration of the middle ear and mastoid process, infective thrombosis of the lateral sinus may occur.

In any case the symptoms are those of pyemia. The lateral sinus is the one most frequently attacked. In infective thrombosis of the lateral sinus there is usually a history of an old discharge from the ear.

Infective thrombosis of the lateral sinus may result from a specific fever, but is usually due to chronic suppuration of the middle ear associated in most cases with carious bone and pus in the mastoid process. Thrombosis of the lateral sinus occasionally follows an operation upon a suppurating mastoid, or develops in an individual who suffers from middle-ear disease who has been struck upon the head, who has had the ear syringed with force, or who has had injected a corrosive or very irritant fluid. Tuberculous bone disease is an occasional cause.

Symptoms.—In most cases there is a history of chronic ear disease. In children the symptoms are more acute than in adults. In any case the symptoms may rapidly become violent. In some cases there are preliminary symptoms of extradural abscess, pus being lodged in the groove of the sinus. It has been pointed out that pus in the jugular foramen may make pressure upon the pneumogastric, spinal accessory, and glossopharyngeal nerves, producing aphonia, hoarseness, dyspnea, dysphagia, and slow pulse (Geo. F. Cott *). Marked headache ushers in sinus-thrombosis. The pain is apt to be localized about the ear and mastoid process, but may become general. There is usually tenderness of the mastoid. There is high fever from the start, but when the clot begins to soften and break down, hard rigors develop and the temperature fluctuates violently. The temperature varies each day between subnormal and 106° to 107° . A chill may occur once or even twice a day, and it lasts from ten to twenty minutes. The pulse is soft and usually rapid. The patient is nauseated, labors under vertigo, is very restless,

* Am. Med., April 19, 1902.

is sometimes delirious, may become dull and stupid, and the muscles of the neck are stiff. Tenderness and marked edema are detected over the mastoid, and the veins of the neck and mastoid region may be enlarged. When the clot extends into the jugular vein there is pain on moving the head and on swallowing, the cervical glands are swollen, and a clot may be felt in the neck. Choked disc exists in about half of all cases. There is often a profuse discharge of pus from the ear, but in some cases the discharge is found to have abated or ceased. Exophthalmos and swelling of the eyelids point to involvement of the cavernous sinus in the process. In early cases there is thrombosis of the lateral sinus alone, or of the lateral sinus and jugular vein. The internal jugular vein may be felt as a cord in the neck. In advanced cases other sinuses become involved (superior petrosal, inferior petrosal, both cavernous, the lateral sinus of the opposite side, the ophthalmic veins, and the torcular Herophili). A patient with sinus-thrombosis is in great danger of developing pulmonary metastasis and septic meningitis (Jansen). Septic meningitis is accompanied by abscess about the sinus. Infective sinus-thrombosis is a very fatal disease and usually runs its course in from seven to ten days, but occasionally lasts for weeks. It is a form of pyemia, and death arises from the causes which have been referred to in discussing that disease.

Infective thrombosis of the cavernous sinus occurs when an infected clot comes from another sinus, from disease of the nasal sinuses, from orbital infection, or from a pyogenic process of the face or lids. It causes pain and the general symptoms of pyemia and also edema of the lids, chemosis, and an extreme degree of exophthalmos. Choked disk may exist. Vision may be normal or impaired. The condition almost invariably spreads to the other eye along the circular sinus.

Infective thrombosis of the petrosal sinus produces pyemic symptoms but no characteristic signs.

The prognosis largely depends upon early recognition. The surgeon should, whenever it is possible, open a mastoid before sinus-thrombosis arises, and should evacuate an abscess about the sinus before a clot forms in the venous channel, or at least before that clot becomes septic (Jansen).

Treatment.—In 1880 Zaufal proposed the operation now practised, and Horsley first did it in 1886. (See article by Geo. F. Cott, in "American Medicine," April 19, 1902.) Infective thrombosis of the lateral sinus is treated as follows: Open and clean out the mastoid, and expose the sinus by the use of the chisel or rongeur (Fig. 476). Follow M. Ballance's advice and expose the sinus from the bulb to the torcular. The jugular vein should now be exposed at the level of the cricoid cartilage and ligated below any clot which may exist. This is done to prevent propagation of an infected clot and diffusion of sepsis. Even if a clot does not exist in the jugular, the vein should be tied in two places and divided, because the sinus may contain infected clot or putrid material even when the vein as yet does not. According to Ballance, the portion of the vein above the point at which it was divided should be extirpated. Some surgeons after ligating the jugular do not excise it, but if it contains or comes to contain a septic clot, incise the vein up to the base of the skull and pack the wound. After attacking the vein open the sinus, and if a clot is found to exist, cut away the wall of the sinus. Introduce a small spoon into the lumen and carry it toward the torcular Herophili, and

scrape away the clot until blood flows. Arrest hemorrhage by plugging a piece of iodoform gauze into the wound and toward the torcular. Jansen opposes removing the entire clot toward the jugular, and does not tie the jugular, believing that to do so increases the danger of thrombosis of the inferior petrosal and cavernous sinuses. He simply removes the soft clot, but does not disturb the solid clot toward the heart. Most surgeons differ from him. Surgeons are of the opinion that it is futile to do any operation if pulmonary metastasis has taken place. In a recent case of the author's in the Jefferson Medical College Hospital the patient recovered after operation in spite of the fact that endocarditis had developed.

Until recently it was thought that the lateral sinus was the only sinus which should be attacked surgically, but in one case Knapp, of New York, requested Hartley to remove from the cavernous sinus a clot which was causing blindness and was due to sarcoma. The operation was successfully executed by Hartley, the incision being the same as is employed to reach a Gasserian ganglion in the Hartley operation. This patient lived several months. Dwight operated upon another case by incision of the sinus (E. W. Dwight and H. H. Germain, "Boston Med. and Surg. Jour.," May 1, 1902). Some surgeons advise removal of the eyeball and curetment of the sinus.

Intracranial Tumors.—An encephalic tumor may originate within the skull. It may have arisen from an external growth invading the cranial cavity, or may be metastatic. A tumor that arises within the cranium may take origin from the periosteum, from one of the membranes of the brain, from the vessels, from the neuroglia, or from the brain-substance.

No region of the body is so liable to tumors as the brain. During the course of a number of years the autopsies of the Munich Pathological Institute are stated by Bollinger to have shown one tumor of the brain in every 85 autopsies. Hale White's experience is that such tumors are even more common than this, and he estimates them at one in every 50 autopsies.

In endeavoring to determine the causes of intracranial tumors we must accord heredity with considerable influence in tuberculoma, and possibly with some force in sarcoma and carcinoma. Tumors of the brain are decidedly more common in males than in females, probably because of the greater male liability to injury, syphilis, and alcoholism.

The majority of cases of tumor of the brain occur between the ages of twenty five and fifty. Children are particularly prone to suffer from glioma and from tuberculous growths. In aged persons a tumor of the brain very rarely develops. In 100 cases of brain tumor collected by Hale White only 2 were aged seventy or over. In 100 cases collected by Mills and Lloyd only 1 was over seventy.

Injury may be responsible for the development of sarcoma, of fibroma, and possibly of other forms, in fact, a syphiloma may arise in a syphilitic person at the seat of an injury.

We use the term intracranial or encephalic tumor not only to include true neoplasms, but also to designate growths of parasitic, syphilitic, or tuberculous origin. It is of importance to attempt to make a diagnosis as to the form of tumor that is present, and this may be possible on account of the fact that in many cases the form affects the symptoms. A useful class-

ification of these growths has been made by Knapp, and is as follows: (1) The infective granulomata, including tuberculous growths, gummata, and actinomycotic areas; (2) connective-tissue growths; (3) epithelial growths; (4) aneurysms. The most common of all these tumors is undoubtedly that due to tubercle. In fact, Gowers estimates that if we exclude syphiloma, tubercle is responsible for one-half of the cases, and glioma and sarcoma together for one-third.

Tuberculous Tumors (Tuberculous Gummata; Tuberculomata).—Tuberculous tumors are the most common form met with. They are at least four times as common in children as in adults. They may be single, especially in adults, but are often multiple, especially in children; and multiple growths may be very wide-spread. According to Allan Starr, these growths are most common in the cerebral axis (especially in the basal ganglia), next in the cerebellum, next in the cerebral cortex, and are least common in the centrum ovale. A tuberculous tumor usually arises in the pia mater, particularly in an arterial distribution, but may begin in a ventricle, or even in the brain-substance. Some of these growths are distinctly subcortical. The tubercle bacilli responsible for the condition are carried by the blood. A large tuberculous tumor is due to the coalescence of many foci. It undergoes caseation in the center, and is surrounded by a zone of softened or sclerotic brain-substance. Tuberculous meningitis is present in two-thirds or three-fourths of the cases of tuberculoma.

Gummatous Tumors (Syphilomata).—We find a single gumma, but, far more often, syphilitic growths are multiple. Such a growth may be round, or may be irregular in outline; in fact, the outline is frequently blurred and indistinct. Some of these growths are soft, and some, which contain a quantity of connective tissue, are hard. A syphiloma usually arises from the membranes, and, hence, is generally on the surface of the brain; and the membranes in the region of the growth usually show distinct inflammation.

Actinomycosis.—This is a very rare condition, in which the mass may remain solid like a tumor, but is far more apt to break down into an actinomycotic abscess.

Sarcomata. Injury seems to play a considerable part in the production of intracranial sarcoma. Any variety of sarcoma may arise. As a rule, at least in the beginning, the growth is single; but it may be multiple, or may become so. The majority of sarcomata arise from the membranes or from the periosteum, but some cases take origin from beneath the cortex. Early in their progress these growths may be encapsulated, but some of them, from the very start, are infiltrating; and even those that were at first encapsulated later infiltrate. *Endothelioma* is sometimes met with. What is called *angioma of the brain* is, in reality, *angiosarcoma*. A *pneumoma* is usually sarcomatous.

Gliomata.—A glioma is a growth so ill defined and so slightly differentiated in appearance from the brain-substance that it may easily be overlooked in an exploratory operation. It arises much more frequently from the white than from the gray matter, and develops from the neuroglia of the cerebrum, of the cerebellum, of the pons, or of the medulla oblongata. A glioma may be soft or may be hard; and soft gliomata are probably, in reality, sarcomata. Hemorrhage is very apt to occur in these growths.

Fibromata.—Intracranial fibroma is a rare growth. It is of firm consistence, is encapsulated, and may grow to a large size. Such growths can be readily enucleated. Injury seems occasionally to be responsible for their formation.

Osteomata.—Osteophytic growths not uncommonly take origin from the inner surface of the skull, but the osteomata arising in the dura or in the brain substance are rare. Such growths, however, occasionally occur.

Cholesteatomata. These tumors are fibrous growths covered with endothelium and containing layers of cholesterol. They are particularly apt to arise in the pia mater, but may begin in either of the other membranes or in the brain substance. A cholesteatoma is commonly called a *pearl tumor*.

Enchondromata and **true neuromata** are rare, and **lipomata** are exceedingly uncommon.

Adenomata.—An adenoma occasionally springs from the conarium, or the pituitary body.

Carcinomata. Primary intracerebral carcinoma is rare, but does occur. Secondary carcinoma is more common, and may follow cancer of any part of the body, although it is most apt to follow cancerous growths about the face and neck. A primary growth may begin in the meninges or in the lining of the ventricle. Intracerebral carcinomata may be single or multiple. They are soft and non-encapsulated growths.

Cysts.—Mills says that cysts arise about an old hemorrhage, are small retention-cysts of a vascular plexus, or are porencephalic. Dermoid cysts are extremely rare.

Symptoms.—They are divided into two sets. (1) General, due to increase of pressure, and (2) *local, localizing*, or special, arising because of the part of the brain involved.

In some cases general symptoms are absent, in some special symptoms are absent, in others even tumors of large size produce no recognizable symptoms, either general or special. A large infiltrating growth, a *glioma*, for instance, may produce no symptoms at all if situated in a silent region, and if it destroys brain substance as it grows, so that intracerebral pressure is not increased.

General Symptoms.—The chief general symptoms are headache, vomiting, and choked disk. All of these may be present, any one of them may be absent, any two of them may be absent, and in some cases all of them are absent. Other general symptoms that may or may not be present are vertigo, general convulsions, insomnia, mental failure, and somnolence or partial stupor.

Headache. This is the symptom most commonly present. It occurs earlier or later in a very great majority of cases.

At first it may be noted only at certain times of the day and it is usually complained of most on rising in the morning. The headache of brain tumor when once established is intense in most cases, and as a general thing it is practically continuous, with episodes of increased violence. In rare cases it is *paroxysmal*. In some cases it is trivial, in some few cases it never arises at all. The headache of brain tumor usually interferes with sleep. It may be general, one-sided, frontal, or occipital. The situation of the pain is without localizing value unless there is tenderness on percussion or pressure over the seat of pain, which is sometimes noted in growths of the meninges or cortex.

Headache is less common in children. In very young children the explanation of this is found in the open fontanelles and the expansile cranium. In older children in the fact that gliomata are common in children and gliomata may not cause intracerebral pressure.

The dura is sensitive, as Cushing says to "pull or pressure, not to an incision." The headache of brain tumor is due to stretching of the dura.

Vomiting—Vomiting is present at times in many of the cases. It may happen occasionally or it may never occur.

It is usually cerebral, that is, vomiting with a clean tongue without nausea, and without any relation to the taking of food. In some cases it is projectile quantities of vomitus being suddenly projected from the mouth. It may, however, be associated with nausea, and in some cases there is nausea without vomiting. It is apt to be most severe on getting up, especially on rising in the morning. It is apt to be most severe when headache is most intense.

The worst attacks of vomiting occur in cases of cerebellar tumor.

The cause of vomiting is uncertain. Some believe it to be due to stimulation of the vagus center, others, to reflex stimulation of a vomiting center in the medulla. If associated with vertigo it may arise from the auditory centers.

Choked Disk (*Optic Neuritis, Papillitis, Descending Neuritis, Papilloedema*) This is a most important symptom. When present it is, as Cushing says, one of the "most reliable" signs of tumor. It is present in 80 per cent. of all cases. It may be noted in a few weeks after a tumor begins to grow, in a few months, or longer. It may come on rapidly or gradually.

It is particularly common and severe in growths beneath the tentorium. It is decidedly less common in tumors of the motor cortex. It is nearly always bilateral, but it is common to find it more marked in one eye than in the other. That it is worse on one side suggests, but *only suggests*, that the tumor may be on the side on which the choked disk is worst. Monocular choked disk is very rare. When it exists it indicates that the growth, in all likelihood, is situated near the back of the orbit on the same side as the choking of the disk. Gowers recently recorded a case of unilateral choked disk due to a tumor compressing the left optic nerve ("Lancet," July 10, 1909).

Choked disk may exist for some time and attain a high grade without noticeably impairing vision, but ultimately it leads to retinal hemorrhage, white atrophy, and blindness. When atrophy begins vision wanes. The presence of choked disk does not *prove* the existence of tumor. The cerebral edema of Bright's disease may cause a condition known as albuminuric retinitis which practically is not to be distinguished from the choked disk caused by tumor. Cushing believes that the processes are identical in tumor and Bright's disease. Choked disk may occur in meningitis, brain abscess, cerebral syphilis, sinus thrombosis, myelitis, infectious diseases (typhoid, influenza, diphtheria and other conditions), toxemias from lead, arsenic, and alcohol, anemia, diabetes, or as an hereditary or family disease.

The cause of choked disk has been much disputed. Some believe that the condition is a neuritis due to a toxic condition of the cerebrospinal fluid. Others believe that it is not inflammatory, but is a papillo edema due purely to mechanical pressure, and is an edema or dropsy. The latter theory is largely held by surgeons because they have become convinced by experience that relief of intracranial pressure relieves or cures choked disk. De Schweinitz and Hollaway ("Therapeutic Gazette," July 15, 1909) make the following state-

ment in regard to mechanical pressure causing choked disk: "That this is the only etiological factor may with propriety be disputed, indeed, it seems certain that a combination of factors must be active in the production of this condition, but increased intracranial pressure is the one of which we have most certain knowledge."

Cushing, of Baltimore, who has done such notable work on this subject, believes that "almost all, if not all cases of choked disk are primarily of mechanical origin and do not justify the term neuritis" ("Keen's Surgery," vol. iii). The presence of choked disk is disclosed by the ophthalmoscope.

Convulsions.—Generalized convulsions may occur and children are especially liable to them. Many cases of supposed general convulsions have an unobserved local beginning which is a focal symptom.

Vertigo.—Mills says it is noted in one-third of all cases and is due to dural, ocular, or labyrinthine irritation.

Insomnia is often due to headache and is apt to be associated with restlessness, lack of emotional control, and irritability. It is most pronounced in cases of syphiloma and some forms of malignant disease, and is worse in adults than in children.

In rare cases there is somnolence or partial stupor rather than insomnia. In such cases slow speech is often noted.

Mental Failure.—There is often great lack of emotional control, characterized by irritability and outbreaks of anger. Failure of memory is common and change of character is the rule. There may be great slowness of thought and of mental response to stimuli, with defective power of orientation. Progressive mental deterioration may occur. There may be mental depression, apathy, or mental excitement. Tumors in certain regions may cause delusions, illusions, or hallucinations.

Hysteria and neurasthenia sometimes arise.

Pulse and Respiration.—Whereas the pulse is often slow, it is very variable, and I agree with Cushing that "pressure symptoms which characterize acute lesions (namely, rise in blood-pressure; slow, vagus pulse, and Cheyne-Stokes respiration) are conspicuous by their absence" ("Keen's Surgery," vol. iii).

Special Focal or Localizing Symptoms.—These symptoms, when present, indicate the situation of the growth. If the tumor is in a silent region there will be no focal symptoms. General symptoms may exist without focal symptoms and focal symptoms may exist without general symptoms.

Among localizing symptoms we should mention various forms of aphasia, hemianopsia, paralysis, Jacksonian epilepsy, sensory disturbances (to touch, pain, or temperature), sensory aura, disturbances of taste and smell, impairment of muscular sense, alteration or impairment of reflexes, nystagmus, and incoordination.

Diagnosis.—In *abscess* the symptoms develop much more acutely than in *tumor*. It is true that some cases of abscess last for months, but in them intervals of complete remission of symptoms occur, which is not the case in tumor. An abscess follows middle ear disease or some other pyogenic process or perhaps a head injury. There may be fever and leukocytosis. Choked disk is far less common than in tumor.

Chronic meningitis from syphilis exhibits periods of increase and periods of subsidence of the symptoms, and usually palsy of one or more cranial nerves. The symptoms may pass away under the use of mercury and iodid of potassium.

Examination of the fluid obtained by lumbar puncture may make the diagnosis evident.

In *Bright's disease* symptoms strongly suggestive of tumor may arise (headache, vomiting, and choked disk) with, perhaps, but little change in the urine. The difficulty in diagnosis becomes evident when we recall that in cases of brain tumor the urine may contain casts and albumin.

Ependymitis with ventricular dropsy may cause symptoms resembling tumor with hydrocephalus.

The x rays may aid us in diagnosis and many brain tumors can be skia graphed. Lumbar puncture may aid in the diagnosis, but it must be used with the greatest care, because in tumor the withdrawal of any considerable quantity of fluid may be followed by sudden death.

Cause, Duration, and Termination.—A brain tumor, unless caused by syphilis, is a certainly fatal lesion if not removed by operation.

Some brain tumors grow for years before they produce symptoms. Some grow with great rapidity. When pressure symptoms appear the patient's life will terminate in a few months unless an operation is performed. It is usually stated that the average duration of life is three years.

Sudden death may occur at any time.

Horsley states that in a very few cases brain tumors have disappeared after mere operative exposure, the tumor not having been removed. Cushing has had the same experience, and regards such an amazing disappearance as due to the cystic degeneration of a glioma.

The situation of a tumor is determined not only from localizing symptoms but also from their mode of onset and manner of combination. In some cases the symptoms are not characteristic, in others they are definite. The more marked the signs of compression, the less the value of localizing symptoms. The nature of the tumor, its depth, and whether it is single, and if other tumors exist is, if possible, determined. Localizing symptoms may be due to irritation or destruction of functioning power. Irritation causes spasm, and destruction induces paralysis. Convulsions which are local or which begin locally are known as *Jacksonian epilepsy*. A local convulsion points to an irritative lesion of, or immediately adjacent to, the center which presides over the muscular movements of the part convulsed. Local paralysis points to a destructive lesion of the center which presides over the movements of the paralyzed part. In some cases a center is damaged and the muscular movements it controls are paralyzed, but the adjacent brain-areas are irritated and the muscles they represent are attacked with spasms. In some cases an apparently paralyzed part becomes convulsed, the center not being completely destroyed and sudden hyperemia serving to awaken spasm. Always note the order of invasion of different regions and observe if spasm is followed by muscular weakness or anesthesia.

1. Lesions in the Cortical Motor Area.—A slow growing tumor which irritates the cortex will cause tonic or clonic convulsions on the opposite side of the body. These convulsions have a local beginning (*Jacksonian epilepsy*). After a time paralysis may develop (*monoplegias* and perhaps ultimately *hemiplegia*). An irritative lesion of the lower third of this area causes spasm of the opposite side of the face, angle of mouth, or tongue, and this condition is often associated with tingling. The spasm may remain limited or may extend widely and may even become general. An irritative lesion of the middle third of the

cortical area causes spasm, which is limited to or begins in the fingers, thumb, wrist or shoulder. An irritative lesion of the upper third of the cortical motor area causes spasm, which is limited to or begins in the toes, ankle, leg, or hip. If such lesions exist, an aura is occasionally felt in the affected region before the spasm begins, and there is often numbness after the spasm. Destructive lesions of the motor area cause local paralysis, which may be preceded by local spasm of the same parts, and is often associated with local spasm of other parts. If paralysis comes on unpreceded by convulsions the lesion is *subcortical* rather than cortical, that is, it is in the white matter between the motor area and the internal capsule.

2. **Tumors of the anterosuperior portion of the prefrontal region** give no definite localizing symptoms, but produce general symptoms. Mental disorders may arise in tumors of any area of the brain, but in tumors of the prefrontal region they are most apt to occur. The intelligence is nearly always impaired, and there is apt to be mental apathy, loss of memory, irascibility, and pronounced change of character. As the tumor grows it may subsequently involve the motor region, which in all probability lies entirely in front of the fissure of Rolando.

In tumors of the prefrontal region there may be focal convulsions or local palsy on the opposite side, due either to a spread of irritation from a superficial tumor to the motor cortex or to involvement by a deep tumor of the commissural fibers which join the frontal lobe and the motor cortex.

3. **Tumors of the Antero-inferior Portion of the Frontal Lobe.**—In a right-handed man tumor of the second left frontal convolution causes *agraphia*, and of the third left frontal convolution, *motor aphasia*. In a left-handed person these localizations are on the right side of the brain.

4. **Tumors of the parietal lobe** may occupy a silent region of this lobe. The centers for general sensibility and for the muscular sense are back of the fissure of Rolando in the parietal lobes. Hence a tumor in this region may cause disturbance of muscular sense and general sensibility in the limbs without spasm or palsy (Durante). There may be word blindness when the left angular gyrus is affected.

The extension forward of a parietal tumor will involve the motor zone and produce spasm or palsy. Extension backward will involve the occipital lobe and produce hemianopsia.

5. **Tumors of the occipital lobe** are apt to produce *lateral homonymous hemianopsia* (blindness of the nasal half of one retina and the temporal half of the other retina. If the right side of the brain contains the lesion the right side of each retina is blind, and vice versa). Lesions of the cuneus and of the calcarine fissure are especially apt to produce hemianopsia. A lesion of the occipital cortex may produce it. Tumors of both occipital lobes cause blindness. In tumor of an occipital lobe color vision only may be affected (Cushing). Tumor of the optic radiation may produce hemianopsia (that is, growths of the chiasm, optic nerve, a pulvinar may, but it is not certain that a growth of the quadrigeminal bodies or of the external geniculate body can).

6. **Tumors of the temporosphenoidal lobe** frequently produce no symptoms. In the temporal lobes the cortical centers for hearing are placed, and each center is connected with both auditory nerves, but the crossed auditory bundle is larger and more active than the direct (Francesco Durante, "Brit.

Med. Jour.," Dec. 13, 1902). Tumors in the left lobe are particularly to cause deafness and may cause *word deafness*. Tumors at the apex of lobe may cause perversion or impairment of taste and smell.

7 **Tumors of any size in or about the corpus striatum** cause *hemiplegia* by pressure upon the internal capsule. Pressure upon the optic thalamus produces homonymous hemianopsia and hemianesthesia. Growths of the basal ganglia produce intense optic neuritis and early pressure because of distention of the ventricles. Tumors of the corpora quadrigemina are to involve the crura, and later the third nerve. Ocular symptoms are all present (loss of pupillary reflex and nystagmus). If the third nerve is involved there are paralysis of the motor oculi area on the side of the lesion (extropia, strabismus, dilated pupil, and drop lid) and hemiplegia of the opposite side of the body from pressure upon the crus. This condition is a form of *cranial paralysis*.

8. **Tumors of the Pons.**—Pontine lesions produce symptoms by pressure upon the particular nerves which come from this region, with or without the evidences of pressure upon the motor path. Forms of crossed paralysis may exist. Lesions in the lower half of the pons may effect the fifth, sixth, and seventh nerves on the side of the lesion and the limbs on the opposite side. The auditory nerve may be involved in the lesion. In crossed paralysis the face on the side of the limb paralyzed is usually not affected, but in extensive tumors it may be paralyzed. *Conjugate deviation* of the eyes occurs *away* from the *facial paralysis*. In tumors of the upper part of the pons the pupils may be first contracted from irritation of the third nerve nuclei and later dilated from destruction of these nuclei. Anesthesia as a symptom of pontine tumors is not nearly so common as is motor paralysis, and convulsions are rare.

9. **Tumors of the Medulla.** An extensive lesion inevitably causes death. Cranial nerves only may be involved, but crossed paralysis may take place. Vomiting is common, retraction of the head is not unusual, respiratory and circulatory disturbances and dysphagia are frequently noted. Sometimes there is numbness and occasionally there are convulsions; usually there is incoordination, because of pressure upon the cerebellum.

10. **Tumors of the Cerebellum.**—In general it may be said that tumors of the cerebellum cause headache, vomiting, vertigo, choked disk, and blindness. Tumors of the middle peduncle cause sudden uncontrolled movements of the trunk, either toward the side of the tumor or away from it. Vertigo and nystagmus are common. Symptoms are frequently complicated by evidences of pontine disease proper.

Tumors of the middle lobe of the cerebellum cause a sense of loss of equilibrium and obvious unsteadiness in attempting to walk or even to stand. The patient has a tendency to fall, there are giddiness and vomiting.

Tumors of the cerebellar hemisphere produce no localizing symptoms. The usual unsteadiness of gait is due to pressure upon the middle lobe (Nagel).

11. **Tumors of the Hypophysis Cerebri.**—The pituitary body may be subjected to pressure from, or become involved in, tumors of the region above it, or tumors or cysts may spring from it directly. Tumors of or tumors pressing upon the hypophysis may in some cases cause acromegaly, as

others impotence, genital infantilism, a tendency to fat deposit, and stunted stature. There is intense headache, amblyopia due to primary atrophy (no preceding choked disk), appearing often as a bitemporal hemianopsia (Cushing, Jour. American Med. Assoc., July 24, 1909).

Any brain tumor which causes internal hydrocephalus may thus cause pressure on the hypophysis and lead to the development of hypophyseal symptoms (Cushing *).

Treatment.—If any doubt exists as to the nature of a brain tumor, give the patient a course of iodid of potassium, and as doubt is the rule, we almost invariably administer it. Give the drug at first in small amounts, but rapidly increase it until heroic doses are taken (100 or more grains a day). Mercury should also be given hypodermatically or by inunction. If iodid of potassium and mercury really relieve the symptoms, and if the improvement is not merely temporary, operation is unnecessary, although it may be demanded later in order to remove an irritant scar. If antisyphilitic treatment fails, the question of operation must be considered. The test of success is improvement in the choked disk. If this improves, the treatment is succeeding; if it does not, the treatment is a failure. It should not be persisted in over six weeks if there is no improvement in the eye grounds. To delay operation further may mean blindness. We must always bear in mind that in certain cases of tumor the symptoms temporarily improve under antisyphilitic treatment. The term *operable case* does not necessarily mean a tumor which can be entirely removed by operation. Some tumors which can be only partially removed should be operated upon. An operable case is one in which an attempt may be made to remove the tumor and in which the tumor can be entirely removed or in which a part can be removed, the removal of this part promising relief. We are justified in being radical because without operation a brain tumor is a certainly fatal malady. In many cases of undetected tumor excision for cure is not attempted because of the absence of alarming symptoms or because of the inaccessible situation of the growth. In all cases operation is, first of all, exploratory. Tumors of the dura which have not infiltrated the brain, many cortical and some subcortical growths, are operable. Cerebral cysts if accessible should be opened and drained in hope that

Fig. 264. Case of cerebellar tumor. Flipping of flap after osteoplastic exploratory operation.

*For full consideration of localizing symptoms see particularly the writings of Roberts, Mills, Allen Starr, Dana, Dercum, Osier, and Cushing, which have been freely used in the above section.

benefit will result. Some subtentorial tumors can be removed. In certain cases it is justifiable to attempt the removal of a glioma if the growth is in an accessible region. Byrom Bramwell maintains that tumors at the base, tumors of the pons and medulla, of the corpus callosum, of the basal ganglia, and of the deeper parts of the centrum ovale are irremovable. Most tumors at the base are inoperable, but some few are operable. Surgeons now regard some tumors of the cerebello-pontine angle as operable, but agree with Bramwell's views as to growths in the other situations he mentions. Frazier has concluded that "if the tumor is found to be very vascular and of the infiltrating type, it is very questionable . . . as to whether any attempt whatsoever should be made to extirpate" ("Univer. of Penn. Med. Bulletin," April-May, 1906), and with this opinion I certainly agree. In tumors which are very extensive complete removal is usually out of the question. There is no use in removing secondary malignant tumors. It often happens that the brain itself (as in syphilis) is so extensively diseased, or that other organs (as in tuberculosis) are so involved, as to render attempts at removal of the tumor futile or actual removal useless. Mills thinks that 50 per cent. of cerebellar tumors can be attacked surgically ("New York and Phila. Med. Jour.," Feb. 11-18, 1905). He classifies operable tumors of the cerebellum as follows: 1. Tumors situated entirely or chiefly in the lateral lobe. 2. Tumors upon or even invading a part of the vermis or middle lobe. 3. Tumors of the cerebello-oblongatopontile angle. Among inoperable tumors are most gliomata and infiltrating sarcomata, metastatic tumors, and multiple tumors. Bramwell tells us* that he has studied eighty-two cases of intracranial tumor, and he considers that in only five of them could the tumor have been entirely removed. In 157 reported cases the tumor was either not found or not removed, in 104 reported cases the tumor was found, and in some of them it was removed (Ransohoff, in "Jour. Am. Med. Assoc.," Oct. 11, 1907). The conclusion is that though some tumors of the brain may be successfully removed, extirpation is feasible in only a small minority of cases and is to be decided on only after careful study of all the indications and contraindications offered by the case. When an operation is decided upon, some surgeons apply an apparatus to the arm and the blood-pressure is taken just before the operation and at frequent intervals during it. Thus by noting a great fall in blood-pressure they get early warning of dangerous shock, learn when to hasten, and if the operation should be temporarily abandoned and be completed at another time (**two-stage operation**). We may be driven to abandon operation after cutting the bone and dural flaps, and if we are forced to stop, we restore the bone and dura to position, and complete the operation after a day or two. I agree with Frazier that the lessening of hemorrhage by temporarily clamping the carotids in the neck is not free from danger, and it is not proper to do more than apply Crile's clamp to the vessel on the side operated upon. In a brain-tumor when the dura is first opened there is usually at once marked bulging of the brain, which is called "*initial bulging*"; after working for a time on a brain, even when there is no tumor, bulging occurs from traumatic edema, which is called "*consecutive bulging*." That consecutive bulging may occur is a sound reason for operating rapidly (Frazier). The mortality from tumor operations is large, death being due to shock and hemorrhage. Hays col-

* Edinburgh Med. Jour., June, 1894

lected 122 cases in which the tumor was removed: the mortality was 60 per cent. Operations completed at one séance give a larger mortality than two-stage operations. During the operation an erect posture causes the brain to recede and permits of extensive exploration under the dura (Ransohoff-Cushing). The same thing is accomplished by lumbar puncture (Cushing). The fibromata constitute the best cases for operation. In operating on a cerebral tumor make a large osteoplastic flap. If on opening the dura the tumor is not visible, and if the localizing symptoms were reasonably positive, the surgeon is justified in making an exploratory incision through the cortex to see if there is a subcortical growth. Operations for cerebellar tumors are peculiarly difficult because of the large blood sinuses, because of the limited space obtained to work through, because of the great bulging after the dura has been opened, because of the impossibility of reaching the anterior, mesial, or upper surfaces through the incision, because of the liability to injure the pons and medulla, and because of the difficulty of retracting the parts (Frazier, "New York and Phila. Med. Jour.," Feb. 11-18, 1905). In approaching tumors which are not within a cerebellar hemisphere by a one-sided exposure of the cerebellum, it is usually best to remove a considerable portion of the hemisphere in order to obtain free access to the growth. I prefer Cushing's "pass saw" incision and bilateral exposure. This enables the surgeon to dislocate the sound lobe outward and so obtain room to work upon the lobe containing the tumor. The diagnosis of cerebellar tumor is usually doubtful, hence practically all operations are at first exploratory and are then made extensive or radical as the case demands. Operation must be early, because cerebellar growths quickly cause blindness. Sir Victor Horsley, McArthur, Hochenegg, Von Eiselsberg, and Cushing have operated for tumor of the hypophysis. Removal of a healthy pituitary body from dogs is sure to be fatal, as the gland is necessary to the life of the dog. Removal of a healthy pituitary in man would in all probability prove fatal. Diseased pituitaries have been successfully removed. Perhaps in these cases the function of the gland was more or less compensated before operation was done. If the tumor is associated with acromegaly, removal of the tumor may greatly benefit the acromegaly. One route of approach to the hypophysis is from the side, just as to reach the Gasserian ganglion. Another route is across the frontal sinus, then dividing the septum of the nose, removing the turbinated bones, and breaking through the sphenoid. Though thorough extirpation is feasible in but few cases of brain tumor, operation should often be performed for palliative purposes. Grainger Stewart, Annandale, Horsley, Macewen, Cushing, and Keen have advocated *palliative trephining* in certain cases. Simple trephining is of little value. In order to really relieve pressure the dura must be opened and left unsutured, so that hernia cerebri may follow. Cushing has had some cases of extraordinary improvement in cases of cerebral tumor after trephining on the right temporal region and removing a piece of the dura. The operation is called by Cushing a *decompression operation*. The brain bulges through the dural opening, but the dense temporal fascia stitched together over it prevents elongation. It is the temporosphenoidal lobe that bulges, and the right side is selected because word-deafness might ensue if the operation were done on the left side. I have seen several of Cushing's cases. One of them, a colored man, had been almost blind for some time and was unconscious and had rapidly

failing respiration when the operation was performed. He was so much benefited that he returned to work and has useful vision and no pain. I have had several very gratifying results in my own practice. In cases of cerebral tumor subtemporal decompression, and in cases of cerebellar tumor suboccipital decompression, may be performed.

Decompression may relieve choked disk and thus retard or prevent optic atrophy and blindness. Cushing demonstrates that intracerebral pressure is the chief element in choked disk.

This procedure is of value in diminishing excessive intracranial pressure and thus relieving headache and choked disk, and decreasing the tendency to sudden death from inhibition of the heart or from respiratory failure. The usual method of decompression will not relieve the headache caused by tumor of the hypophysis. This headache is due to distention of the dural box in which the gland is placed, and can be relieved only by incision of the dural box (Harvey Cushing, "Jour. American Med. Assoc.," July 24, 1909).

We conclude that in most cases of brain tumor operation should be performed for exploration; in some cases extirpation may be performed; in most cases extirpation is impossible, and the surgeon must be content with the palliative influence of Cushing's decompression operation. A tumor of the brain if not cured by anti-syphilitic treatment is of necessity fatal if unoperated upon, and exploratory operation is not very dangerous.

In a case of brain-tumor if operation is refused, if extirpation is impossible, or if decompression fails, it may be necessary to use the bromids for convulsions and morphin for headache. The headache is often benefited by purgatives, courses of potassium iodid, the ice-bag to the head, and the application of a hot iron to the nape of the neck.

Operative Treatment of Epilepsy. The shock of an accident or a cerebral concussion may establish epilepsy, especially in those predisposed by heredity or other causes. Traumatic epilepsy, *Le Dentu* tells us,* may be due to: (1) Bone fragments from skull fracture; (2) outgrowths of bone due to tumor; (3) cicatrices of meninges resulting from laceration of membranes by bone fragments; (4) chronic meningitis which ends in sclerosis of membranes; (5) cysts resulting from intracranial hemorrhage at the point of fracture; (6) arteriovenous aneurysm. We would add: (7) tumors of the brain; (8) sclerosis of the cortex. We refer here, in speaking of traumatic epilepsy, purely to the condition when it follows a head injury, and this is the common meaning of the term. Remember that epilepsy, as shown by Sachs, may follow a long forgotten injury. Before undertaking a brain operation for epilepsy it is a sound rule to remove all sources of definite peripheral irritation. I have seen apparent cure follow the removal of a tender cicatrix and follow circumcision of a patient laboring under phimosis. Briggs reported a case of epilepsy in which there was a distinct depression of a portion of the skull. There was also necrosis of the tibia, and after the cure of the necrosis the convulsions ceased. The removal of supposed peripheral irritation, however, is beneficial only occasionally. Are operations upon the skull and brain curative? Surgeons are much less enthusiastic than they were a few years ago. I believe operation can cure less than 5 per cent of cases, but it is important to remember that in some cases in which operation

* *La Presse médicale*, June 9, 1864.

seems to have failed medical treatment becomes much more efficient than it was before the operation. The high rate of cure (70 per cent.) once claimed for operations was due to failing to follow the patient sufficiently long. A patient should not be reported as cured until at least three years, and better, five years, have passed without any evidence of the disease. Another source of error was a failure to understand that any traumatism may improve epilepsy for a time. "The administering of an anesthetic, the shock of an injury, the traumatism of an operation, just like a febrile seizure, may interrupt an epileptic habit and cause a patient to go for weeks or months without an attack" (the author, in "Medicine," Feb., 1904).

Operation must never be indiscriminately applied. In some cases it gives hope of relief, in others it is obvious that it would be utterly futile. In order to determine if a case is or is not suitable for operation it must be studied with great care. The history must be carefully obtained, particularly as to hereditary predisposition, the first convulsion, and its supposed cause. The question of injury, recent or old, should be thoroughly investigated, and it is a sound rule to have the head shaved and then examine for a scar and for a depression. Convulsive seizures must be studied by an expert, hence the patient should be in a hospital, constantly watched by a trained nurse, until one or two fits have occurred. The nurse watches the convulsion and describes it in writing, noting particularly if it had a local beginning. The general health must be investigated.

I am accustomed, for surgical purposes, to make the following classification of epilepsy. It is a modification of Sir Victor Horsley's classification (the author, in "Medicine," Feb., 1904):

1. Reflex epilepsy, the surgical treatment of which I shall not discuss in detail.
2. The common non-traumatic, idiopathic, or essential epilepsy, in which the attacks are general and are without a local onset.
3. Idiopathic epilepsy with a local onset of attacks (focal or Jacksonian epilepsy).
4. Traumatic epilepsy. This may be subdivided into two forms: (a) attacks without a local onset; and (b) attacks with a local onset (focal or Jacksonian epilepsy).
5. Jacksonian epilepsy due to gross brain disease (tumor, aneurysm, etc.).
6. Epilepsy following infantile cerebral palsy.
7. The posthemiplegic epilepsy of adults.

1. **Reflex Epilepsy.**—Remove the supposed cause of irritation. When epilepsy follows traumatism and a scar is found on the scalp, excise the scar. This is an imperative duty if the scar is tender or the seat of an aura.

2. **Essential or Idiopathic Epilepsy.** Operation upon the brain is useless. If persistent headache exists, it is then proper to trephine and open the dura for exploration. Such an operation is done to relieve headache. Some claim remarkable results from bilateral excision of the cervical ganglia of the sympathetic (page 777). The operation is a theoretical one and of doubtful utility. It was founded upon a misconception as to the cause of epilepsy, and favorable reports are no more favorable than have been set forth regarding various other now abandoned procedures.

3. **Idiopathic Epilepsy with Local Onset of Attacks (Focal or Jacksonian Epilepsy).**—Many of these cases begin in young children who have had infantile

tile palsy, the traces of the palsy having disappeared. In such cases the convulsions may begin on one side, and in fact may be nearly limited to one side. If, from the very beginning, the attacks began in one group of muscles or in one extremity, whether or not they spread to the rest of the body, and if the case is seen within two years of the first attack, the surgeon is justified in exposing the brain and excising the irritated portion of cortex. This operation, it is true, cures very few cases, but it benefits many for a considerable time and seems to make them more amenable to medical treatment. In the vast majority of cases fits recur, but rarely as severely as before. After fits have been going on for two years operation offers no prospect of cure, as the association fibers have surely degenerated. But, even in very old cases, if the attacks are frequently repeated and thus threaten life, the excited center should be removed to save life.

In cortical excision more of the cortex than the excited center is of necessity removed, because, in order to get the entire center, we must go wide of it. Paralysis of the parts controlled by the extirpated cortical area follows. The paralysis is seldom permanent except to the finer movements. The operation gives the best prognosis in young persons, and when done early in the case. The return of fits after apparent cure is thought to be due, at least in some cases, to the formation of *adhesions* between the brain and its membranes. Various unsatisfactory attempts have been made to prevent adhesion by the insertion of silver foil, gold foil, rubber tissue, egg shell membrane, and Cargile membrane. In operating for cortical epilepsy a large osteoplastic flap is required. In the previous remarks we dealt with partial epilepsy and with generalized epilepsy in which, from the first, the attacks had a local beginning. If cases of apparent idiopathic epilepsy develop Jacksonian attacks (attacks with a local beginning), it is useless to excise the cortex. The entire cortex is diseased, though one region is particularly unstable.

4. **Traumatic Epilepsy.**—Always remember that a traumatism to a person who becomes epileptic may have been only a coincidence; the condition may be essential epilepsy and the traumatism may have had nothing to do with it. Epilepsy ensuing upon traumatism may not begin until months or even several years after the injury. In the earliest attacks consciousness may or may not be lost. The causative injury may have been slight or severe. "An injury may cause a hemorrhage or a depressed fracture; may be followed by a scar upon the membranes; may occasionally lead to the development of an innocent or malignant tumor or a cyst, or may merely induce some trivial change in the subtle chemistry of the nerve-cells" (the author, in "Medicine," Feb., 1904). Injury may produce general epilepsy or Jacksonian epilepsy. If an identified traumatism exists, the surgeon should operate even after years. When the traumatism has not left definite evidence, the surgeon is justified in making an exploration any time up to the termination of the third year after the accident. The earlier the operation, the better the prognosis. The best prognosis of any form of epilepsy is given by Jacksonian epilepsy of traumatic origin.

"In focal epilepsy with evidences of skull injury or depression, trephining is imperative and somewhat promising. The dura should invariably be opened, even if it seems in good condition. A dural scar should be extirpated.

The brain should be examined by sight and by touch, and should be explored with the little finger and with the dural separator to well beyond the limits of the opening in the dura. If a tumor is found, it should be removed; if a scar upon the brain exists, it should be extirpated; if a cyst is discovered, it should be drained; and if there is any obviously damaged area in the brain tissue, it should be unhesitatingly cleared away. If nothing obvious is found on exploration, and if the attacks have been distinctly focal in origin, it is justifiable to extirpate the motor center from which the discharge seems to originate.

"When Jacksonian epilepsy has followed an injury in the motor region, the chances of effecting a cure are much better than they are when the epilepsy has followed an injury in the sensory region. When it has followed an injury in the frontal region, operation affords very little hope of cure.

"When the condition is not focal but essential epilepsy, the surgeon will remove a scalp scar; and if there is any evidence of bone injury, he will trephine the bone, open the dura, and explore the brain. It is needless to say, however, that in such a case he will not extirpate any of the cortex.

"In cases of focal epilepsy I use the osteoplastic method of operating. In cases of generalized epilepsy I use the simple trephine and leave the button of bone out, as a means of effecting a prolonged modification in the intracerebral pressure" (the author, in "Medicine," Feb., 1904).

Bramwell maintains that when traumatism is followed by epilepsy and the epileptic discharge starts from a cortical center which is not beneath the scar, the surgeon should trephine first at the seat of injury, and if this fails, he should trephine over the excited center.

5. **Jacksonian Epilepsy due to Gross Brain Disease.**—The treatment of this condition is the treatment of the brain disease.

6. **Epilepsy following Infantile Cerebral Palsy.**—In this group of cases the palsy is manifest. It is justifiable to operate upon a child but not later in life. The prospect of benefit is poor even in a child.

7. **The Post-hemiplegic Epilepsy of Adults.**—Operation is useless. Our conclusions are that these operations sometimes seem to cure epilepsy, but so, occasionally, does any operation. White records* ninety trephinings in which, though no cause was found for the epilepsy, great relief followed, and two cases were apparently cured; he mentions benefit or apparent cure following tracheotomy, ligation of the carotid artery, incision of the scalp, etc. The same effect may be obtained by a great shock, high fever, the administration of an anesthetic, or an accident. The fact seems to be that any operation, by means of nervous shock, may interrupt the epileptic habit; but in ordinary operations the fits tend after a time to recur and soon reach their old standard of frequency. In the special brain-operations with removal of obvious lesions or extirpation of discharging centers the fits usually recur, but they will rarely reach the old standard of frequency, and will be more amenable to medical treatment.

In non-traumatic chronic epilepsy without localizing symptoms trephining is not justifiable unless persistent headache calls for it as a means of relief from intracranial pressure. Annandale has recently advised us to consider experimental operation in such cases when the drug-treatment has failed

*"The Supposed Curative Effects of Operations *per se*," *Annals of Surgery*, Aug. and Sept., 1891.

and when the patient's condition seems hopeless. He says there is no chance of improvement without operation, and operation may possibly disclose a removable lesion.* After trephining for epilepsy five years should elapse without a convulsion before cure is reasonably assured; and if convulsions arise, they must at once be met by medical treatment. A man having once had a convulsion may at any time have others; hence he should always be watched. It is not unusual for a few convulsions to occur soon after an operation for epilepsy, and then to cease for a considerable time. These early fits result from habit (*habit fits*). Among the operative procedures suggested for the treatment of epilepsy may be mentioned circumcision, clitoridectomy, ocular tenotomy, ligation of the vertebral arteries, removal of the cervical ganglia of the sympathetic (page 777) (Alexander, Jonnesco, Jaboulay), and the actual cautery to the head (Féré).

Operative Treatment of Insanity (see the author in "Journal of Nervous and Mental Diseases," June, 1904).

1. **Epileptic Insanity.**—The conditions which call for operation on a non-insane epileptic (page 837) call for it on an insane epileptic. It is sometimes justifiable to operate if there has been a head injury, and operation may lessen the number and diminish the violence of the attacks. If focal seizures exist, we may proceed as for focal seizures in the sane. In status epilepticus we may operate to relieve pressure. It will be observed that operation is for the convulsions and not for the insanity.

2. **Paresis.**—I do not advocate operation in paresis. If we believe in traumatic paresis, we may be inclined to advise operation. Personally I do not believe that genuine paresis is ever cured; the lesions of the disease are widely disseminated; the pons, medulla, and even the cord may be diseased and the lesions cannot be removed.

3. **Non-traumatic Insanity and Paranoia.**—Operation cannot cure the insanity and is not to be advised.

4. **Hypochondriacal Delusions.**—Operation is useless. Some practice it with the idea of getting rid of a delusion by removing a part to which the attention is directed. Such attempts always fail, because it is the insanity which causes the delusion, not the delusion which causes the insanity.

5. **Operations for Traumatic Insanity.**—A psychosis constructed on the basis of a traumatic neurosis never calls for operation. The only cases in which operation is ever justifiable are those in which traumatism is the direct cause. Insanity may begin at once or soon after an injury, but is often unrecognized for weeks or even months. Nearly all of these cases are predisposed to insanity and the injury has been only an exciting cause. Traumatism is the direct cause in about 2 per cent of cases of insanity.

"An antecedent injury may have directly induced the alienation; it may have had no bearing at all upon the latter; or it may have produced an insanity by fear and shock, and not by creating a direct brain lesion. Again, the head injury, by increasing the individual's susceptibility to alcohol and to the effects of the sun, may, if this person drinks alcohol or exposes himself to the rays of the sun, be indirectly responsible for lunacy."

"In insanity following an injury to the head there may be various supposed causative lesions. A fracture of the skull, with or without depression;

* Edinburgh Med. Jour., April, 1894.

the development of an exostosis; sclerosis or softening of the cortex; edema of the membranes or of the brain itself; cerebral hyperemia or congestion; thickening of the membranes; adhesion of the membranes to the skull, to each other, or to the brain; new-growth; inflammation of the membranes; or minute, slowly developing, wide-spread nutritive changes. The injury may be assumed to be the cause of the insanity if the insane condition becomes manifest almost at once or soon after the accident; but if the symptoms do not appear until long after the accident, the traumatism may be considered to be the directly exciting cause in some cases, and not in others. It may be blamed if, between the time of the accident and the appearance of the insanity, there has been a marked change in the patient's disposition, temperament, or character; if he has developed headache, insomnia, irritability, passionate outbreaks of temper, moodiness, or lapses of memory; if he has plunged into immorality or excesses in alcohol; if he has displayed a tendency to neglect business or family obligations; and if he has shown increased susceptibility to alcohol and to the sun. Sometimes epilepsy may develop during this period. (Richardson, 'American Journal of Insanity,' July, 1903. The author's 'Address on Surgery,' delivered before the meeting of the Medical Society of the State of Pennsylvania, May 18, 1897.) If there were none of these intermediate changes in the normal mode of thinking and way of acting, one cannot count the traumatism as causative. Many persons that have received severe head injuries have shown these changes, but have never gone insane. I have been studying this point for a number of years, and have decided that quite a few patients that have been trephined for fracture or for meningeal hemorrhage have subsequently shown pronounced and permanent changes in character and disposition. Of the number that show such changes, many never go insane, but some do. Such an insanity is distinctly traumatic in origin." (The author in the "Journal of Nervous and Mental Diseases," June, 1904.) The prognosis is very unfavorable; some recover after operation, many do not. Some recover without operation. Sometimes operation cures by removing a lesion; sometimes by shock, etc. Some cures following operation did not result from the operation.

On what cases should we operate?

We should operate on cases "in which insanity has soon followed a head injury; if the site of the trauma is indicated by a scar, a depression of bone, local tenderness, fixed headache, or some localizing symptom, motor or sensory,—operation should positively be undertaken. In a case in which the insanity has developed later, in which the intermediate period between the injury and the development of the insanity has shown the change from the normal mode of thinking and way of acting previously alluded to, and in which the site of trauma is indicated by any of the evidences mentioned above—operation should positively be performed. One should not operate upon a case simply because there is a dubious record of an antecedent fall or blow, which merely suggests the possibility of a traumatic origin for the insanity. In any case in which there are positive signs of increased pressure it may be considered proper to trephine as a palliative measure." (The author in the "Journal of Nervous and Mental Diseases," June, 1904.)

Abdominal, Gynecological, and Genito-urinary Operations. If an insane person has a disease which is dangerous to life or which is productive of

pain, discomfort, or ill health, he or she is entitled to be cured, if possible, by a surgical operation. The removal of pain and other depressing influences may result in great improvement in the general health and in notable mental improvement. The operation may thus indirectly exercise a beneficial influence on the insanity, but the influence is not direct and it is never justifiable to do such an operation as oophorectomy upon an insane woman unless the condition of the ovaries would call for it in one not insane.

Operations on the Skull and Brain.—As a preliminary it is well to note that urotropin given by the mouth quickly appears in the cerebrospinal fluid, and that the fluid contains the maximum amount in from one-half hour to an hour after ingestion. The presence of this drug decidedly inhibits the growth of bacteria in the fluid. We believe it wise to give this drug in all cases in which meningitis is threatened or exists (S. J. Crowe, in "Johns Hopkins Hospital Bulletin," April, 1909).

Trephining (for a Fracture of the Skull).—Shave the scalp, scrub it with ethereal soap and sterile water, wash it with sterile water and then with alcohol or ether, scrub with a brush wet with corrosive sublimate solution (1:1000), and wrap the scalp in wet corrosive sublimate gauze (1:2000). The instruments required are a scalpel, a dissector, hemostatic, dissecting, and mouse-toothed forceps, trephines of several sizes (Fig. 464), a periosteum elevator, Hey's saw, rongeur forceps, a bone-elevator, scissors, straight and curved on the flat, a dural separator, a tenaculum, small curved brain needles and large curved needles for the scalp, a needle-holder; catgut, fine silk, silkworm gut, and Horsley's wax. Provide a sand-pillow. The patient should be anesthetized unless he is unconscious, and should be placed upon the back with the shoulders a little raised. A sand pillow is placed under the neck, and his head is turned away from the side to be operated upon. The position of the surgeon is such that the patient's head is a little to his left. A large semilunar incision is made with the base down, which incision goes through the periosteum, and the flap is lifted. The bleeding vessels of the flap are caught with forceps. The fracture is sought for and found. The pin of the trephine is projected beyond the crown and is set upon sound bone, the crown overhanging the line or edge of the fracture. The surgeon tries to avoid the region of a sinus or large artery. A gutter is cut in the bone, the pin of the instrument is withdrawn, and the trephining is completed. In going through the diploe bleeding is copious. The inner table feels very dense. Stop from time to time, clean

Fig. 464.—Galt's conical trephine

out the gutter in the bone with the dissector, and try the bone with an elevator to see if it is loose. When the fragment is loose enough, pry it out. If the surgeon desires to replace the button, hand it to an assistant,

who places it at once in a bowl of warm normal salt solution, kept warm by standing in a basin of water at 105° F., or who puts it in warm carbolyzed towels. The edges of the opening should be rounded with a rongeur, and the bone, if depressed, must be elevated. Sometimes it may be necessary to remove splinters and fragments of bone. After removing the fragments the edges of the opening should be smoothed by the use of the rongeur forceps. The

dura should be examined to see if injury exists, and hemorrhage must be stopped. Bleeding from the dura is arrested by passing a ligature of silk or catgut threaded in a small curved needle under the vessel on each side of the wound, and tying the ligatures (*suture ligatures*). Bleeding from the pia is arrested by direct ligation, by suture ligature, or by gauze packing. Bleeding from the diploe is arrested by the use of Horsley's wax. The wound is cleansed, the edges of the dura are sutured with catgut or fine silk, in some cases the button of bone is reintroduced, in other cases some chips are cut from the bone and scattered upon the dura, but in most cases no attempt is made to fill up the gap in the bone. The scalp is sutured with silkworm-gut, and horse hair or gauze drainage is employed for a day or two. Sterilized gauze dressings are put on, a rubber-dam is laid over them, and a gauze bandage wet with bichlorid of mercury is applied.

Instead of the trephine some surgeons use the chisel or gouge and hammer to remove a portion of the bone. Other operators, believing that this procedure may cause concussion, employ the surgical engine.

Osteoplastic Resection of the Skull.—Wolff suggested this operation, and in 1889 Wagner performed it. It is employed for the removal of tumors

Figs. 465-467.—Hudson's burrs.

and the Gasserian ganglion, for focal epilepsy, and for exploration. It is the operation of choice when a large opening is needed, as when the operation is, first of all, for diagnosis. A horseshoe-shaped incision is made through the scalp and pericranium, a groove corresponding to this incision is cut in the bone by special gouges or chisels. Some surgeons prefer a saw attached to a surgical engine; some make trephine openings and then cut from within outward by the Gigli wire saw (Obalinski). Cushing, of Baltimore, does what is called the *combined* method. I prefer this to any other plan. It is rapid and free from all danger of wounding the dura. I make two or several openings with Hudson's burr. This excellent instrument divides bone with great rapidity but does not divide the dura. In fact, one cannot divide the dura with it, for the burr binds as soon as it is through the bone. Figs. 465-467

shows Hudson's burrs. The sides of this bone flap are rapidly cut down by Hudson's improvement of the DeVilbiss forceps (Fig. 468). The upper margin is cut on a bevel with the Gigli saw. Because of this bevel when the flap is restored to place the upper edge of the flap rests on a shelf of bone and does not press on the brain. By whatever method performed, three sides of the bone-flap are cut through, but the bone is left attached to the scalp. It is a good plan to save the scalp from detachment by temporarily nailing it in place. The bone is then broken outward, the fracture taking place at the base of the bone-flap, the dura is opened a little distance from the edge (sufficient space being retained for sutures), and the exploration is made and the operation is performed. When we are ready to suture the dura, we note if the brain bulges greatly. If it does, manipulation will surely injure it, and we should cause the brain to recede before suturing by placing the patient nearly erect or by

Fig. 468.—Hudson's modified DeVilbiss forceps.

performing lumbar puncture. After suturing the dura the bone which is still adherent to the pericranium is restored to its proper place, and the scalp is sutured.

Besides restoring a flap of bone into position, or replacing a button of bone, or strewing the dura with bone-fragments, other methods of closing the opening have been practised—for instance, heteroplasty with a devaluated bone-plate and heteroplasty with a cellaloid plate or other foreign material.*

Osteoplastic Resection of the Skull by the Use of Stellingma's Trephine—The concussion inflicted by the mallet I believe adds to shock, may increase or cause hemorrhage, may extend a line of fracture or produce fracture, and may diffuse a purulent collection. For these reasons I prefer a different plan. The surgical engine gives satisfaction to some, but it is difficult to render it sterile, and it runs at such a high rate of speed that regulation is troublesome and the instrument is dangerous except in the most careful hands. The trephine shown in the cut (Fig. 471) has proved satisfactory. It has since been modified by substituting screws for spikes in the pivot plate. Dr. Park suggested putting a handle to the spiked plate to keep it from slipping. The area of bone to be removed is carefully determined, as suggested by Mills (see Figs. 469 and 470), the plate is screwed into the skull

* See Bretano in *Deutsche med. Woch.*, May 17, 1894.

the scalp is cut with the knife-blade, the base of the flap being made narrow; the saw is substituted for the knife in the instrument. The bone is cut by short, quick cuts, making no attempt to swing the saw through the entire length of the incision at each turn of the wrist. When the inner plate is nearly cut through, the division is completed by a small osteotome. The operation can be completed on an ordinarily thick skull in from eight to eighteen minutes. See article by author in "Annals of Surgery," July, 1903.) I still use this method, but not so frequently as formerly, preferring Cushing's combined plan to any other.

Trephining the Frontal Sinus.—This operation may be employed for inflammation of the lining membrane of the sinus or for empyema. Make a vertical incision in the middle of the forehead, starting one and one-half inches above the nasion and terminating at the root of the nose. The button of bone is removed and the opening is enlarged if necessary. The mucous

Fig. 106. Cranial areas for osteoplastic operations with the Stellwagen trephine, these areas corresponding to the regions of the left hemisphere, with definite landmarks. (Mills.)

Fig. 107. The motor region outlined on the skull, previous to osteoplastic operation with the Stellwagen trephine. x, Point for the insertion of the pin of the Stellwagen trephine; y-z, base line. (Mills.)

membrane is incised, the opening into the nose is found and is dilated, and a drainage-tube is passed into the nose from the sinus, the upper end being left in the sinus. In some severe cases Jacobson advises us to curet the sinus, to disinfect it by the use of silver nitrate or chlorid of zinc, and to insulate an "aseptic powder." In some cases resect the mucous membrane. I prefer an osteoplastic resection to trephining the frontal sinus.

Trephining the Mastoid (operation for mastoid suppuration, page 548).

Technique of Brain-operations (after Horsley and Keen).—Instruments as for fractured skull. In focal epilepsy a faradic battery is required. Always shave the scalp, and always antisepticize it. In localizations, mark out the fissure upon the scalp with an anilin pencil, with iodin, or with silver nitrate. Have the patient semirecumbent. Mark three points upon the bone with the center-pin of the trephine before incising the scalp (both ends

of the Rolandic fissure and the point at which the trephine is to be applied. Make a semilunar flap three inches in diameter, with the base below. Control bleeding in the flap by forceps pressure. If the operation is by trephining, the one and a half inch trephine should be employed, but if a smaller trephine is used, the opening must be enlarged with a rongeur. Before enlarging the opening, separate the dura from the bone by a dural separator. In most cases an osteoplastic flap is preferable to trephining. It is always employed in explorations for tumor. As a rule, open the dura and examine the brain. The dura is lifted by mouse-toothed forceps and is opened with scissors.

Fig. 471. Stellwagen's trephine.

Fig. 472. — Combined osteoplastic operation. First step. Incision through superficial tissues and bone.

along a line a quarter of an inch from the bone-edge, a broad pedicle of dura being left uncut. Hemorrhage is arrested by pressure and hot water or by passing a thread of silk or catgut around any bleeding vessel by means of a curved needle. In some cases packing must be retained or forceps must be kept on. In packing, endeavor to use but one piece of gauze, so as to avoid leaving in a forgotten piece. Upon opening the dura cerebrospinal fluid flows out, the stream being increased with each expiration. Absence of pulsation of the brain points to abscess or tumor, and a livid color indicates subcortical growth. An old laceration is brownish. If the brain bulges through the opening, it means increased pressure (tumor, abscess, effusion into the ventricles, etc.). After opening the dura employ no antiseptics, especially when the surgeon intends using electricity to locate a center. Irrigate only with warm salt solution. In operating for tumor the dura is opened and in some cases the brain is incised. The tumor is turned out by the finger, or, if this is impossible, by the dry dissector, the scissors, the dull knife, or the sharp spoon. If the entire tumor cannot be removed, it is sometimes proper to take away as much as possible. The removal of a portion often retards the growth of the remainder, and the trephining, by lessening cerebral pressure, relieves the symptoms and prolongs life. After removing a tumor arrest distinct points of bleeding with the ligature alone or the ligature passed around the vessel by means of a needle. Pack the tumor cavity with gauze and bring the

end of the strand out of the wound. Stitch the dura with silk and suture the scalp with silkworm-gut. In electrifying the brain faradism is employed of a strength about sufficient to move the fibers of the exposed temporal muscle. The best electrode is that of Cushing (Fig. 475). It is a "glass unipolar electrode carrying a fine platinum wire core, coiled into a spiral at the end" (Cushing, in "Keen's Surgery," vol. iii). The other pole is attached to an extremity "preferably on the homolateral side." During the electric test the

Fig. 473 — Combined osteoplastic operation. Second step. Bone flap turned down.

Fig. 474 — Combined osteoplastic operation. Third step. Showing exposure of brain by removal of dura flap.

patient must not be deeply anesthetized. A careful observer watches the muscular movements. If, for instance, the surgeon wishes to remove the thumb center, he moves the electrode from point to point until he obtains thumb movements. The region is sliced away bit by bit until the center which is responsible for the conclusive movements is removed. It will be found impossible to remove only the thumb center. Adjacent centers are sure

Fig. 475 — Showing terminal and connection of Cushing's electrode. (natural size). Instrument should be 16 inches or more in length.

be more or less damaged, and a certain amount of paralysis follows the operation. If we wish to *tap the ventricles*, Keen directs the trephine opening to be one and one fourth inches behind the external auditory meatus and the same distance above the base-line of Reid (Fig. 476, a). A grooved director or metal tube is passed into the brain in the direction of a point "two and one half to three inches above the opposite meatus." The normal ventricle will be entered at a depth of two to two and one fourth inches, but the dilated ventricle will be entered sooner. The moment of entry is marked by lessened

resistance and a flow of cerebrospinal fluid. Drainage can be mainly by introducing a rubber tube. This operation has been employed in cephalus. Kocher punctures the ventricle 2½ cm. from the midline and in front of the fissure of Rolandi. After an aseptic cerebral operation, as do not drain unless hemorrhage has been considerable. In many cases trephining replace the bone, but not when the bone is diseased, is in is very compact, or if it is desired to alter pressure. The dura is sutured continuous suture of silk or catgut, the scalp is sutured by interrupted worm-gut sutures.

Operation for Mastoid Suppuration.—The instruments required for this operation are a scalpel, a gouge, a chisel, a mallet, curets, a pit dissector, dissecting and hemostatic forceps, and needles. Provide a bag to place under the neck. An incision is made one quarter of an inch posterior to the auricle and down to the bone, and in the direction

Fig. 476.—Opening the mastoid antrum and the lateral sinus; exposure of the bone and puncture of the descending horn of the lateral ventricle. a, temporal bone; b, ascending cornu of lateral ventricle (1 cm. deeper); c, inner surface of petrous antrum; d, lateral sinus (Kocher).

long axis of the mastoid. The bone is bared and examined at a point in the line of the incision, which is on a level with the ear (Fig. 476, c). The bone will usually be found softened and thus open the mastoid antrum. The bone-opening is made at Macewen's *suprameatal triangle*, a space bounded by

of the zygoma, the posterior bony wall of the meatus, and an imaginary line joining the two. If the mastoid is opened in this triangle, the antrum is entered directly and there is no chance of wounding the lateral sinus. If, in the adult, pus is not found on opening the mastoid antrum, gouge downward and backward, but with great care, so as to avoid the lateral sinus. If there be any possibility of the existence of pus in the groove of the sinus, the sinus should be unhesitatingly exposed. After evacuating the pus from the mastoid gouge away bony septa, enlarge the opening between the mastoid and the middle ear with the gouge and remove the posterior bony wall of the meatus (avoid the facial nerve on the floor of the meatus), turn the head toward the side operated upon, and irrigate the mastoid with salt solution, dust with iodoform, pack with iodoform gauze for a few days, and then introduce a silver drainage-tube. Treat the causative ear disease. Shield and Macewen operate on inveterate cases of mastoid disease as follows: A thick flap is raised behind the auricle, the flap including the orifice of any sinus and being "left attached by its stalk." The auricle is "detached forward and the soft parts over the mastoid are turned backward by horizontal incision." The "lining membrane of the canal is separated from the bone." The mastoid is opened and dead bone and caseous matter are removed, overhanging edges are chiseled down, and the posterior bony wall of the external auditory meatus is gouged away. The skin-flap is pushed into the cavity and is held in place with pads of gauze. The margins of the flap may be sutured, but this is not necessary. Macewen calls this procedure "papering" the cavity with skin.*

If mastoid suppuration has established *abscess in the temporo-sphenoidal lobe*, trephine, one and a quarter inches behind and one and a quarter inches above the middle of the external meatus (Barker's point), and search for pus as directed on page 821. If *abscess of the cerebellum* exists, trephine below the line of the lateral sinus. "The position of the lateral sinus is indicated by a line running horizontally outward from the occipital protuberance to within about an inch of the external auditory meatus, and thence downward to the mastoid process" (Owen's "Manual of Anatomy"). If *infective sinus thrombosis* exists, break into the lateral sinus (Fig. 476. d) from the mastoid opening and proceed as directed on page 824.

Linear Craniotomy. Instruments as for any brain operation, plus, however, several kinds of rongeur forceps. Make a large flap. Trephine the skull a finger's breadth from the sagittal suture, and the same distance back of the coronal suture. Rongeur the bone away in a line parallel with the sagittal suture and a safe distance from the longitudinal sinus, up to a point in front of the lambdoidal suture. Remove the pericranium which covered the bone excised. Insert the dural separator, or pass it along the margins. In some cases an additional portion of the bone is removed over the fissure of Rolando. Various suggestions have been made as to the direction and situation of bone-sections. Bleeding is arrested and the flap is closed without drainage.

Removal of Gasserian Ganglion.—(See page 781).

Operation for Infective Sinus-thrombosis.—(See page 824).

* *Lancet*, Feb. 8, 1896.

The Decompression Operation (Decompressive Trephining).—This operation is employed particularly in cases of inoperable brain tumor. It differs from palliative trephining in the fact that the dura is incised and an opening left to permit of bulging of the brain. The bulging relieves pressure. By Cushing's method we get a hernia of the brain, but not a fungus cerebri. I have followed Cushing's recommendation in tumors, and have used it in fractures of the base of the skull, and I believe it saves vision and life (in the latter condition it is done on both sides).

Cushing and Bordley have performed it in cases of uremia and improvement has followed ("Am. Jour. of Med. Sciences," Oct., 1908). They suggest that the operation be used in certain cases of renal disease when medical

Fig. 477.—Sketch of the intermusculotemporal field of operation, showing exposure with intertemporal bone defect partly made (Cushing in "Keen's Surgery").

treatment and lumbar puncture have failed to abate uremic symptoms, or when blindness is impending.

The effect of the operation in cases of brain tumor is sometimes extraordinary. Its most prominent benefit is in abolishing choked disk. It must not be done directly over a tumor, because the bulging tumor might become the seat of hemorrhage.

It is, of course, useless in relieving blindness, for blindness means atrophy, but it is often very valuable in *preventing* blindness. When choked disk exists, operation should be done early even if there is good vision. If in advanced cases any sight remains, it should be performed. Now and then there is an unfavorable result, for instance, the development of retinal hemorrhages or the loss of vision, which was good previous to operation. (See Deschweinitz and Hal-

loway on "Operative Treatment of Papillo-edema Dependent upon Increased Intracranial Tension," "Therapeutic Gazette," July 15, 1909.) The permanence of the relief to the choked disk is variable. It is not always permanent.

Cushing's subtemporal decompression is done upon the right side, as a rule, but in some cases on the left side. An objection to doing it on the left side is that the bulging of the left temporal lobe may cause word-deafness. A curved incision is made through the skin and subcutaneous tissue, the flap is turned down, the temporal fascia is incised in the direction of the muscle-fibers be-

Fig. 478.—The suboccipital exposure showing opening partly made and Cushing's "cross bow" incision (Cushing in "Keen's Surgery").

neath it, the temporal muscle is split and not cut, the periosteum is separated from the bone, the soft parts are retracted, the bone is opened as the surgeon prefers, and the opening is enlarged with a rongeur. The dura is opened and radiating incisions are made through it toward the edges of the bone gap. The wound is closed by four layers of fine silk sutures.

Fig. 478 exhibits the exposure for suboccipital depression as done for subtemporal tumors. The same exposure is obtained in order to remove a cerebellar tumor.

XXIV. SURGERY OF THE SPINE.

Congenital Deformities. Myelocle or Rachischisis.—This condition is due to deficiency in the formation of the vertebral arches, the cord being rudimentary, the medullary plates having failed to coalesce, the central canal not having formed, and the endothelium which should line it being exposed. If the entire cord is involved, the condition is called *amyelia* or *total rachischisis*. If a part of the cord is involved, the condition is called *partial rachischisis*. In partial rachischisis a portion of skin is absent in the midline. At this area is a circular, dark-red focus surrounded by a very thin and glistening membrane which becomes continuous with the skin. A dimple at the upper part and a dimple at the lower part of the dark area indicates the situation of the central canal above and below. Victims of rachischisis are usually stillborn or at most live but a few days.

Spina Bifida. This is a deformity similar to the one just discussed, but in it the cord is much more developed. The first accurate description of it was given by Tulpus in 1685. It is a congenital sac of fluid due to vertebral deficiency, permitting protrusion of the contents of the spinal canal in the median line. In this condition the cutaneous epiblast is adherent to the spinal exiblast, because structures from the mesoblast have failed to grow between. The laminae or spines of one vertebra or of several vertebrae or of many vertebrae may be deficient, most frequently in the lumbosacral region. In very rare cases there is division of the vertebral bowing and the projection is forward and to the side. A case in which there are ununited laminae but no protrusion is called *spina bifida occulta*. Sometimes there are two protrusions in one person. In spina bifida the dura does not cover the sac because it is cleft as well as the laminae. There are three distinct varieties of spina bifida: 1. *Meningocele*. In this condition the dura is cleft (Hildebrandt), there is a protrusion of the arachnoid, fluid gathers in the arachnoid meshes and "distends this so as to form one continuous cavity which is traversed by nerve roots" (Henle, in "A System of Practical Surgery" by von Bergmann, Bruns, and von Mikulicz. Translated and edited by Wm T. Bull and Carlton P. Flint). The cord is not in the sac. 2. *Meningomyelocele* (the commonest form) is a protrusion of arachnoid, the sac containing cerebrospinal fluid, nerves, and cord-substance. The cord may spread upon the sac wall or it may pass through the sac and reenter the canal. A cutaneous dimple or furrow indicates that the cord is attached and hence is within the sac. 3. *Syringomyelocele* is great distention of the central canal, the sac-wall being formed of the thinned cord and the spinal membranes. A spina bifida varies in size from that of a walnut to that of an infant's head; it grows rapidly during the early weeks of life, it is usually sessile, but may present, where it joins the body, a definite constriction, or even a pedicle; the base of the sac is covered with healthy skin, and the fundus is covered only by thin epidermis or by the spinal membranes themselves. Pressure upon the tumor may diminish its size and increase the tension of the anterior fontanelle, and possibly cause convulsions or stupor. The cyst is translucent, and the margins of the bony aperture are distinct. Crying, coughing, or pressure upon the anterior fontanelle makes the tumor

more tense. Spina bifida is apt to be associated with club-foot, with hydrocephalus, and with rectal or vesical paralysis. Spina bifida usually causes death (90 per cent. of cases die during the first year of life). A few meningoceles and a very few meningomyeloceles undergo spontaneous cure by growth of the vertebral arches constricting the neck of the sac. The sac may remain distended with fluid or may shrink. Syringomyelocele is invariably fatal. The cause of death may be rupture of the sac or marasmus. The x-rays show the bony gap. *Spina bifida occulta* is a cleft in the vertebral column without any protrusion of the cord or the membranes. In this condition there is usually a profuse growth of hair in the skin over the bony gap and the hairy condition may be much more wide-spread. In some cases the hair is present at birth; in others it appears at puberty. Trophic changes and deformities may exist in the lower extremities.

Treatment.—Very small protrusions which grow slowly and are covered with sound skin may be treated by the use of a compress and bandage, by an elastic bandage, or by applications of contractile collodion. It was formerly regarded as proper to tap and drain the sac. Injection was used by many. The skin being cleansed, the child was placed on its side and a little chloroform was given. A fine trocar was plunged obliquely in at the side of the sac through sound skin, little or no fluid being drawn off, and 3j of Morton's fluid injected (iodin, gr. x; iodid of potassium, gr. xxx; glycerin, 3j). The trocar was withdrawn and the puncture was sealed with a bit of gauze and iodoform collodion. The child was put to bed. If injection proved successful, the sac was found to shrink; if the injection failed, it was the custom to repeat it at intervals of from seven to ten days (Jacobson, White). Surgeons now prefer excision of the sac. Whenever possible the incision should be through healthy skin. If the sac contains nerves they should be placed within the canal. Bayet treats it as he would a hernia. Robson in some cases excises the entire sac. Operations upon children much under the age of five have an enormous mortality. Operations are comparatively safe when the child reaches the age of five. We should not operate if there is hydrocephalus or extensive paralysis, if the mass is very large and growing rapidly, or if there are other marked deformities. A ruptured sac should be operated on at once, otherwise death is practically certain. Operations for spina bifida have been done successfully immediately after birth (Lovett, in "Am. Jour. Orthop. Surg.," Oct., 1907).

Sacrococcygeal Tumors.—Dermoids external to the sacrum are occasionally seen in this region. Dermoids also arise between the rectum and sacrum. In the lower sacral or coccygeal region the cutaneous structures sometimes fail of complete coalescence and a *post-anal dimple* or *sinus* is the result. Such a sinus is lined with skin and its wall contains numerous glands and often hairs. It may inflame or suppurate. If it blocks up at the outlet, a form of dermoid develops. Teratomata, lipomata, and hydatid cysts may develop in the sacrococcygeal region.

Treatment.—Dermoids require extirpation. If a post-anal dimple causes no trouble, it is let alone; otherwise it is dissected out. It may or may not be possible to remove teratomata. Lipomata and hydatids are extirpated.

Anosacral Cysts.—These cysts develop between the sacrum and rectum and originate from remnants of the post-anal gut and neurenteric canal. Such cysts may be multilocular or unilocular. They can be detected by a finger in the rectum.

Treatment.—Some of these growths are removed after osteoplastic resection of a portion of the sacrum; others are removed by incising the rectal wall.

Tumors of the Spinal Cord.—Tumors may arise from the cellular tissue, fatty tissue, the nerve roots, the membranes of the cord, or from the vertebra (*extramedullary tumors*). They may arise with the cord (*cord tumors proper or intramedullary tumors*).

Extramedullary Tumors.—Syphilomata, hydatid cysts, tuberculomata, and inflammatory masses or adhesions may compress the cord and produce symptoms indistinguishable from genuine tumor. Among extramedullary tumors are secondary carcinoma, sarcoma (primary or secondary), fibroma, myxoma, lipoma, chondroma, and neuroma. Dermoid sacral cysts may exist. Lipoma, fibroma, and certain cysts may be congenital.

Injury of the back sometimes seems to bear a causal relation to extramedullary tumors.

The symptoms are due to pressure upon nerve-roots and the cord.

Symptoms.—The most prominent symptoms are pain in the back and evidences of nerve-root irritation.

The early or irritative symptoms are pain and stiffness of the back, usually very severe and interfering with sleep, shooting pains in the area of the implicated nerve-roots, and sensory abnormalities in the same area. There may be hyperesthesia of a limited area. The area of distribution from one or two roots is involved in pain, sensory disturbance, and slight motor impairment. In some cases the nerve-roots of one side only exhibit irritation and the symptoms are strictly unilateral. In other cases the symptoms are bilateral, but are most marked on one side. In some cases the symptoms are symmetrically bilateral and indicate pressure upon the cord rather than upon nerve roots. Muscular spasms may occur. There may be lateral curvature of the back, the concavity of the curve being on the side of the tumor. Sooner or later paralytic symptoms come on (motor and sensory paralysis). They may be due to pressure upon and destruction of nerve roots or to compression of the cord. When anesthesia exists there may be a zone of hyperesthesia above its upper limit. As motor palsy develops from root compression the pain usually abates. The muscles undergo atrophy.

A tumor may, by cord pressure, produce the symptoms of compression-myelitis, locomotor ataxia, or myelitis. Contractures or paraplegia may arise from tumor. The location of the growth can be inferred by a study of the territory of paralysis and the zone of sensory disturbance. The tumor is always situated somewhat above the upper limit of anesthesia. In many cases the diagnosis is impossible. Gradually increasing painful paraplegia, with pain in the back and with hyperesthesia or anesthesia after a time appearing and ascending from the feet toward the trunk, points to tumor as a cause. The paralysis is usually spastic, but may be flaccid, or it may be spastic at first and become flaccid. In spastic paraplegia the reflexes are increased. In flaccid paraplegia they are decreased. In spastic paraplegia there are ankle clonus, the Babinski sign (extension of the great toe or all the toes when the sole of the foot is irritated), Gordon's paradoxical reflex (extension of the great toe or all the toes when pressure is made upon the deep calf muscles), and Oppenheim's reflex (extension of the great toe or all the toes when the handle of the percussion

hammer is drawn along the inner edge of the tibia so as to make pressure from above downward). Trophic lesions are apt to arise in the trajectory of nerve involvement. The sphincters are usually involved. Growths outside the membranes produce particularly pain and spasm; growths within the membranes produce especially motor paralysis and anesthesia. Symptoms that are unilateral were at first unilateral, or which are most marked on one side, are very significant.

Intramedullary Tumors.—These tumors develop in the substance of the cord. These are far less common than extramedullary growths. These growths are, as a rule, primary and solitary and do not produce symptoms of pressure until they attain the size of a hazel nut. The most common tumors are glioma, sarcoma, and tuberculoma. Syphiloma occasionally arises. Most tumors in cord substance are small, but the glioma may involve practically the entire cord. A tumor is often for a time limited to one side of the cord, but later it presses upon and finally involves the opposite side. When the cord is pressed upon, degeneration occurs. In some cases a wrench or bruise of the back is supposed to be causal. Glioma may be congenital.

Symptoms.—They are at first, in most cases, very uncertain. In some cases, however, paralysis develops early.

There is often pain in the back, but it is not nearly so severe as in extramedullary tumor. The most prominent symptom is a slow developing motor palsy. In some cases the palsy is at first unilateral, but later becomes bilateral. Irritative root symptoms are absent (spasm and darting pain). Anesthesia or hyperesthesia develop. The sphincters are involved and trophic disturbances arise. There may be spastic paraplegia or flaccid paraplegia. If the tumor is in or presses upon the anterior corner there will be limited muscular atrophy. Tuberculoma produces the symptoms of transverse myelitis.

In glioma there are paresis and muscular atrophy. Although sensibility to pain, heat, and cold are lost, sensibility to touch is preserved (sensory dissociation).

Treatment of Tumors of the Cord.—If syphilis is suspected, give the patient a course of heroic doses of iodid of potassium, and administer mercury hypodermatically or by inunction. In a focal lesion not due to dissemination of a known malignant growth, perform the operation of laminectomy to permit of exploration and possibly of removal. The laminae of at least three vertebrae should be removed and the tumor is looked for distinctly above the upper level of the zone of anesthesia. It is not necessary for the patient to wear a spinal support after the performance of laminectomy. McCosh truly says that operation for spinal-cord tumor is decidedly more hopeful than for brain tumor, because localization is much more accurate and removal can be effected with less permanent damage. Lloyd collected 51 operations; 10 per cent. died and 31 per cent. were actually cured or improved. Joseph Collins ("Med. Record," Dec. 6, 1902) collected 70 cases of spinal tumor, 30 of which were operated upon. In 12 the operation was a success, that is, the pain disappeared and motor power returned; in 8 the operation was partly successful, that is, the pain disappeared and the motor power improved, in 10 the operation failed and death occurred within a few weeks. If the tumor is found to be irremovable, McCosh suggests division of several nerve-roots to relieve the pain.

Acute osteomyelitis of the vertebræ is a rare disease; it may be associated with osteomyelitis of other bones, may be secondary to some distant suppurative focus, but may occur alone. Infections of the viscera not unusually accompany it. In many cases there is a history of trauma. Any part of a vertebra may suffer from it. This condition may follow cold, overexertion, or traumatism, and is more common in the first two decades of life than in elderly people. The process may be superficial, or it may involve the bone deeply and widely. Suppuration always occurs; sequestra generally form; and phlebitis is a dangerous complication. Any region of the spine may be attacked, but the lumbar region is particularly liable to invasion, next the dorsal, next the cervical. The sacral region is least often affected. The situation of the abscess varies with the situation of the disease. If the vertebral bodies are diseased, the pus passes forward (retropharyngeal, mediastinal, psoas, or pelvic abscess). If the vertebral arches suffer, the pus passes backward (lumbar or dorsal abscess). The membranes of the cord, the cord itself, the nerves, and the vertebral articulations are frequently involved in the process. Staphylococci, streptococci, or other pyogenic bacteria may be cultivated from the pus.

Symptoms.—The general symptoms are those of osteomyelitis. The local symptoms depend on the seat of disease. If the posterior portion of the column is diseased, there is a hard swelling, which, in the neck, is in the middle line; in the dorsal and lumbar regions, in the middle or to the side; and in the sacral region, invariably to one side.

Rigidity of the spine always exists. If the vertebral bodies are affected, rigidity is noted, the spine is tender, and special symptoms appear, their nature dependent on the region affected (retropharyngeal abscess, etc.). Occasionally symptoms of meningomyelitis are noted. The constitutional symptoms of sepsis are marked. The condition is sudden in onset, and purulent collections diffuse widely and rapidly. These points enable the surgeon to make a diagnosis between osteomyelitis and Pott's disease. In osteomyelitis angular deformity very rarely arises, because the patient is obliged to be recumbent and because hyperostosis is taking place. The mortality, according to Hahn, is 60 per cent. Death may be due to pachymeningitis, pneumonia, empyema, retropharyngeal abscess, invasion of the cord, or amyloid disease (H. S. Warren, "Boston Med. and Surg. Jour.," May 7, 1903).

Treatment.—The patient is kept recumbent. His constitutional treatment is such as will combat sepsis (food, stimulants, etc.). A parietal area must be incised and disinfected. If bone denuded of periosteum is found, it is touched with a solution of chlorid of zinc or with the actual cautery. If a sequestrum exists, it is removed. A drainage-tube is inserted and dressings are applied (Muller, Makins, Abbot, and Chipault).

Typhoid Spine.—It was pointed out by Gilney in 1880 that typhoid fever may leave as a legacy a painful, stiff, and weak back. Seventy-four cases of this condition have been reported (F. W. White, in "Jour. Am. Med. Assoc.," Feb. 13, 1908). The muscles of the back are found to be rigid and there is tenderness of one or more vertebræ. The pain may only be appreciated on motion, but in some cases there is aching even when the patient is at rest. The pain may be localized, may run into one or both thighs, or may be felt

in the abdomen. The symptoms arise at an uncertain period after the fever, develop rapidly, and are occasionally associated with transient episodes of fever. Kyphosis or lateral curvature may develop. (See L. W. Ely, "Medical Record," Dec. 20, 1902). Usually the patient is hysteric. The condition is due to osteitis and periosteitis, or chronic osteomyelitis. The prognosis is excellent.

Treatment.—The use of a plaster or leather jacket; counterirritation by the hot iron; later, massage and electricity.

Cervical Rib.—This condition was first described by Hunauld in 1743. The anterior limb of the transverse process of the seventh cervical vertebra, which has an independent center of ossification, may develop into a separate bone of large size, known as a cervical rib. Such a rib may form on one

Fig. 479.—Cervical ribs

side or on both. It may scarcely reach beyond the transverse process, it may project well beyond the transverse process and have a free end, or it may constitute a complete rib which fuses anteriorly with the sternum, the cartilage of the first rib, or with a cervical rib of the opposite side.

Most instances described were found in the dead body, although Tillmanns collected 26 cases among the living (Carl Beck, in "Jour. Am. Med. Assoc.," June 17, 1905). Of late x-ray findings indicate that the condition is much more common than was formerly supposed. I have seen 4 cases. It may never produce any uneasiness, and hence may escape detection and seldom does produce trouble in youth. It may lead to damage of the subclavian artery (Keen's case developed aneurysm), or gangrene of the hand may result from bending or blocking of the vessel, or neuritis of the brachial plexus may arise from pressure. When sufficiently large to produce venous or vascular trouble,

a cervical rib can be felt and the pulsating artery over it is very distinct and higher than natural in the neck. The x-rays confirm the diagnosis. The treatment, when the rib is causing trouble, is excision of the rib with its periosteum (page 720). (See Kammerer, in "Annals of Surg.," Nov., 1901, on "The Diagnostic Difficulties.")

CONDENSED DIFFERENTIAL DIAGNOSIS TABLE OF SPINAL DISEASES AND CONDITIONS WITH WHICH THEY MAY BE CONFUNDED.

Spinal Curvatures.—There are four chief forms of spinal curvature: (1) Lateral curvature (the scoliosis of the older surgeons); (2) posterior curvature (the excorvation, gibbosity, or kyphosis of the older surgeons); (3) anterior curvature (the lordosis of the older surgeons); and (4) angular curvature (from spinal caries). The normal spine has four curves: the *cervical* curve, the convexity of which is forward; the *dorsal* curve, the convexity of which is backward; the *lumbar* curve, which is convex anteriorly, and the *pelvic* curve, which is concave anteriorly. The dorsal and the pelvic curves, which are primary, are due to the formation of the cavities of the chest and pelvis, and depend upon the shape of the bones (Treves). The cervical and lumbar curves, which are compensatory, depend upon the shape of the intervertebral discs, and only appear after birth when the erect position is assumed.

Fig. 480.—Lateral dorsal curvature to the right, and compensatory lumbar curve to the left

Scoliosis.—Scoliosis is a non-pathologic distortion of the spine characterized by rotation and lateral bending, hence the name, rotary lateral curvature (Plate 8). It is functional or organic.

Functional scoliosis is caused by any prolonged alteration in the relationship normally existing between the axis of the shoulders and the axis of the hips.

SPINAL CURVATURE.

PLATE 8.

Rotary lateral curvature of the spine.

1

The etiologic factors depend upon the maintenance of faulty postures in occupations, especially during period of growth. School-life is especially influential in producing the condition because school furniture is adapted to the average requirements of a given class, and therefore a very small proportion of pupils are able to find desks and benches that are suitable. Properly furnished modern schools are supplied with desks and seats that are adjustable to each occupant. Gould ("The Ocular Factors in the Etiology of Spinal Curvature," *H Augustus Wilson, "New York Medical Journal," July 12, 1906*) has directed attention to the errors of refraction that produce head tilting and thereby induce scoliosis. In adults, scoliosis is observable in blacksmiths, fencing masters, and waiters, where excessive use of the right arm produces an asymmetric posture of the body.

When functional scoliosis is not corrected or occurs in rachitic or indolent children, it results in organic or permanent changes in the contour of the bones composing the spinal column. Organic scoliosis may be congenital, caused by prenatal deficiencies or augmentations of the spinal column (see X-ray).

There is no pathology, but post mortem examinations reveal a confirmation of Wolfe's law that prolonged alteration of the normal functions always results in changes of anatomic structures. In extreme cases the bones of the spinal column become extensively altered in shape, the ribs are altered in contour, and the thoracic and abdominal viscera are forced into unnatural positions and assume abnormal shapes, their functions often being materially altered.

Diagnosis.—The patient is usually taken to the physician because of apparent elevation of one shoulder, or because one hip is thought to be larger than its mate, or one mamma larger than the other. Dressmakers and corset makers are generally the first ones to direct attention to the faulty posture (as scoliosis occurs in eight girls to one boy). A patient suspected of having scoliosis should be nude at the time of inspection, as clothing hampers the normal action and tends to conceal the movements of the body. The accompanying diagnostic table (page 858) is a condensed comparative statement of the important features in diseases and conditions that may resemble scoliosis in some respects. It is only by carefully studying the symptom-complex that a definite decision can be reached. It is frequently observed that patients with mild types of functional scoliosis can sit or stand erect for a few minutes and thereby deceive even a critical observer. The habitual posture, as well as the rapidity with which the patient returns to the distorted position after temporary voluntary correction, demand careful attention. Young children, when aided by parents or teachers, often temporarily assume an approach to a normal posture without actual correction. The ease with which their surrounding joints yield in compensatory action is often overlooked. A patient with contracture of the pectoral muscles will elevate the shoulders into an apparent correction of stoop or round shoulders instead of throwing the shoulders well back, a posture that is to them impossible.

Goldthwait has directed attention to forward curves of the scapula that often present in patients who are stoop-shouldered and has devised an operation for its correction.

In the same way, a patient who has preternatural contracture of the hamstring tendons, either unilateral or bilateral, will often conceal that condition

by bending the knee or knees enough to permit the pelvis and trunk to bend forward.

Treatment consists especially of removing the cause. If the eyes produce head tilting, proper refraction will be necessary. Adenoids should be removed. The clothing should be regulated to avoid constriction and the shoulder straps should fit close to the neck and not be allowed to slip on to the shoulder-joint.

Contractures of the pectoral muscles should be stretched by corrective manipulations. Hamstring contracture should be removed by corrective manipulation. Hoke ("A Study of a Case of Lateral Curvature of the Spine: A Report on an Operation for the Deformity," "American Jour. Ortho. Surg.," vol. 1, November, 1903, p. 169) has devised an operation of rib resection for cosmetic purposes. Every effort should be made to prevent the *occurrence* of scoliosis. The successful treatment of scoliosis depends on preventing its progress. It is essential that it should be fully understood that braces of any kind, as corsets and constricting clothing, are not only useless and irrational but positively harmful. Especially injurious are the ready-made varieties of braces and spinal supports. Each individual patient requires careful study to determine the special characteristics that may be present. Remedial measures should be employed that meet the peculiar individual requirements of each case.

School gymnastics are generally more harmful than beneficial in cases of scoliosis. No one but a physician should prescribe the gymnastic work. The soft bones may be still further distorted by injudicious exercises.

The first requirement in the application of applied physical culture is to secure the hearty cooperation of the patient. Without such cooperation progress cannot be expected.

No gymnastic apparatus of any kind is required when the patient can be instructed in the proper methods of autoresistance. There are over four thousand movements of the body that may be employed in remedial physical culture. From this vast assortment those may be selected that are suitable to the peculiar conditions of the patient. At first the least tiresome forms are to be employed, and gradually and progressively others are resorted to until the patient presents a strong robust personality. Usually about a year is required for the purpose, as the progress must be essentially educational. Training in developing muscle action goes hand in hand with instruction in walking, in sitting, and in all the postures assumed by the human body in the various occupations of the patient.

In organic scoliosis, where the distortion is more or less of a permanent character, much can be accomplished in preventing the progress of the condition as well as in aiding correction by removing any rigidity that may be present. By increasing the flexibility we facilitate muscular development in much the same manner as in functional scoliosis.

When rigidity is present it must be considered in the same light as rigidity of any other joints. Its presence prevents muscular development. Manipulative measures are similar in effect to those employed in fibrous ankylosis of any joint, and are peculiar to the parts involved. In the majority of cases the force for manipulative correction must be applied through the interposition of the ribs, and the great danger of producing fractures of these structures should be realized. One familiar with the dangers as well as the technic will have

little difficulty in avoiding the former and applying the latter. In no instance is a layman warranted in undertaking the procedures that are necessary, and only a physician with experience in scoliosis will successfully carry such cases to a satisfactory termination.

In severe cases of organic scoliosis plaster-of-Paris jackets and other forms of fixation appliances are occasionally applied for definite purposes during the developmental stages. Such appliances should be made to order to fit the peculiarities of the patient and should never be the shop-kind that are extensively advertised. Much valuable time is often lost during the use of unmechanical and unsuitable apparatus, during which the bony changes become permanent and beyond repair.

Anteroposterior curvature (not from spinal caries or from hip-joint disease) is an increase of the normal anteroposterior curves. Increase of the dorsal curve is *posterior curvature*, *kyphosis*, or *excurvation* (Fig. 481, A); increase of the lumbar curve is *anterior curvature*, *lordosis*, or *saddle-back* (Fig. 481, B). Both lordosis and kyphosis are apt to be present. Scoliosis has nearly always some anteroposterior curvature associated with it. Lordosis is apt to be compensatory, to prevent the center of gravity going too far forward. Lordosis is found in pregnant women and in very fat men. In an old man kyphosis arises from flattening out of the vertebral discs from pressure. Rheumatic gout may cause anteroposterior curvature. Anteroposterior curvature is often due to paralysis of the erector spinæ mass (from infantile paralysis). Pseudohypertrophic paralysis causes lordosis.

Symptoms and Treatment.—The symptoms of anteroposterior curvature are as follows: the thorax is flattened or pigeon-breasted; the shoulder-blades are widely separated and the scapular angles project; the abdomen is protuberant; the patient complains of backache and soon tires. A recent kyphosis disappears when the patient lies upon his stomach. The facts that the erector spinæ muscles are soft, and that pain is absent on concussion transmitted to the back, separate kyphosis from caries. Lordosis is unmistakable. When the spine is movable, employ the same plan of treatment as in lateral curvature, suiting the gymnastics to the deformity (Roth). In painful kyphosis with partial ankylosis endeavor to make the ankylosis complete in order to prevent pain, obtaining this result by applying a plaster jacket which laces up and letting the patient wear it for several years.

Angular curvature (*spinal caries*; *spondylitis*; *Pott's disease*) is usually due to tuberculous caries of the vertebral bodies, and occurs particularly in children who are predisposed to tuberculosis, but it may arise at any age. Any portion of the spinal column may be attacked. The dorsolumbar region is most prone to suffer. The chief cause is tuberculosis, but syphilis and secondary cancer of the vertebra are occasional causes, and acute osteomyelitis is a very rare cause (page 856). Blows or strains may act as exciting causes. Angular curvature may develop after an exanthematous fever.

The cancellous tissue of the anterior portion of the vertebral body becomes

Fig. 481 — Kyphosis (A) and lordosis (B).

primarily carious, or the inflammation begins in an intervertebral disc. (The changes of tuberculous osteitis have previously been set forth pages 229, 256, and 505.) The body of the vertebra and the vertebral disc are destroyed, and the process extends to adjacent vertebrae. The weight which rests upon the spinal column causes softened bone to crumble, compresses the diseased vertebrae and discs, and produces angular deformity (the anterior part of the column formed by the vertebral bodies is shortened, the posterior part is not, and hence the spines project). In some cases the disease is spontaneously arrested by organization of inflammatory products, and ankylosis (fibrous or bony) in deformity is nature's cure. In most cases, however, the disease spreads and caseous pus is formed, which, according to the point of formation and the route it takes, causes lumbar abscess, dorsal abscess, psoas abscess, or post-pharyngeal abscess (pages 161 and 162). In some cases the spinal cord is compressed, but in most cases it is not, and even when it is compressed, paraplegia is rare and is usually temporary. Compression of the cord may be caused by the displaced vertebrae or by inflammatory material or caseous matter between the bone and dura mater, but is most often due to pachymeningitis. Caries of the cervical region constitutes a more dangerous disease than caries of either the dorsal or the lumbar region (*dangerous* pressure occurs more easily). Death may be caused by exhaustion, sepsis, hemorrhage, amyloid disease, pneumonia, peritonitis, pleuritis, tuberculous dissemination, pressure upon the cord, or inflammation of the cord or its membranes.

Symptoms. The sufferer from Pott's disease, if a child, grows tired easily, his disposition alters, he becomes moody and irritable, and complains of vague pains in many places, is disposed to lean, rest, or lie down, and walks with the back rigid, which produces a peculiar gait. A painful spot is found by pressing upon the spines. Paradoxism to the back causes pain. Spasm of the erector spinae mass is detected (Hilton, Golding-Bird). It is not proper to seek to develop pain by jarring the back or by pressing the head downward. The posture of the child and the muscular rigidity prove the existence of inflammation, and to seek to develop pain by the methods referred to may do harm, and at best can only call attention to what is already known. Pain in the back, which is increased by motion, by pressure, and by vertebral jars, may be absent until late in the case. Distinct pain and tenderness in the back often mean abscess-formation. Neuralgic pains pass into distant parts (sciatica, intercostal neuralgia) and are often linked with muscular spasm. A chronic bilateral pain in the trunk or extremities is suggestive of Pott's disease. "Chronic bilateral belly-aches in children are almost diagnostic" (Jordan Lloyd). The pain of dorsal caries can be relieved by lifting the shoulders; the pain of cervical caries, by traction on the head. Cramp in the legs occurs in dorsal and in lumbar caries. The presence of the knuckle due to bending the spine at an acute angle is a very important sign of the disease. In many cases angular deformity appears late; in some cases it does not appear at all. An angular deformity is detected sooner in those regions where the normal curves are posterior than where the normal curves are anterior (Jordan Lloyd). The deformity appears early in the dorsal region, but late in the cervical and lumbar regions. In some rare cases lateral deformity occurs. Rigidity is an early sign of great importance. It is always present. Rigidity is manifest very early in cervical

caries, tolerably early in lumbar caries, late in dorsal caries. Lloyd gives the following practical rules to enable us to detect rigidity.* In the cervical region: seat the patient in a chair and tell him to nod the head affirmatively. Stiffness in nodding points to occipito-atloid disease. Tell him to look far to the right and then far to the left. Stiffness of these motions suggests atlo-axoid disease. Tell him to place his shoulders against the back of the chair and carry his eyes back along the ceiling. Stiffness in this movement indicates disease below the second cervical vertebra. It is practically useless to examine the dorsal region of an adult for rigidity, but such an examination can be made in a child. Place the patient prone on an adult's lap, mark the tip of each spinous process with an anilin pencil, then make the child stand up straight on the floor, and observe if any of the pencil marks fail to come nearer together. If it is seen that two or more marks do not approach each other, there is rigidity which prevents approximation. To test for rigidity in the lumbar

Fig. 482.—Plaster of Paris jacket (Sayre).

Fig. 483.—Plaster of Paris jacket and jury-mant applied (Sayre).

region lay the naked patient prone upon a couch. Grasp the patient's ankles and raise the pelvis from the couch. If the lumbar spine is flexible, the pelvis can be lifted without raising the chest from the bed, and the maneuver deepens the hollow of the loin. If the lumbar spine is stiff, the maneuver lifts the trunk and produces no alteration in the vertical outline of the lumbar spines. If a child with Pott's disease is asked to pick up something from the ground, because of rigidity or pain on movement he will not bend the back, but will bend the knees or get upon the knees. Paralysis may exist, and it is due to pachymeningitis more often than to pressure from bone. Cervical caries causes dyspnea and torticollis, the head requiring support with the hands. Dysphagia indicates abscess. In adults the first signs of Pott's disease to attract attention are headache, backache, neuralgia, girdle-pain, cramp, or even paralysis. In abscess due to caries of the dorsolumbar vertebrae the pus usually enters the psoas muscle and passes out of the pelvis below the junction of the middle and outer thirds of Poupart's ligament.

* Birmingham Med. Review, April, 1897.

It may point here or may pass to the inner aspect of the thigh and point a little below the spot where a femoral hernia is met with if it exists. In a psoas abscess a mass is always felt in the iliac fossa above Poupart's ligament; in a hernia no such mass exists (J. T. Rugh). In sacral caries there is no deformity and frequently no pain. The diagnosis becomes apparent when bilateral abscess is detected in the buttocks or groins (Jordan Lloyd). If an abscess due to spinal caries opens spontaneously, healing will not occur, but mixed infection takes place and death, as a rule, soon follows.

Treatment of Caries of the Spine.—When recent caries of the spine is active and affects a child; when it is accompanied by pain and fever; and when paralysis threatens, insist upon perfect rest. Place the child supine on a hard mattress, and, if possible, take it, while in a rolling bed, out of doors daily. Leeches, blisters, or the hot iron over the area of pain may do good. When the activity of the process abates, apply a fixation apparatus. In diseases at or near the vertebro-occipital articulation, as long as dyspnea persists, keep the patient supine with a small hard pillow under the nape of the neck (Hilton) and a sand-bag on each side of the head and neck. After several months mechanical support can be given by Furneaux Jordan's method. Jordan applies his support as follows: The patient lies on a flat, hard table, his arms are raised above his head, and traction is made upon the head by means of a pulley and a weight. Cotton pads are placed over the ears, the back of the neck, and the clavicles, and are held in place by a flannel bandage applied as a figure-of-eight on the head, neck, and chest. The flannel bandage is overlaid with plaster-of-Paris bandages.* In disease of the cervical region below the axis, or of the dorsal region above the seventh vertebra, use Sayre's jury-mast (Fig. 483), or some other form of head support. Instead of the jury-mast a steel upright may be used to hold the head rigid. Sayre's appliance relieves the spine from the weight of the head and acts admirably. In most cases of dorsal and lumbar caries a steel, leather, or plaster jacket as a fixation apparatus must be employed. The best of all fixation apparatus is Sayre's plaster-of-Paris jacket applied while the patient is suspended (Fig. 482), or better, while the column is in hyperextension. The Sayre apparatus applied in this manner is used for the treatment of caries of the lumbar region and the lower half of the dorsal region. When all subjective signs cease, substitute for Sayre's jacket a felt or sole leather jacket which laces down the front. Caries of the upper half of the dorsal region is often treated by a Sayre's jury mast (Fig. 483); but if the jury-mast fails, it may be necessary to place the patient horizontally in "an open corset, fitted to the back from occiput to sacrum, and combined with pulley extension to the head and pelvis."†

During the course of caries of the spine have the patient eat fat forming and nutritious food, insist on a plentiful supply of fresh air, and administer tonics and antituberculous drugs. Sea-air is very beneficial. When all active disease ceases and only angular curvature remains, use an apparatus to combine extension with mechanical support, the plaster jacket being generally employed.

Spinal abscesses are treated as indicated on pages 163, 164, and 707.

* See "Children's Deformities" by Walter Pre.

† Jordan Lloyd, in Birmingham Med. Review, April, 1897.

Paralysis in Pott's Disease.—Partial or complete motor and sensory paralysis may develop in the course of vertebral caries. It may be due to the pressure of tuberculous material or to pachymeningitis with thickening of the membrane. In only 2 per cent. of cases of paralysis is the paralysis due to the pressure of angled bone (Willard). The paralysis may come on gradually. There are weakness in walking or actual inability to walk, exaggerated reflexes, muscular rigidity, and impaired sensation in the legs, and loss of control of the bladder and rectum. Caries in the high dorsal region is more apt to result in paralysis than in any other region, because of the small size of the canal. Pressure in the cervical region is highly dangerous.

Treatment.—We must remember that angulation is the rare cause, tuberculous masses the common cause. Treatment for paralysis due to tuberculous masses is the full open-air treatment of tuberculosis, with rest, fixation, and progressive straightening of the spine. The patient is kept in bed (see Treatment of Tuberculosis, page 246) on a Bradford frame and with his head overextended (Willard). If after one year the condition is not notably improved, do laminectomy and clear away tuberculous masses. If angulation is the cause of the paralysis, we consider gradual correction, forcible correction, and laminectomy.

Gradual Correction of Angular Deformity.—Pressure is made upon the hump with the hand, and while the hand is thus held the weight of the body is allowed to bear upon it above and below. Something is perhaps gained and then plaster of-Paris is applied, somewhat later a little more gain is obtained, and so on. This method is safer and more satisfactory than forcible correction.

Forcible correction of angular deformity is advocated by Chipault and Calot in cases of Pott's disease without abscess. Forcible correction is only used, if used at all, in angular deformity of the middle and lower part of the dorsal region. It is not used in the cervical, upper dorsal, or lumbar regions. Before it is used a skiagraph should be taken, to show if bony ankylosis exists or if there is an abscess. If there is an abscess, it must be treated surgically, and must heal before forcible correction is attempted. If bony ankylosis exists, it must not be broken down. Only recent cases are suited for this treatment, and only cases in which very few vertebrae are involved (Gabaert). The operation is unjustifiable if any organs are tuberculous, and if a patient is in very poor health. It is said by its advocates to be particularly indicated when the deformity interferes with respiration or digestion, or when there is paraplegia, especially if paraplegia is due to disease of the mid-dorsal region. The advocates of the operation claim that it does not injure the cord or its membranes. The operation is not entirely safe, and a number of deaths have been reported. Chloroform must not be given, as it seems to possess special dangers in this condition. Gabaert* points out certain disasters which may follow forcible correction; they are: death during anesthesia; rupture of an abscess; subsequent paralysis of the legs and bladder; disseminated tuberculosis; and shock with convulsions and death. Forcible correction can be carried out as follows: the patient is anesthetized with ether and is placed face down; one assistant holds the feet, another the head, another supports the abdomen, and another the pelvis. While strong traction is made on the head and feet the surgeon

* Ann. de la Soc. Belge, July 15, 1898.

makes *forcible* pressure on the projection. After the correction of the deformity a plaster-of-Paris support is applied so as to include the neck, trunk, and pelvis, the site of the gibbosity being left exposed in order to avoid ulceration. A plaster-of-Paris support is used for at least six months. After forcible correction a large gap exists, and this does not fill up with bone, but with dense fibrous tissue, and in some cases the spines and laminae ankylose. When the support is first removed, there is usually a reappearance of the deformity to some degree. In some cases Cabot resects the spines and laminae of the diseased vertebrae, and performs osteotomy of the ankylosed vertebral bodies.* Personally I do not believe in forcible correction and I do believe that the alleged dangers are real dangers and that the operation is unsafe.

Laminectomy is warmly advocated by some surgeons for paraplegia from spinal caries. This operation is rarely necessary, but in some few cases is imperatively demanded. Many cases recover from paraplegia without operation—operation in these cases has a very heavy mortality (25 per cent.); and many are not benefited at all by it. If degeneration of tracts in the cord has occurred, operation cannot help the paralysis. Nevertheless, in some cases laminectomy has certainly cured palsy and saved life.

Laminectomy should not be undertaken until treatment by rest and fixation and extension has been applied for at least one year. Laminectomy may become necessary in cervical caries to prevent asphyxia. The operation enables the surgeon to remove masses of inflammatory material which make pressure on the cord, and also to free the cord from pressure due to angulation. The dura should not be opened unless there is evidently trouble beneath it, in which case it is incised and any tuberculous area removed, the dura being subsequently sutured. Ménard removes the transverse processes of the diseased vertebrae and the heads and necks of the associated ribs in order to give the surgeon access to diseased vertebral bodies.

Spondylitis Deformans (*Bechterew's Disease*).—This is the name usually applied to osteoarthritis of the spine (page 650). In this disease osteophytic formation takes place at the vertebral borders, and the vertebrae become ankylosed. The vertebral bodies, as a rule, are most affected by the disease, but any portion of a vertebra may be attacked, and often the heads of the ribs are anchored to the spine by bone.

The disease may begin in infancy, childhood, youth, adult life, or old age.

Symptoms.—There are decided and persistent pain and tenderness of the spine, and occasionally evidence of pressure on the nerve-roots. Early in the case deformity is apt to occur, because at this period there is inflammatory softening.† The deformity is not angular, but is usually a total kyphosis, the column being bent forward from above and made into a single curve. Lateral curvature may occur. In many advanced cases and in some comparatively recent cases the spine becomes rigid and ankylosed, and when it does, there may be evidences of irritation of the posterior nerve-roots. In this condition there is rigidity of part or of the entire spine, other joints escaping. If the entire spine is involved, there is rigid cervico-dorsal kyphosis, a condition which causes the neck to stick forward and the head to appear as if forcibly driven down between the shoulders. If the entire spine is involved, the lumbar spine is rigid and the normal lumbar curve dis-

* F. Cabot, in *Archiv Prov. de Chirurgie*, Feb., 1897.

† J. Jackson Clarke's book on "Orthopedic Surgery."

appears. As a consequence the patient stands in an unnatural attitude, the hips and knees being partly flexed, and the legs and feet being in a condition of external rotation. In Bechterew's disease there are compression of the posterior nerve-roots, severe pain, muscular atrophy, and ascending degeneration of the cord. What Marie calls *spondylitis rhizomelique* is said by Osler to be a form of arthritis deformans. There is rigidity of the spine, shoulders, and hips, but no nervous lesions, as in Bechterew's disease.

Treatment.—Cure is impossible, but amelioration can be obtained.

The local and constitutional treatment is as for osteo-arthritis in any region (page 652). If curvature begins, a mechanical support must be applied.

Injuries of spinal ligaments and muscles, which may complicate more serious injuries or may exist alone, are caused by wrenches, twists, and violent muscular efforts (as in lifting). Railway accidents may be responsible for these sprains and strains. The injury is called "*railway spine*" when it is caused by a railway accident.

Symptoms.—Injuries of the back, even without cord-injury, are frequently linked with very deceptive nervous symptoms. Symptoms are often severe, but are usually temporary. In some few cases the symptoms are persistent. Secondary disease of the cord is extremely rare. Any region may be affected, but the lumbar is most usually injured, and the entire spine may suffer. The three marked symptoms are pain, tenderness, and stiffness of the back. At the time of injury, and for a while after, there is often marked shock, and hysterical excitement is occasionally observed. The cardinal symptoms may arise very soon, but may not become severe for a day or two. The pain is not acute when at rest, but becomes acute on movement.* The pain is felt in the back, and sometimes darts into the extremities. The muscles of the back are rigid, the spasm being due to pain. The patient is very careful not to twist or bend the spine, because to do so increases pain. In a one-sided injury the rigidity is unilateral, and this symptom cannot be simulated. Often, but by no means always, the region of the back is swollen and the skin is discolored. The tenderness is not of the skin, but of the muscles. Firm pressure on a spot of real tenderness causes rapid pulse (Mannkopff). The vertebral spines are regular and are not mobile. There is no distant paralysis or hyperesthesia unless the cord is damaged (though in some rare cases the bladder and the rectum are paralyzed when no cord-lesion can be detected, and hyperesthesia may exist over the spines). Moullin tells us that the extremities feel weak because they are deprived of proper support on account of the immobility of the muscles of the back. For the same reason the action of the abdominal muscles is interfered with, and the power of micturition and of defecation is impaired (there are constipation and difficulty in emptying the bladder).

The **treatment** of recent injuries comprises rest, the application of an ice-bag, and leeching over the painful area. After a day or two hot fomentations, tincture of iodine, compression by adhesive strips, and inunctions of ichthyol and lanolin are used; and, later still, massage, douches, and frictions with a stimulating liniment are employed. Phenacetin helps to relieve pain, though in some cases opium is necessary.

* Moullin on "Sprains."

Traumatic neurasthenia is apt to arise after the *immediate* effects of the accident subside. In this condition the patient grows tired easily and complains of pains and aches in the back and loins, interfering with or preventing work; paresthesia and numbness exist in the extremities; in many cases sexual intercourse is impossible because of premature ejaculation or of incapacity for erection; there are dyspepsia, eye-strain, insomnia, loss of memory, rapid and irregular pulse, cardiac palpitation, and mental depression or confusion. The reflexes are usually exaggerated, but they can be exhausted more easily than can the exaggerated reflexes of organic cord disease (because of irritable weakness). Some rigidity and tenderness exist in the back, and the skin over this region is often hyperesthetic. Attacks of retention of urine may occur. Hypochondriasis is not unusual.

Treatment of Traumatic Neurasthenia.—Employ rest, tonics, massage, douches, and frictions to the back. Secure sleep, and endeavor to bring about a gain in weight. If sexual incapacity or seminal emissions worry the patient, dilate the urethra with steel sounds.

Traumatic hysteria develops only in those predisposed by a neuropathic hereditary tendency; traumatic neurasthenia may arise in any one. In the first-named disease the accident is only the *exciting* cause; in the second disorder it is *the* cause. Many cases of so-called "railway spine" are really examples of traumatic hysteria. Traumatic hysteria and neurasthenia may be associated. Neurasthenia is a condition of exhaustion associated with a number of chronic disorders; it forms a foundation on which hysteria is apt to build its structure. The structure of hysteria is made up of morbid impressionability, hyperesthesia of centers, lowered self-control, and sensitiveness of the peripheral nervous system. The accident plays a double part in producing traumatic hysteria—first, by its effect on the mind (psychical traumatism); second, by its effect on the body, which anchors the attention to one point. An area of pain or stiffness often serves as an autosuggestion which undergoes morbid magnification when viewed through the distorting medium of hysteria. Erichsen taught that the symptoms of what he named "railway spine" arose from inflammation of the cord and its membranes, a view now abandoned. A blow given to a hysterical person causes a feeling of numbness, and thus negative sensation from local shock may establish the idea of paralysis, or traumatism, acting as a suggestion, may inhibit motor representations and destroy the normal ideas of motion and feeling (Charcot and Pitre). Terror always causes a feeling of loss of power in the legs, and the terror of the accident may thus develop the idea of paraplegia. The site of a traumatism may localize symptoms: for instance, a blow upon the eye may cause amaurosis or blepharospasm. It is important to remember Charcot's saying that a hysteria long latent and unrecognized may be awakened into obvious activity by a blow or an accident. Pitre shows the same to be true of epilepsy. A not unusual lesion is hysterical traumatic monoplegia, not coming on at once after the accident, but usually some days afterward, and presenting flaccid muscles, the electrical reactions and reflexes remaining normal, but the muscular sense being lost (Pitre). The muscles usually waste. The skin of the paralyzed limb is anesthetic or analgesic. There may be anesthesia limited to a limb, hemianesthesia, or general anesthesia.* Hysterical paralysis is usually associated with the

* J. Mitchell Clarke, in *Brain*

permanent stigmata of hysteria—concentric contraction of the visual field, pharyngeal anesthesia, convulsive seizures, and hysterogenic zones (Clarke and Pitre). The permanent stigmata may be latent. Hysterical phenomena lack regularity of evolution, and they may be produced, altered, or abolished by mental influences or by physical forces which produce no effect on organic disease. In most hysterical conditions the general health is not profoundly impaired.* In making a diagnosis of hysteria we must be most careful to exclude both malignant disease and imposture, because hysteria is a sort of diagnostic waste-basket into which we cast most things which we fail to understand. Babinsky proposes that we should call phenomena hysteria only when they can be produced or can be cured by suggestion ("Brit. Med. Jour.," Jan. 23, 1909, p. 234).

Treatment—By moral means chiefly. Gain the confidence of the patient. Suggestion is of great value. In many cases separation from family and friends is necessary and isolation is desirable. The Weir Mitchell rest-cure is often the best plan of treatment, and all its details should be carried out faithfully.

Malingering.—Persons often pretend to suffer from maladies of the spinal cord or column as a result of accident, which diseases do not exist in them. Some get well upon the rendering of a favorable verdict by a jury (**litigation backs**). In any case always examine carefully, so as to be able to exclude malingering. Note the patient's behavior and motions when his attention is diverted from his disease. *Meningomyelitis* can be excluded if there be no spasm, paralysis, hyperesthesia, paresthesia, or anesthesia at a distance (A. Pearce Gould). If pain has lasted for months; if pressure downward upon the head or shoulders does not increase pain; if the vertebrae are movable and there is no angular displacement, exclude *caries*. Gould states that when there are wasted muscles, when moderate spine movement is painless, but effort in bringing the body erect causes pain in the erector spinae region, the trouble is a *strain of the erector spinae muscle*. If the muscle is not wasted and the pain is in bending forward rather than in straightening up, the *vertebral ligaments* are the seat of trouble. Unilateral spasm cannot be simulated. The administration of ether may dispose of a pretended paralysis, the patient moving the suspected extremity while drunk from the anesthetic.

Concussion of the Spinal Cord.—This term has no definite pathological meaning. It is probable that the condition is one of laceration of capillaries and of cord-substance.

The **symptoms** are shock, intense pallor, nausea, often vomiting, and sometimes syncope. With this condition special symptoms may be linked—as temporary paralysis, a girdle-sensation, numbness and loss of power in the limbs, hiccough, torticollis, coarse tremors, pains in the back and limbs, areas of anesthesia and analgesia—depending on the portion of cord lacerated.

Treatment.—The treatment in concussion of the spinal cord is the same as that for sprains. Traumatic neurasthenia and hysteria or organic cord-disease may follow this injury.

Contusion of the spinal cord may arise from a blow or a sprain, but it is usually due to extreme flexion of the spine. It causes hemorrhage into the gray matter of the cord (*hematomyelia*). The symptoms are motor and sensory palsy and diminished reflexes. Some cases recover, but others end in myelitis.

* Read the works of Thorburn and Pitre

Wounds of the spinal cord are rare and are usually fatal. A knife is sometimes thrust in between the occiput and atlas. Wounds above the origin of the phrenic nerves cause almost instant death. Gunshot-wounds are the most usual form, the cord being damaged by the bullet and by bone-fragments.

In the American Civil War gunshot injuries of the cord were very rare ($\frac{1}{4}$ of 1 per cent. of all wounds), but at the present day in war they represent more than $\frac{1}{4}$ of 1 per cent. of all wounds, the increase in frequency being due to the increased penetrating power of the modern military bullet (Surgeon-General Robert M. O'Reilly, in "Keen's Surgery," vol. iv). The mortality is about 60 per cent.

A revolver bullet or a small-caliber bullet fired at long range may produce vertebral fracture without cord injury and any bullet may fracture a process of a vertebra without cord injury. If the laminae are fractured the cord is almost sure to be injured. The cord may be concussed, lacerated, or cut across by bone or bullet, or compressed by bone or blood. The bullet may lodge or may perforate.

Treatment.—In a suspected wound of the cord do an exploratory laminectomy, arrest hemorrhage, and if the cord is divided, suture it. If a bullet is lodged, remove it.

Compression of the spinal cord may be due to blood or to inflammatory exudate, as well as to displaced bone (page 872). *Compression from blood* may be due to *extramedullary* hemorrhage or to *intramedullary* hemorrhage. *Extramedullary* hemorrhage causes sudden pain in the back, the pain radiating from compressed nerve-roots; hyperesthesia and paresthesia in the area of the radiated pain; spasm of vertebral muscles supplied by the compressed nerves, sometimes of muscles whose nervous supply is below the lesion; tremors; convulsions; retention of urine; paralytic symptoms following the signs of irritation, but no absolute paralysis (Mills). A girdle-sensation is usual. *Intramedullary* hemorrhage causes pain, a girdle-sensation, abolition of reflexes, and paralysis. Spasms, rigidity, and paralysis come on early. Bed-sores may form, and retention of urine and incontinence of feces may be observed. Paralysis from hemorrhage is rapidly progressive from below upward (crawling paralysis).

Treatment.—If paralysis from spinal-cord bleeding extends rapidly and life is endangered through the probable involvement of a vital center, perform a laminectomy, remove the clot, and arrest the hemorrhage. It is wise always to open the dura and inspect the cord. Extramedullary hemorrhage may be arrested by sutures or by packing. Intramedullary hemorrhage may be arrested by suture-ligatures or by packing. If an extramedullary clot is extensive, it is proper to make a second laminectomy near the lower end of the spinal column in order to permit the surgeon to wash it out thoroughly. The dura must be sutured and drainage is to be employed. If there is paraplegia, complete anesthesia of the paralyzed parts, and entire abolition of the deep reflexes, operation is probably useless, but it is justifiable to try it because of a possibility that the cord is not completely divided. In some cases with persistent paraplegia the operation should be undertaken. If operation is not undertaken, have the patient lie upon his side, apply a spinal ice-bag, and give morphin hypodermatically. If hemorrhage

continues in the cord and if the patient be plethoric, perform venesection. To promote absorption of the clot and exudate give a combination of carbonate and acetate of ammonium, order pilocarpin, and employ spinal galvanism and not douches.

Fractures and dislocations of the spine are very rare. The spinal regions most liable to injury are the atlas-axial, the cervicodorsal, and the dorsolumbar (Treves). A vertebra may be fractured alone, but dislocation without fracture, except in the upper cervical region, very rarely occurs. These two lesions, dislocation and fracture, are so often associated that the term *fracture-dislocation* is used by many surgeons to include them both. The causes of fracture and dislocation are direct force (seldom) and indirect violence (commonly). In fracture by direct force the laminae and spinous processes are most apt to suffer. In most cases the fragments are not greatly displaced. A fracture by indirect force may result from a fall on the shoulders, from a weight falling on the shoulders, or from a fall on the buttocks. Forced flexion or overextension is the commonest cause. In fractures from indirect force the cord generally suffers. In some cases the displacement of the vertebrae lacerates the cord, the vertebrae return into place, and no deformity is detectable. Fracture-dislocation from direct force may occur at any part of the column, and in this accident the posterior vertebral segments are driven together, and the cord, as a rule, escapes injury. Fracture-dislocations from indirect force most commonly happen in the dorsolumbar region, but are met with in the cervical and dorsal regions. In the cervical region reduction can usually be secured, but in the lumbar region reduction is impossible.

Symptoms.—In fracture-dislocation great displacement is unusual, but

Fig 484. Spine sawed. Fracture of the spinous processes of the seventh cervical and first and second dorsal vertebrae. Fracture of the bodies of the fifth, sixth and seventh cervical vertebrae with displacement backward of the upper fragment. Total crush of the cord. The section passes a little to one side of the cord which is seen in place and the staining of the cord by hemorrhage into its substance shows plainly through the membranes even in photograph. The spinous processes of the second and third dorsal vertebrae were found fractured at the operation, and were removed (Thomas)

some is almost always recognizable (irregularity of the spines or angular deformity). There are pain (which is increased by motion), tenderness, ecchymosis, and motor and sensory paralysis. Priapism, cystitis, and retention of urine often occur. Horsley has pointed out that in many cases paralysis passes away only to recur subsequently, the recurrence being due to edema of the cord. In some cases of spinal injury there is *temporary paralysis* due to *shock*. *Persistent paralysis* may be due to laceration of the cord, division of the cord, or compression of the cord by bone, blood-clot (Fig. 485), or products of inflammation. The extent of paralysis depends on the seat of the cord injury. We must always try and decide if the spinal cord is completely divided or hopelessly crushed (Fig. 484). When the symptoms are not immediate in onset, when all the muscles below the seat of injury are not completely paralyzed, when there is some retention of sensation, when reflexes are present and muscular rigidity exists, we may be sure that the cord is not completely divided. When the cord is completely divided the symptoms are immediate, there are absolute flaccid motor paralysis and complete sensory paralysis (loss of appreciation of pain, touch, and temperature). The line of anesthesia is definite and

Fig. 485. Fracture of the cervical spine, cord compressed by bone and lamina. Hemi-lamina into the cord at the seat of the lesion and below the lesion (Warren Museum). (From Smith's "Treatment of Fractures." Drawn by Byrnes.)

Fig. 486. Lesion of spine between fifth and sixth cervical vertebrae. Note position of arms due to paralysis of subscapularis, brachialis anticus, supinator longus, and deltoid muscles intact. Elbow flexed, shoulders abducted and rotated outward (after Thörlburn).

suddenly terminates (Walton). The bladder and rectum are paralyzed and there may be priapism. All the reflexes, superficial and deep, except perhaps the plantar, have disappeared. There is no pain, there are no muscular spasms, there is vasomotor paralysis with sweating of the paralyzed parts, and the symptoms persist and do not vary (J. J. Thomas, in "Boston City Hospital Med. and Surg. Reports"). There is usually tympanites (Walton). If this latter symptom group is due to shock, it will usually be temporary, but occasionally, even when so caused, it persists some considerable time.

It is also probable that concussion of the cord may in some cases simulate complete division. As Walton says, no symptoms *prove* a hopeless crush of the cord; it is the persistence of the symptoms which does prove it ("Jour. Nervous and Mental Diseases," Jan., 1902); I would add the *unchanging persistence* of the symptoms proves it.

A. J. McCosh ("Jour. Amer. Med. Assoc.," Aug. 31 and Sept. 7, 1901) points out that definite pressure is indicated by marked symptoms and absence of reflexes. When there is not definite pressure, the symptoms are irregular; there is incomplete palsy, or muscles of the same group show different degrees of paralysis; anesthesia is partial; signs of irritation are not distinct, and there are patches of hyperesthesia and zones of paresthesia. If in doubt, at the end of twelve hours perform an exploratory operation.

The **prognosis** depends on the amount of damage done to the cord. Fracture-dislocations in the cervical region produce obvious deformity, stiffness of the neck, and irregularity of the spines, and a displaced vertebra may occasionally be detected by a finger in the pharynx. Crepitus can rarely be detected unless a spinous process is fractured. The Rontgen rays aid diagnosis. The seat of cord injury may be determined by a study of the palsy and other symptoms.

Fracture-dislocation of the atlas or axis usually causes instant death. When the displacement is only trivial, the patient may actually recover, but will probably die of secondary cord disease. Dr. N. J. Blackwood of the U. S. Navy records a case of fracture of the atlas and axis and forward dislocation of the occiput on the spinal column, life having been maintained for thirty-four hours and forty minutes by artificial respiration, during which time laminectomy was performed on the third cervical vertebra ("Annals of Surgery," May, 1908). Lofton has recorded a case of recovery after dislocation of the anterior arch of the atlas on to the odontoid process ("N. Y. Med. Jour.," April 18, 1908). In injury of the third cervical vertebra the phrenic nerve is involved, the diaphragm is paralyzed, and death soon occurs. In fracture-dislocation of the fifth cervical vertebra the subscapularis muscles are paralyzed, but the biceps, brachialis anticus, supinator longus, and deltoid escape, and the patient assumes a characteristic attitude (Fig. 486). In Jones' case of fracture of the fifth cervical vertebra no operation was performed, but the patient partly recovered and became able to walk, but with a spastic gait ("Lancet," Nov. 28, 1903). If the sixth cervical vertebra is dislocated, there is palsy of the muscles of the hand. In injuries below the sixth vertebra no muscle of the arm, forearm, or hand is paralyzed at first, although after some days paralysis may develop. Damage to the cord above the sixth cervical vertebra produces anesthesia of the body below the injury and of the entire upper extremity except the shoulder. In injury just above the upper level of the seventh cervical there are body-anesthesia and anesthesia of the outer surfaces of the arms and ulnar margins of the forearms and hands. In any cervical injury there are body-anesthesia and diaphragmatic respiration, and in cases without paralysis of the arms there is sure to be pain. Injuries of the dorsal spine can be accurately located. There is paralysis of motion and sensation up to, or almost up to, the seat of injury. The arms are not paralyzed. Very great pain in the legs occurs if the lumbar enlargement is involved. In injury of the twelfth dorsal or

upper lumbar vertebra there are paralysis of the bladder and rectum, an incomplete anesthesia, and a partial motor paralysis of the limbs.

Treatment of Fracture-dislocations.—When dislocation of the body of the vertebra obviously exists, the surgeon may attempt reduction by extension and rotation. The maneuver is very dangerous in the cervical region and, as deaths have happened, some eminent surgeons advise against reduction when the injury affects that region. Walton's plan for a unilateral cervical dislocation is as follows: Give the patient ether and hold him erect and sitting on a chair. The surgeon stands behind the patient and holds the head with both hands. The first motion is a slight degree of rotation to carry the dislocated process forward and "unlock" it. The head is then rocked toward the sound side and somewhat backward and finally the process is replaced by rotation. No force is used (Clopton, in "Interstate Med Jour," Jan. 1908. Quoted in General Surgery by John B. Murphy, 1909). After reducing a fracture dislocation of the cervical region, place the patient in bed, elevate the head of the bed a few inches, and immobilize the neck and head. In fracture-dislocation of the dorsal or lumbar region the traditional plan is to straighten the spine, gently if possible, and to put the patient upon his back upon a water bed or upon air-cushions. Empty the bladder every six hours with a soft catheter, which is kept strictly aseptic. Take every precaution to prevent bed-sores. Some surgeons advocate reduction of the deformity by extension and counter extension, and the application of a firmly fitting but removable jacket with the suspension collar (as used in Pott's disease). If this plan is employed, the head of the bed is raised and the collar is fastened to it. Every day extension is made gently from the shoulder in dorsolumbar fracture and from the chin and occiput in cervical fractures. Extension may be maintained permanently until cure. Surgeons have come rather slowly to a belief in laminectomy. One deterrent factor has been the high mortality. Lloyd collected the records of 159 operations and found that 59 patients died almost at once and 39 died later. Some employ purely expectant treatment in vertebral fractures. My own feeling is that when simply a spinous process or some other part is fractured, and there are no cord symptoms, we may treat the patient expectantly, following Burrell's advice, and fixing the patient in bed on a Bradford frame and having him carefully nursed and watched. Reduction by extension and counter extension is dangerous and unjustifiable if there is marked kyphosis and if cord symptoms exist. I agree with Burrell that it should only be done if operation is refused, or if there are no cord symptoms and no marked kyphosis ("Annals of Surgery," Oct., 1905). If it is attempted it must be done slowly and as gently as possible because it may cause grave or even irreparable damage to the cord. I fear to delay, and, with Burrell, Lloyd, Walton, and others, operate when the patient recovers from shock, if there seems to be even a gleam of hope that operation may help him. To wait when pressure exists means that during every hour of delay the pressure is damaging the cord. Another reason for operating is that we cannot know the condition of the cord without direct inspection. The operation to be performed is laminectomy. As before stated, this is to be done even if we suspect division or hopeless crush of the cord. In some cases, it is true, we may commit the error of operating when there is only concussion, but such a mistake is less grave than to fail to

operate when there is bone-pressure or hemorrhage. An objection filed by the neurologist against laminectomy is that portions of cord above and below the level of the fracture may be damaged (Fig. 485), but, as Lloyd says, this fact does not forbid operation, but renders it necessary to make a wider exploration than has been the custom. In many cases after prompt laminectomy we get some considerable improvement, and this improvement may be sufficient to enable a man to earn a living. It is true that statistics would indicate that late operations have been more successful than early ones, but these figures must be analyzed in the light of the knowledge that many of the fatalities after early operation would have occurred if no operation had been done, and some improvements after late operation would have occurred to as great or a greater degree after early operation. The prognosis of any operation, early or late, is never gratifying, and Thorburn feels no confidence in obtaining improvement except in injuries of the laminae, hemorrhage, or injuries of the cauda equina, as he says laminectomy in the cervical region is followed by death, and laminectomy in the dorsal region, though not commonly fatal, is seldom followed by recovery of function. Our statistics of early laminectomy will show fewer deaths and fewer useless operations if we do not operate till shock abates. As Lloyd says ("Phil. Med. Jour.," Feb. 5, 1902): "It is therefore evident that if we operate immediately after the injury we will have failures that should not be charged against the operation itself, and, if possible, we should wait before operating until the question can be settled whether the patient will overcome the shock or will succumb directly to the effects of the injury." All surgeons operate for compound fracture, for hemorrhage, and for cases with marked bone-pressure. If early operation were not performed and if pachymeningitis arises, operation is called for.

My own convictions are that if symptoms are significant, we should explore, as soon as shock has passed away, even if we think it probable that the cord has been divided; and if it is found divided, it should be sutured. If in any case we are in doubt twelve hours after the injury as to whether or not pressure exists, we should explore. If soon after the accident we think pressure by bone exists, we should operate. If the case is improving, we should not operate even if there are pressure-signs, unless there is a chance that pressure is due to bone, in which case we should operate. As McCosh says, pressure by blood or inflammatory exudate may pass away; pressure by bone cannot. Even long after an injury laminectomy may be productive of some benefit.

The rather radical views set forth above regarding the advisability of operating even if the symptoms point to complete division of the cord arose largely from a knowledge of the well-known case operated upon by Stewart for total division of the cord. In a case of gunshot wound of the dorsal spine treated at the Pennsylvania Hospital by Francis T. Stewart, and reported by Francis T. Stewart and Richard H. Harte ("Phila. Med. Jour.," June 7, 1902), an exploratory incision made three hours after the injury showed that the spinal cord was completely divided. There was a fracture of the lamina of the seventh dorsal vertebra. The spines and laminae of the seventh and eighth dorsal vertebrae were removed. The bullet-hole was recognizable in the membranes, and the bullet and some bone-fragments were removed.

When the dura was opened, the ends of the completely divided dorsal cord were found to be three-quarters of an inch apart. Stewart freshened the ends and brought them together with two sutures of chromicized catgut. In this case a considerable degree of restoration of function took place. At the time of the operation, three hours after the injury, there were complete paralysis and absence of reflexes below the seat of injury; but sixteen months later the patient was able voluntarily to flex the toes, flex and extend the leg, flex and extend the thighs, and, while sitting, lift an extended leg from the floor. The movements of the lower extremity became more forcible when reinforced by contracting the muscles of the upper extremity while making them. The patient could stand with one hand resting on the back of a chair and could get herself from her bed to her chair by sliding. The bowels were under perfect control, and there was no incontinence of urine when she was awake, although there was occasionally some when she was asleep. There were occasional cramp-like pains in the lower limbs. The sense of touch, temperature, pain, and position were perfect all over the previously paralyzed parts. Below the knee the localization of sensation was not so accurate. There was a slight amount of muscular rigidity; and on each side an ankle and patellar clonus, which was easily exhausted. When the sole of the foot was tickled, the big toe flexed, the thigh abducted, and there was slight contraction of the anterior tibial, the ham-string, and the tensor vagina femoris muscles. There were no reactions of degeneration and no trophic changes. There had never been any bed-sores. George Ryerson Fowle ("Annals of Surgery," Oct., 1905) operated on a gun-shot wound of the dorsal spine eleven days after the injury. He removed the laminae of the tenth, eleventh, and twelfth dorsal vertebrae and found the cord divided, the bullet lying between the severed ends. A piece of dura one-eighth of an inch wide was intact. The bullet and blood-clot were removed. The cord was sutured with three sutures of chromicized gut, which included the dura and more sutures were taken through the dura only. The ends of the cord were easily approximated. The patient recovered from the operation. Twenty-six months later voluntary motion was found to be practically lost in the area below the injury, although when supported by the hands he could stand and when in a frame could move a little by a swinging movement. He is able to tell when his bowels or bladder are about to move, and, if furnished promptly with a utensil, does not soil himself. When asleep, he passes urine involuntarily. Both legs exhibit spastic rigidity, but there are no reactions of degeneration. Patellar reflex on each side exaggerated. Ankle clonus is found on one side, but not on other. There is complete anesthesia of the affected area except in a region five inches in length on the outer side of the right thigh. Touch is appreciated but not correctly localized. In connection with the foregoing important cases we would note that Dr. Estes, of Bethlehem, has also operated upon a case of complete division of the spinal cord, in which suturing was followed by some restoration of function.

In the light of these positive reports we must ask ourselves if we have not been wrong in the view that the spinal cord cannot regenerate. If there is even a chance that we have been wrong, we must reverse our former conservative treatment and follow a radical plan. The three cases strongly suggest the possibility of some regeneration, but do not prove it. The cord may

have appeared to be completely divided and yet minute undivided bundles may have escaped recognition. Again, as Fowler suggests, there may be a nerve anastomosis through uninjured portion of the dura or between adjacent nerve-trunks which arise above and below the lesion. At my request Dr Samuel Lloyd, of New York, kindly wrote me a personal communication setting forth his views on this important subject. They are as follows: "The question of the regeneration of the spinal cord after traumatism of the spine deserves careful consideration in all cases that are operated upon. Up to the present time, however, although a number of operators have reported improvement following suture of the spinal cord in these cases, a careful analysis does not substantiate the fact that that improvement is due to an actual regeneration. It is a recognized fact on the part of all who have had experience with the surgery of the spinal cord that in almost every instance a certain amount of improvement is noted during the first few months. This is probably due to the fact that at the time of the injury minute hemorrhages occur into the adjoining segments, and that pressure is also increased in those portions of the cord by the inflammatory exudate and edema. Within a short time after the injury these conditions improve, and there seems to be an improvement in function; but in every case of spinal suture yet reported the amount of improvement may be explained by these facts. In no instance has there been a complete recovery of function, but in every one there has remained more or less permanent disability. This, however, should not discourage attempts at spinal suture, and in every case operated upon the dura should be opened and the condition of the cord examined. In those cases where a complete destruction has occurred and where the extent of it is not over three-quarters of an inch, it may be possible to cut out the lacerated portions and compate the surfaces by a series of sutures placed in the dura. In all these cases the patient should be put up in a plaster retaining bandage in extreme extension, even the head being thrown back so as to relax as much as possible the tension on the line of suture. The operator should be very sure, however, that there are no undestroyed fibers traversing the lacerated area, for the destruction of these in case regeneration did not occur would increase the amount of paralysis." With the views of Lloyd I am in entire agreement, and in future I shall follow this plan, bearing in mind that it is often impossible to tell whether the spinal cord is completely divided or seriously damaged without examining it, and it can be examined only by exploratory operation; therefore, if the serious symptoms already indicated exist after shock has passed away, exploratory operation should be performed; if pressure exists, it should be removed; and if the spinal cord is found to be completely divided, it should be sutured. It is well to remember that Abbe's experiments have shown that there may be great difficulty in bringing the divided ends of the cord into apposition. In order to effect this it may be necessary to resect a vertebra.

Operations on the Spine.—Operation for Spina Bifida.—A. W. Mayo Robson maintains* that operation is not demanded when the sac is of small size and is well protected by sound integument; that operation is proper when a large portion of the column is fissured, or when paraplegia or hydrocephalus exists, that operation is advisable only in meningocele, in

* Annals of Surgery, vol. xxii, No. 1.

cases in which the integument is thin and translucent, in cases in which the cord is flattened out or the nerves are fused. Robson has closed the osseous defect by transplanting periosteum.

Instruments Required.—Scalpels, dissecting and hemostatic forceps, scissors, mouse-toothed forceps, rongeur forceps, dural separator, Hagedorn needles and needle-holders, silk, silkworm-gut or catgut.

Operation.—Surround the sac by elliptical incisions. Find the neck of the sac, and if it contains no visible nerves, ligate it and cut off the protrusion. Push the stump into the canal. Freshen the bone-margins and spring a piece of celluloid beneath them to close the gap (Park). Suture over the stump with small sutures of catgut.*

Treves's Operation for Vertebral Caries.—(See page 707.)

Laminectomy.—The instruments required for laminectomy are Horsley's bone-cutter, dissecting, mouse-toothed, and hemostatic forceps, scalpels, bone-cutting forceps; rongeur forceps, a dry dissector, a periosteum elevator; sequestrum forceps; small scissors, straight and curved on the flat, a chisel and mallet; retractors; blunt hooks; a probe; tenaculum forceps; a spoon-curet, a sand-pillow; fine needles, curved and straight, large needles, and a needle holder.

In the operation of laminectomy the patient lies prone and a sand pillow is placed under the lower ribs. Make a vertical incision over and down to the vertebral spines, the middle of the incision corresponding to the seat of injury or disease. The sides of the spinous processes and the laminae are cleared. The periosteum is incised in the angle between the laminae and spines, and is lifted away from the arches. The spinous processes are cut off close to their bases by means of the bone-cutter forceps, the laminae are removed on each side with the same instrument or the rongeur, and the dura is exposed. In some cases of fracture fragments will be found on exposing the vertebra, or a blood-clot will be seen between the dura and the bone; in other cases the dura must be opened with scissors vertically in the middle line while it is grasped with mouse-toothed forceps. After reaching and removing the compressing cause, or after failing to find or remove it, it is best not to close the dura completely, because if we do so, cord pressure may result from hemorrhage. The dural wound is left open or is partly closed. I used to insert a drain of rubber tissue, but have given it up. Horsley shows that it is not necessary, and if we refrain from draining we lessen the tendency to headache, temporary pyrexia, and rapid pulse, which frequently follow laminectomy. The superficial parts are stitched with silkworm gut and dressings are applied.

Puncture of the spinal meninges, or lumbar puncture, was devised by Quincke, and has been carefully tested by many surgeons. It is the operation for withdrawing cerebrospinal fluid from the subarachnoid space of the cord. It is employed as a means of diminishing cerebral pressure in hydrocephalus, cerebral tumor, uremia, and tuberculous meningitis, but in these cases it has proved of little or only of temporary therapeutic value. It may be of some service in cerebrospinal meningitis. The condition of a patient with a fracture of the base of the skull is sometimes temporarily improved by

* A full consideration of the various plans of operating will be found in an article by Marcy, in *Annals of Surgery*, March, 1895.

the operation. Pain is often temporarily relieved. In the performance of a brain operation the brain may bulge so that the dura cannot be sutured. Lumbar puncture makes suturing possible. Puncture is the preliminary step of spinal anesthesia. In some cases the examination of the fluid has been of great diagnostic value. The fluid is not only subjected to a naked-eye study, it is also studied microscopically and bacteriologically. If the fluid from the puncture gives no positive finding, the operation should be repeated (Lorge). When a diagnostic tap is made we must know the appearance, nature, and pressure of the fluid normally.

Normally the fluid is clear, transparent, and alkaline under a pressure of from 40 to 60 millimeters of mercury (Dana), its specific gravity is from 1.006 to 1.008, and from 5 to 10 cc. will flow out at a tap. It contains a very few endothelial cells and leukocytes. In cases of increased tension it flows out more forcibly, rapidly, and profusely (brain tumor, hydrocephalus, meningitis, and some infectious conditions). When there is meningeal inflammation the specific gravity is increased. In apoplexy and other hemorrhages beneath the cerebral arachnoid, in fracture of the base of the skull, and in hemorrhage beneath the arachnoid of the cord, the fluid contains blood. Laceration of the brain tissue without subarachnoid or ventricular hemorrhage does not make the fluid bloody. The fluid is turbid in purulent meningitis of the cord or brain. Lumbar puncture is of great diagnostic use in the cerebral hemorrhage of the newborn and in some fractures of the base of the skull.

The chemical study of the fluid is sometimes of value.

In intracranial tumor, purulent meningitis, subarachnoid hemorrhage of the brain or cord, and apoplexy albumin is increased. The normal fluid contains a substance resembling or identical with glucose. This is often absent in meningitis and is increased in saccharine diabetes.

In uremia the chlorids are diminished.

Cytdiagnosis (a microscopic study of the cells of the fluid) may furnish useful information. Lymphocytosis suggests a tuberculous lesion rather than an acute meningeal inflammation. Lymphocytosis occurs also in syphilis of the brain and cord, locomotor ataxia, paresis, and uremia.

Bacteriologic study by cover-glass preparations or cultures may give important information. In over 75 per cent. of cases of tuberculous meningitis of the brain membranes the fluid contains bacilli. Stadelmann has reported 37 cases in which tubercle bacilli were found in the fluid.* In tuberculous meningitis the fluid may or may not contain tubercle bacilli. In cerebrospinal meningitis the cerebrospinal fluid contains the meningococcus. In this disease lumbar puncture is unnecessary if the nasal mucus contains the diplococcus intracellularis. The operation of lumbar puncture is simple, and if done with proper precautions, is harmless. The back should be carefully sterilized and thorough asepsis must be preserved in every detail. The patient may lie on the right side with the left knee well drawn up, may lie prone, with a pillow under the belly, or may sit in a chair, with the body bent forward. The site of the intended puncture may be frozen with ethyl chlorid, but no general anesthetic is required. A Pravaz syringe is employed. The needle, which should be 3 inches in length, is guarded by the surgeon's index-finger and the point is inserted $\frac{1}{2}$ inch to the right of the median line and between the third

* Berliner klinische Wochenschrift, July 8, 1895.

and fourth lumbar vertebrae. It is pointed upward and a little inward under a spinous process. In a child the needle enters the canal at a depth of from 2 to 3 centimeters; in an adult, at a depth of from 4 to 6 centimeters. The fluid is permitted to fall drop after drop into a sterile test-tube. In some cases but a few drops of fluid will be obtained; in other cases many cubic centimeters may be removed. It is not wise to draw for diagnostic purposes over 5 cc. from a child and 10 cc. from an adult. If we evacuate too much cerebrospinal fluid, the ventricles are emptied and compression of the cerebellum may arise. The flow should be spontaneous and suction ought not to be used. Sometimes nausea, vertigo, and severe headache follow the operation, and sudden deaths have been reported. For a number of hours after tapping the patient should remain recumbent.

Horsley's Operation for Chronic Spinal Meningitis.—Sir Victor Horsley ("Brit. Med. Jour.," Feb. 27, 1909) states that during the past ten years he has operated on a number of cases for what he calls chronic spinal meningitis. Such cases are commonly confused with tumor, are much more frequent than tumors, and are often cured or greatly improved by operation. The first published case of this sort was reported by Spiller, Musser, and Martin ("Univ. of Penn. Med. Bulletin," March, 1903). Martin performed laminectomy, found a "circumscribed meningitis," and cured the patient. In these cases a fluid accumulation is found and this fluid is stagnating and under pressure. The cord passes into a condition of scleroglossis. The symptoms are pain, advancing loss of power in the legs, perhaps slight kyphosis, and eventually progressive and fatal paraplegia (compression paraplegia).

The pain in these cases involves an extensive area, not as in extramedullary tumor a small area supplied by one or two nerve roots, and there may be hyperesthesia over an entire extremity, which does not occur in extramedullary tumor (Horsley, *Ibid.*). Horsley has never seen absolute abolition of tactile sense. The operation consists in laminectomy, opening the theca, washing it out with mercurial solution (1 : 500 followed by 1 : 2000), and closing without drainage.

XXV. SURGERY OF THE RESPIRATORY ORGANS.

DISEASES AND INJURIES OF THE NOSE AND ANTRUM.

Foreign bodies in the nose are usually introduced through the anterior nares, but in rare instances they enter by way of the posterior nares. Small particles are often expelled spontaneously, larger pieces collect mucus and epithelium and become fixed. Some materials swell after lodgment.

Treatment.—In many cases anesthesia is required. Illuminate the nostril, and, if the foreign body can be seen, insert a hook back of it and effect its removal by means of forceps. Some foreign bodies require to be pushed back into the nasopharynx. Occasionally expulsion may be effected by inserting a rubber tube into the unblocked nostril and telling the patient to blow forcibly through the tube. In serious cases a specialist should be summoned to remove a portion of the turbinated bone or to perform whatever operation he thinks best.

Inflammation and Abscess of the Antrum of Highmore (of the Maxillary Antrum). The source of this disease may be inflammation of the nose or periostitis around the roots of the teeth. In some cases the natural opening into the meatus is patent; in other cases it is partly or completely blocked. Caries and necrosis may arise. The **symptoms** are pain, edematous swelling of the face, and thinning of the bone so that it may crepitate under pressure. When pus has formed, if the antral opening is patent, certain positions of the head will cause a purulent flow from the nose, and if a speculum is inserted pus may be seen as it flows into the nose. The opening of the maxillary antrum into the nasal channel is at the summit of the antrum, hence the antrum drains when the head is inverted. The ethmoidal cells and frontal sinus drain best when the patient is upright. Wipe the interior of the nose and place the patient with his head between his knees. If the nostril fills with pus, it comes from the antrum (Cobb). In severe cases the jaw expands, the eye protrudes, and great tenderness of the alveolus exists. Percussion exhibits a dull note. In making a diagnosis it is well to take the patient into a dark room, insert an electric light into the mouth and note the diminution of light-transmission on the diseased side as contrasted with the sound side. Transillumination may be easily practised by the use of a cautery electrode, protected by a small glass vial. Any cautery battery may be employed (plan suggested by Ohls). Exploratory puncture will settle a doubtful diagnosis. This may be by way of the lower meatus, the canine fossa, or the alveolar process.*

Treatment.—Before pus forms order the use of hot fomentations and remove any diseased teeth. When pus has formed, evacuate it at once. Before performing a severe operation try the effect of opening into the antrum from the nose, by means of Krause's trocar, followed by insufflation of iodoform. If this procedure fails, other means may be employed. If the disease arises from a carious tooth, pull the tooth and push a trocar through its socket into the antrum. If the teeth are sound,

* Cobb, in Boston Med. and Surg. Jour., May 7, 1896.

bore a hole with a large gimlet or with a bone-drill above the root of the second bicuspid tooth and one inch above the edge of the gum. A counter-opening should be made into the inferior nasal meatus. A drainage tube is pulled from the first opening into the nose and is allowed to protrude from the nostril. Irrigate daily with normal salt solution. In three or four days discontinue through-and-through drainage, but prevent the first opening closing until the discharge ceases to be purulent. In severe cases make a free incision through the canine fossa by means of a chisel.

Distention and Abscess of the Frontal Sinus.—The usual cause is an injury which may long antedate the symptoms. This injury causes or leads to blocking of the infundibulum; secretion accumulates and distends the sinus, and in some cases pus forms. In many cases the fluid slowly accumulates, and it requires years to produce marked symptoms. In other cases infection takes place, and the symptoms are positive and violent. If the outlet into the nose is not permanently blocked, the fluid may discharge itself from time to time. In the chronic cases there is rarely much pain. The chief sign is a swelling of the inner or upper part of the orbit, which swelling progressively increases and finally displaces the eye. If at any time acute symptoms supervene, there will be pulsatile pain, discoloration, and tenderness.

Treatment.—In some cases it is possible to pass a trocar upward from the nose into the sinus, and so drain and irrigate. In most cases an incision should be made through the soft parts, and the sinus opened by a trephine or chisel. After the sinus has been opened it must be curetted. The opening into the meatus should be restored and enlarged, and a drainage tube must be passed from the forehead incision into the nostril. I usually prefer to open the sinus by making an osteoplastic flap in the anterior wall.

DISEASES AND INJURIES OF THE LARYNX AND TRACHEA.

Edema of the Larynx (Edema of the Glottis).—The causes of edema of the larynx are: acute laryngitis; chronic diseases, such as tuberculosis, malignant disease, or syphilis; inflammatory disorders, such as diphtheria and erysipelas; acute infectious diseases; Bright's disease; aneurysm; whooping cough; pneumonia; quinsy; wounds of the larynx; wounds of the neck; scalds and burns of the larynx, and the inhalation of irritating vapors, such as those of ammonia and sulphur. The symptoms are sudden and rapidly increasing dyspnea, respiratory stridor, huskiness of the voice, and finally aphonia. The swollen epiglottis may be felt with the finger and may be seen with the help of a mirror.

Treatment.—In cases in which edema of the larynx is not excessively acute introduce a gag between the teeth, hold the mouth open, take a knife wrapped to within one-quarter of an inch of its point, make multiple punctures into the epiglottis, and favor bleeding by the inhalation of steam. In severe cases perform intubation or tracheotomy.

Wounds and Injuries of the Larynx.—The larynx may be injured internally by foreign bodies, and externally by blows and cuts. A condition often met with is *cut throat*, the result usually of a suicidal attempt on the part of the patient or a homicidal effort on the part of an assailant. The cut of the suicide is usually in front; as a rule, it misses the great vessels, but divides the

cricothyroid or thyrohyoid membrane. The epiglottis may be incised, or even be cut off. If a large vessel is cut, death rapidly occurs. The immediate dangers of cut throat are hemorrhage, suffocation by blood in the windpipe and bronchi, or by displacement of parts, and entrance of air into veins. The secondary dangers are pneumonia, infection and sepsis, exhaustion, and secondary hemorrhage. The remote dangers are stricture and fistula (Keetley).

Treatment.—In wounds of the throat arrest hemorrhage, remove clots from the larynx and trachea, bring about reaction, asepticize the parts as well as possible, suture the deeper structures with silver wire, catgut, or kangaroo-tendon, and the superficial parts with silkworm-gut, dress antiseptically, and place a bandage around the head and chest so as to pull the chin toward the sternum. If laryngeal breathing is much interfered with, perform tracheotomy. Feed the patient through a tube until union is well advanced. The old method of leaving the wound open is to be condemned. When sutures are used, primary union may be obtained. This fact was proved by Henry Morris.

Scalds of the Glottis.—(See section on Burns and Scalds.)

Foreign Bodies in the Air-passages.—The lodgment of foreign bodies in the air-passages is a frequent accident. Small solid bodies are usually expelled by coughing. Liquids and solids rarely pass beyond the larynx (except in laryngeal disease or palsy, wounds of the floor of the mouth, cut throat, and in people unconscious or very drunk). In vomiting during or after the administration of an anesthetic, or in the vomiting of drunkards, the vomited matter may find its way into the larynx or lungs. There is great danger of this accident in an operation upon a patient with intestinal obstruction who has stercoraceous vomiting. In most instances of foreign bodies lodged in the air-passages it will be found that the object was being held in the mouth when a sudden deep inspiration was taken (often during laughter). The symptoms are immediate, due to obstruction by the body and to spasm, and secondary, due to the situation of the body and the changes it undergoes or induces.

Lodgment in the pharynx causes violent dyspnea. The body can be seen or felt.

Lodgment in the Larynx.—In a severe case the patient fights madly for air; his face becomes livid and cyanotic; his veins stand out prominently; speech is impossible, though he may make noises and utter harsh cries; violent coughing begins, and then vomiting; he tries to force a finger down his throat and clutches at his neck; sweat pours from him; he feels a sense of impending dissolution, and he falls unconscious, with incontinence of feces and urine.* In a less severe case violent dyspnea gradually departs and the patient lies exhausted; but dyspnea and cough are liable to recur suddenly at any time because of spasm, and they may be induced by a change of position. These attacks of fierce spasmodic cough are not at first linked with expectoration, but after inflammation begins there is a profuse and often bloody expectoration. Inflammation follows more rapidly the lodgment of a sharp or irregular body than it does that of a round or smooth body. Inflammation is apt to produce edema of the glottis, bronchopneumonia, or ulceration and necrosis of the larynx. Any sort of foreign body in the larynx may at any moment produce

* See Moullin's graphic description in his "Treatise on Surgery."

spasmodic dyspnea, and is always very liable to cause edema of the glottis. The body if bony or metallic can be detected by the x rays.

Lodgment in the Trachea.—The immediate symptoms of a foreign body in the trachea depend on the shape and weight of the body, and whether it becomes fixed in the mucous membrane or moves to and fro with the air-current. A smooth, heavy body falls to the tracheal bifurcation, and, if it does not enter a bronchus, moves with every breath, and by its movement causes violent laryngeal spasm, cough, and whooping inspiration without aphonia. The patient is often conscious of the movements of the foreign body, and the surgeon may detect them with the stethoscope. The foreign body may be found with the Rontgen rays. A foreign body in the trachea is liable to cause death by dyspnea, or it may ascend so as to be caught in the larynx, or may even be expelled. Irregular or sharp bodies lodge in the mucous membrane, produce inflammation, frequent cough, and expectoration, and finally lead to ulceration. Bodies which swell from heat and moisture tend to lodge and to become fixed (seeds may sprout).

Lodgment in a Bronchus. Foreign bodies in the bronchi seriously endanger life. They usually lodge in the right bronchus. When a small lung-area is obstructed the obstructed side shows diminished respiratory movement and murmur with occasional whistling sounds and large moist râles, the percussion-note is normal. When an entire lobe is obstructed all respiratory sounds are absent over it, and over the unobstructed lung respiration is exaggerated; the percussion-note over the obstructed area is at first resonant, but becomes dull. The x-rays will enable the surgeon to detect some foreign bodies in a bronchus. Lodgment in a bronchus may cause bronchopneumonia, abscess, hemorrhage, and even gangrene. In some cases the body has been expelled spontaneously. In rare instances people have lived for years with lodged foreign bodies. If death does not soon follow the lodgment of a foreign body, an abscess is very apt to form.

Treatment.—If a foreign body lodges in the pharynx, try to pull it forward; if this fails, push it back into the esophagus. In lodgment in the larynx or below, if the symptoms are very urgent, at once perform a quick laryngotomy. If the symptoms are not so urgent, get a complete history of the accident and find out the nature of the foreign body. Be sure a foreign body is retained in the respiratory tract, and determine what its situation may be. Often a laryngologist can remove a foreign body from the larynx by means of forceps, a mirror and lamp being used for illumination. The fauces and upper portion of the larynx should have cocaine applied to them to lessen pain and spasm. If the surgeon fails in extraction by forceps, and laryngotomy has been performed, continue the search through the opening in the cricothyroid membrane; if laryngotomy has not been performed, let the larynx be opened by *thyrotomy* (a vertical incision between the ala of the thyroid cartilage, and the separation of these ala to permit of exploration). After a thyrotomy suture the perichondrium with catgut. If the foreign body is in the trachea, perform ordinary tracheotomy; if it is in a bronchus, perform low tracheotomy. Tracheotomy prevents suffocation from laryngeal spasm or edema of the glottis. It may be possible to remove the body in the bronchus through the incision of a low tracheotomy, and this ought to be tried. By this method I succeeded in removing a pin, a bone, a bean, a tack, and a broken tracheotomy

tube from the right bronchus. The foreign body may be expelled through the tracheotomy wound; if it is not expelled, search the trachea and bronchi with Gross's forceps, with probes, with hooks, or with the finger. If the foreign body cannot be found, put the patient to bed and maintain a moist

Fig. 467. Author's case of pin in bronchus removed by operation.

atmosphere in the room. As a rule, when the foreign body is not found, insert a tube. If the foreign body be extracted, do not insert a tube (unless edema of the glottis exists or is likely to come on), do not suture the wound, but cover it with moist gauze and let it heal by granulation. Morphin and sedative

Fig. 468.—Gibbons' case of tack in the right bronchus removed by low tracheotomy, child six years old.

cough-mixtures are given. Gross says that even when a foreign body has long been retained an operation should be performed if the air passages are not seriously diseased. What shall be done when a foreign body is lodged in a bronchus and we are unable to extract it through a tracheotomy wound or by tracheobronchoscopy? True said if "the patient is in danger of death"

cut through the chest-wall and attempt to remove the body. He said this with a full knowledge of the difficulty of locating the body. This difficulty has been partly overcome by the x-rays, and it seems now more certainly our duty to operate than it was a short time ago. Nasilloff proposed to reach the obstruction by the posterior route after rib resection. Curtis attempted this, and though the patient died, his operation proves that the method is feasible. An operation by the posterior route should be performed at once if low tracheotomy fails. The danger of pulmonary collapse will be abolished by the use of a suitable apparatus to prevent it (page 901).

Tracheobronchoscopy.—Dr. Chevalier Jackson of Pittsburg has devised a tracheobronchoscope through which he has succeeded in removing foreign bodies from the trachea and from a bronchus. In 10 cases of foreign body in the bronchus he removed the offender in 7. In 7 cases of foreign body in the trachea he was successful in each case, but 2 of the cases required tracheotomy. Whenever there is dyspnea he always prepares to do tracheotomy ("Annals of Surgery," March, 1908). In Jackson's trained hands the instrument is most useful, but an untrained man with it would be like an untrained man with a cystoscope.

OPERATIONS ON THE LARYNX AND TRACHEA.

Tracheotomy.—The instruments required in this operation are scalpels, dissecting forceps, a dry dissector, hemostatic forceps, scissors, a tenaculum, aneurysm-needle, tubes, tapes, Paquelin cautery, needles, needle holder, a

Fig. 489.—Blood-supply of the larynx and trachea (Esmarch and Kowalzig).

mouth gag, tongue forceps, foreign body forceps, retractors, and, if membrane is present, feathers and a solution of bicarbonate of sodium. In a formal operation give chloroform, but in an emergency case this cannot be done. The patient may be placed supine with a sand pillow under the neck and with the head thrown over the end of the table. If a child, Liston used to wrap it up to the neck in a sheet to prevent movements of the limbs, would seat himself on a chair, place the child upon the nurse's lap, and take its head between his knees. The head must be exactly in the middle line, and extended (in an adult this gives two and three quarters inches of trachea above the manubrium; in a child of ten, two and a quarter inches; in a child of six, about two inches). The operator stands to the right side when the patient is

supine. If bleeding is profuse when the surgeon is ready to open the trachea, place the patient in the Trendelenburg position with the neck extended. The trachea may be opened above or below the isthmus of the thyroid gland. The isthmus in an adult usually lies over the second and third rings (Fig. 490). The isthmus in a child usually lies over the first ring or even over the space between the cricoid cartilage and the first ring. The high operation is always

chosen except in cases where it is desired to search for a foreign body in a bronchus.

High Tracheotomy.—High tracheotomy is preferred because in this region the muscles are distinctly separated (Fig. 490), the main vessels of the neck and the inferior thyroid vessels are not encountered, the anterior jugular veins are small and have very few transverse branches, and the trachea is near the surface (Treves). The surgeon accurately locates the cricoid and thyroid cartilages. An incision is begun at the upper border of the cricoid cartilage, and is carried down precisely in the middle line for about one and a half inches. Treves advises the operator to steady the skin of the neck with the fingers of the left hand and to cut with the unsupported right hand (if the hand be supported, the respirations will interfere with the operation). The skin, the superficial fascia, and the anterior layer of the cervical fascia are incised, the sternohyoid and sternothyroid muscles are separated, and the fascia over the trachea is divided. This fascia is attached above to the cricoid cartilage, and it divides below into two layers to invest the thyroid body and its isthmus. If veins are in the line of the incision, they are pushed aside, but it is not necessary to take the time to apply double ligatures. Even if bleeding is profuse, as soon as the trachea is opened and air enters freely into the lungs, venous congestion is relieved and bleeding is apt to cease. If hemorrhage be violent and the veins are not at once caught by forceps, it may be well to place the patient in the Trendelenburg position before incising the windpipe, in order to prevent the entrance of blood into the lungs. Before opening the trachea the isthmus of the thyroid gland is pushed downward; if it cannot be pushed down sufficiently, a transverse incision is made through the fascia at the upper border of the cricoid cartilage, and the fascia, and the isthmus with it, is lifted off the trachea (Bose's method). A tenaculum is inserted into the cricoid cartilage in order to steady the tube. The back of the knife is turned toward the sternum, a finger being held upon the blade to prevent too deep a cut being made. The knife is plunged, as if it were a trocar, into the mid-line of the trachea above the isthmus, and two or three rings are divided from below upward. The hook is not removed until the operation is completed. If a foreign body is present, an attempt is made to remove it; if success attends the effort, no tube need be worn; but if the body is not found, a tube must be used. In croup or diphtheria remove membrane (by means of a feather and a solution composed of bicarbonate of sodium 3ij, glycerin 3j, water 3x—Parker) and insert a tube. The edge of the cut is grasped with the dissecting forceps, the mucous membrane being included in the bite; the head is placed erect, the tube is introduced, and the tenaculum is removed. Secure the tube by tapes, and suture the wound below the tube. Remove the tube at the first moment consistent with safety. In croup or diphtheria put a screen around the bed, have the air kept moist by steam; remove the inner tube and clean it every two or three hours at first; clean the outer tube whenever required. Clean the larynx and trachea from time to time by means of a feather and Parker's solution. A steam spray atomizer may be used with advantage.

Fig. 490. Parts exposed in tracheotomy (Treves and Kowalzig).

Quick laryngotomy must never be attempted upon a child under thirteen years of age, because of the small size of the cricothyroid space before this age (Treves). In view of the difficulty of introducing a tube and of wearing it so near the vocal cords, laryngotomy should not be performed for croup, diphtheria, or for any condition in which a tube must be long worn. The operation is performed as follows: Make an incision an inch and a quarter in length in the middle line, from above the lower edge of the thyroid to below the lower border of the cricoid cartilage. Divide the skin, superficial fascia, and deep fascia, separate the cricothyroid and sternothyroid muscles, divide the deep layer of fascia, and cut the cricothyroid membrane horizontally just above the cricoid cartilage. The tube must be shorter than the ordinary tracheotomy tube. An operation which opens vertically the cricothyroid membrane, the cricoid cartilage, and the upper rings of the trachea is called "*laryngo-tracheotomy*."

Intubation of the larynx (*O'Dwyer's Operation*)—Bouchot conceived the idea of intubation; O'Dwyer perfected it and made it a genuine scientific proceeding. The instruments required for the performance of this operation are a mouth-gag, an instrument to hold the tube and introduce it, and an instrument for extracting the tube. The collar of the tube has a perforation through which a piece of silk is fastened to draw out the tube. The child is wrapped in a sheet to secure the limbs, is seated in a nurse's lap, and its head is held by an assistant. The jaws are opened and held apart by the self retaining mouth-gag. The surgeon sits in front of the patient, wraps a piece of rubber plaster about the index-finger of his left hand, and passes the finger into the child's mouth until its tip touches the epiglottis. He introduces the holder and tube (observing if the silk is free) along the surface of the tongue until the obturator touches the epiglottis; raises the epiglottis with the left index finger, and passes the tube into the larynx; places the left index finger against the tube, and withdraws the holder with the right hand. The silken thread is tied to the ear, and the nurse is directed to employ the thread to remove the obturator if it becomes obstructed or is coughed up. The tube is removed in two or three days; if breathing is easy, it is not reintroduced; but if dyspnea recurs, it is replaced for two or three days more. If, in introducing the tube, a mass of false membrane is pushed before it into the trachea, breathing ceases, and, if the mass is not at once coughed up, tracheotomy must be performed. Feed these patients on semisolids rather than upon liquids (mush, soft eggs, and corn-starch); and if trouble occurs in swallowing these articles, feed by the rectum or by means of a nasal or an oral tube. In opium-poisoning, in asphyxia, in acute traumatic pneumothorax, and in cerebral injuries, intubation may be associated with the use of Fell's apparatus (page 894).

DISEASES AND INJURIES OF THE CHEST, PLEURA, AND LUNGS.

Traumatic Asphyxia (*Pressure Stasis; The Ecchymotic Mask*).—This is a condition that occasionally arises when the trunk is subjected to sudden and violent compression. The compression may be upon the chest, the abdomen, or both; and in the majority of cases it has been very temporary. The ecchymotic condition arises immediately, and is manifested over the head and neck down to and sometimes below the clavicle. The hue is a

violet lividity. There are a great many spots in the skin in which the color is much deeper, which have been supposed to be hemorrhage, and similar spots exist on the aural, palatine, and pharyngeal mucous membranes. In some cases blood has been effused into the orbit. There has never been a reported instance of intracerebral hemorrhage.

If death occurs, it results from associated injuries. The condition in the cases without severe associated injuries has soon disappeared, and entire recovery has followed. The view generally taught is that traumatic asphyxia is the result of compression of the abdominal veins, causing distention of the superior cava and its tributary veins, this region of the body showing the effect more than the limbs, because of the comparative feebleness of the valves (Villemin). One thing is sure, and that is that the condition is particularly apt to arise if the patient violently struggles to free himself from the compression; and many observers have held the opinion that actual vascular ruptures take place. There are certainly some cases, however, in which there is simply great venous and capillary distention in the skin without rupture, because pieces of skin have been excised and microscopic examination has indicated that there had been no blood effused. (See Winslow, "Medical News," Feb. 4, 1906; Birge, "Cleveland Medical Journal," Sept., 1905; Beach and Cobb in "Annals of Surgery," April, 1904; and Villemin, "Bull. et mém. de la Soc. Chir. de Paris," No. 9, 1906.)

Pleuritic effusion may arise from the lodgment of foreign bodies, from injury by fragments of a broken rib, from tumors, and from inflammation of the lung, but most usually is due to pleuritis. The commonest cause of primary pleuritis is tuberculosis. Inflammatory effusion is nearly always unilateral (except in tuberculous pleuritis, but even this form is often one-sided in origin).

The **signs** of pleuritic effusion are: dulness on percussion over the area of effusion, this dulness, when the patient is erect, being at the lower part of the chest and ascending higher posteriorly than anteriorly (alteration of position alters the situation of the dulness); the intercostal spaces are widened, the intercostal depressions are obliterated, the intercostal muscles are rigid, and their rigidity lessens the mobility of the ribs (Przewalski). No breath-sounds can be detected in the area of percussion flatness when the collection of fluid is large, but in small effusions deeply situated the breath sounds are often audible, the percussion-note above the liquid is hyperresonant or tympanitic, and is often associated, at the edge of the liquid, with a friction sound; posteriorly, high up and near the spine, there are bronchial respiration and bronchophony. In cases of pleurisy with effusion pain almost or quite disappears with the advent of effusion, dyspnea comes on, and the patient lies upon the diseased side. Cough always exists if there is pleuritic effusion, and fever is usually present. In serous effusions the diagnosis may be confirmed by the aseptic introduction of a clean aspirating-needle.

The **treatment** in this stage is to discontinue arterial sedatives and to stimulate if the circulation calls for it. The exudation is removed by the administration of salines, compound jalap powder, or claterium. If these means fail, if the effusion is excessive, or if it is producing dyspnea, at once aspirate. Aspiration should be performed for an effusion which fills the whole chest, which produces great dyspnea, or which has lasted for three weeks. In tuberculous pleuritis early aspiration is not advisable, but aspiration should be

performed if the fluid becomes purulent, if the effusion displaces the heart considerably, and if it adds notably to the dyspnea. If an effusion becomes purulent, the proper procedure is incision, resection of a portion of a rib, and drainage.

Empyema is a collection of pus in the pleural cavity. It may begin suddenly, but rarely does so. Among the causes of empyema are those of serous effusion. Empyema is due to infection of the pleura, and in every case a bacteriological study should be made of the pus to discover the causative bacterium. The pneumococcus is the causative micro-organism in many of the cases which follow pneumonia. Pneumococci live but a short time, and in empyema due to pneumococci these micro-organisms may not be discoverable when the pus is evacuated. In most cases of empyema streptococci or staphylococci can be found in the pus. These micro-organisms may appear in an empyema induced originally by pneumococci (Stephen Paget). In empyema developing during or after typhoid fever typhoid bacilli may be discovered. In putrid empyema various bacteria are found. Bouchard thinks acute empyema has a special organism. Bacilli of tuberculosis are present for a time at least in tuberculous empyema, but may disappear, and are particularly apt to after mixed infection with pyogenic bacteria. Empyema may be due to a wound or contusion, an attack of pneumonia, tuberculous pleuritis, phthisis, influenza, pyogenic infection of a serous effusion, caries of a rib, specific fevers, especially typhoid, peritonitis, abscess of the liver, suppurating hydatid cyst of the liver, subphrenic abscess, malignant disease of the pleura, gangrene of the lung, and pneumothorax.

Acute Empyema.—The *signs* are in reality those of pleuritis with effusion—viz., dullness on percussion, absent breath-sounds over the purulent matter, bulging of the intercostal spaces, and sometimes edema of the skin of the chest. The *symptoms* of acute empyema are dyspnea, pallor, cough, sweats, chills, and usually irregular fever, but fever may be absent. There is marked leukocytosis. The fingers may become clubbed. An empyema may pulsate, particularly an empyema of the left side. The cause of *pulsating empyema* has been much debated. The most probable explanation is that of W. J. Calvert ("Am. Jour. Med. Sciences," Nov., 1905). He says the requirements for such a condition are: "A firmly fixed, pulsating organ; distention of the pleural sac with fluid or air or solid material; and a collapsed condition of the lung." In all probability the thoracic aorta is the "fixed pulsating organ." The left parietal pleura is in close relation with the aorta, and most pulsating empyemas are left-sided. The right parietal pleural may be "pushed against the aorta." If a lung contains air, it is elastic and compressible to a degree that enables it to absorb the aortic impulse; if it is collapsed and solid it cannot, and aortic pulsations are transmitted to fluid in the pleural cavity and the thoracic wall pulsates. A neglected empyema may break into the lung, esophagus, or pericardium, through an intercostal space, or may point in the lumbar region. When an empyema is pointing externally, the condition is called *empyema necessitatus*. A *total empyema* is a condition involving the entire pleural sac. In a *partial or localized empyema* the purulent matter is encapsuled. After an empyema ruptures spontaneously it rarely heals without surgical interference, a *pleural fistula*, as a rule, persisting. A *subphrenic abscess* may

follow an empyema. When an empyema ruptures into a bronchus, pneumothorax arises, as a rule. Empyema may cause death by compression of the heart and lung, pulmonary embolism, pericarditis, peritonitis, cerebral embolism, cerebral abscess, septicemia, exhaustion, or rupture into a bronchus.

A small empyema due to pneumococci occasionally, though very rarely, undergoes spontaneous cure, the pus being absorbed (Stephen Paget).

A small empyema is occasionally cured by encapsulation with fibrous tissue.

Under exceptional circumstances even a large empyema may be cured by breaking externally or into a bronchus.

Empyema is so rarely cured spontaneously that it does not do to trust to nature, and practically almost every case will die without surgical treatment.

Double empyema is a rare and extremely fatal condition.

Chronic empyema may follow an acute empyema, or the condition may be chronic from the beginning. In chronic empyema the lung is compressed, shrunk, and strongly adherent, and the pleura is very thick. In some cases the pleura is over an inch thick. This thickening is brought about by the deposition of layer after layer of fibrin. In not a few cases a chronic empyema succeeds an acute one or is itself maintained because a drainage-tube has slipped into the pleural cavity and remains lodged.

A *closed empyema* is one in which no opening has been made by the surgeon and no opening has formed spontaneously. In a closed empyema the pus is rarely putrid; in an *open empyema* the pus is often putrid.

Treatment of Empyema.—The treatment is purely surgical, and the earlier it is applied the better. To delay allows the pleura to thicken and permits adhesions to form, conditions which prevent lung expansion and retard or even prevent cure. The results of operation are better in children than in adults; in small collections than in large; in recent than in advanced cases; in pneumococcus empyema than in empyema due to other organisms. The surgical methods comprise aspiration, incision, rib-resection, the operation of Schede, the operation of Estlander, and the operation of Fowler (see pages 903 to 908 inclusive).

In acute empyema general practitioners are very apt to *aspirate*, and yet aspiration is almost never curative. It may cure a pneumococcus empyema in a child and an encysted empyema, but even in these it will usually fail. Aspiration is not to be considered a method of curative treatment. It is to be regarded as the surgical treatment only in a tuberculous empyema in a young person with rapidly progressing phthisis, because in such a case incision will probably prove fatal (Lockwood). It is a very useful diagnostic expedient, and enables the surgeon to prove the existence of pus, and the pus which is obtained can be examined bacteriologically. In a very large effusion it is wise to aspirate and withdraw part of the effusion a day or two before operating. This enables the patient to take an anesthetic with greater safety and obviates the danger attending the rapid evacuation of a large amount of pus.

In a recent empyema *incision and drainage* or rib resection and drainage will often cure the case, and yet many of the results are unsatisfactory. In some cases the discharge ceases and yet pulmonary function is not completely restored. In other cases a pleural fistula persists. If a profuse discharge is maintained, amyloid disease may arise. An acute empyema is to be drained by intercostal incision or by resection of a rib (page 904). A chronic closed

empyema is drained in the same manner, and if the lung will not fully expand and remains stationary for one year, Schede's or Estlander's operation is required. An open chronic empyema, in which the lung will not expand requires the operation of Schede, Estlander, or Fowler (pages 906 and 907). Extensive decortication is sometimes impossible, and then Ransohoff's operation may be done. He calls it *division of the pulmonary pleura* (page 908). When there is an external opening which persists and which joins a long, narrow cavity, the condition is spoken of as *pleural fistula*, and pleural fistula is often produced by the prolonged use of a drainage tube and sometimes by caries of a rib. Even if there is no opening on the cutaneous surface, there may be one into a bronchus. A pleural fistula may sometimes be cured by dilatation of the sinus. If this fails, and it usually does, it is the custom to resect one or more ribs.

Before resorting to operative treatment try the injection of bismuth paste. We owe this method to Dr. Emil Beck. This plan will often succeed. Ochsner has strongly commended it ("Annals of Surgery," July, 1909). The injection is made with a glass syringe and the material should fill but not stretch the cavity. After injecting the paste the external opening of the fistula is plugged with gauze. The treatment is begun with solution No. 1 (1 part of subnitrate of bismuth devoid of arsenic and 2 parts of yellow vaselin).

This is used every second day until pus has practically disappeared. Then solution No. 2 is substituted for it (10 parts of bismuth, 60 parts of yellow vaselin, and 10 parts of paraffin). The injections are made often enough to keep the sinus and pocket full. They are made at first every day, then every other day, and so on until, finally, every eighth or tenth day is often enough. If poisoning should arise from these injections Beck advises the injection of olive oil at a temperature of 110° F. to dissolve the paste and favor its evacuation.

Non-traumatic Pneumothorax.—By the term pneumothorax is meant the presence of air in the pleural cavity. As a rule, besides air there is serous fluid or pus. It may be due to the rupture of an empyema into a bronchus; to the rupture into the pleural sac of a tuberculous area, an area of gangrene, an abscess of the lung, an air-cell in a state of emphysema, or of pulmonary tissue softened because of hemorrhagic infarction. The immediate effect of the entrance of air into the pleural sac is to compress the lung, the degree of compression being in proportion to the amount of air present. In severe cases the lung is squeezed against the vertebral column, and the heart, the diaphragm, and even the liver are displaced. In some cases, where the admission of air does not continue, the amount set free in the pleural sac is absorbed. In most cases pyopneumothorax (empyema) follows.

Symptoms. The symptoms usually arise suddenly, and consist of distressing dyspnea, pain in the chest, lividity, and rapidity and weakness of the pulse. In some cases of phthisis the symptoms are not very severe. It has been pointed out that occasionally in phthisis pneumothorax seems actually to benefit the tuberculous area in the lung. The physical signs of pneumothorax are as follows: The affected side of the chest is bulged and immobile, and the heart is displaced, especially if the condition affects the left side. Palpation discovers that vocal fremitus is lessened or absent. On auscultation it is found that the breath-sounds are very feeble or absent. The voice is transmitted as a metallic sound, the râles sound metallic, and on coughing there

may be metallic tinkling. The percussion-note is tympanitic. In some rare cases the percussion-note is dull. When fluid gathers, there is a positively dull note on percussion over the fluid.

Treatment.—Osler says the treatment should be the same as that of pleurisy with effusion. In many cases it is wise to perform paracentesis without suction to remove air and serous effusion. If pus forms, a rib should be resected and a tube inserted (see Empyema). In pneumothorax occurring during chronic phthisis operation is of great service. In cases with rapidly progressive phthisis it is practically useless.

If the opening into a bronchus or air-cell remains patent, aspiration will not get rid of air; the air will enter into the pleura as rapidly as the aspirator removes it. Incision has dangers of its own: the diaphragm is flapping during respiration and may be injured (Fowler), and when the pleura is opened, there is a great alteration produced in the air-pressure in the chest, and the patient may "drown in his own secretions." After incision irrigation is not justifiable, because the fluid may enter a bronchus and produce suffocation (Fowler).

West's rules are those I follow*. West says early incision is dangerous. In an early stage use paracentesis without suction. This will often relieve the patient. If paracentesis does relieve him, wait a while and perhaps repeat the operation if the symptoms again become severe. If paracentesis does not relieve, incise, resect a portion of a rib, and drain. If pus forms, an incision must be made and a portion of a rib resected, to afford exit to the fluid.

Fowler points out that if the lung is bound down by adhesions, incision is dangerous but justifiable. Operation at the proper time often prevents the lung being bound down by adhesions.

Acute Traumatic Pneumothorax.—This is produced by the sudden admission of a quantity of air into the pleural cavity as a result of a wound of the chest-wall. A small quantity of air, or the gradual introduction of considerable air, does not, as a rule, produce very serious symptoms. The sudden admission of a quantity of air causes very dangerous symptoms, and even death. A quantity of air may be admitted rather suddenly as a result of an accident or during the performance of a surgical operation which opens the pleura. It sometimes arises during the removal of tumors from the chest-wall, during operations upon the lung, and during empyema operations. As a rule, when pulmonary adhesions exist, dangerous symptoms do not arise, even when the pleura is widely opened, and adhesions exist in 25 per cent. of empyema cases seen by the surgeon.†

It was formerly taught whenever the pleura is opened there is a strong tendency to the development of pneumothorax, but West has shown that the surfaces of the pleura often cohere with a force superior to pulmonary elasticity, and in such cases pneumothorax does not arise.

In surgical operations in which it is necessary to open the pleura widely (as in operation for sarcoma of the chest-wall) the surgeon endeavors to prevent acute pneumothorax which may prove fatal. This may be done by operating in the Sauerbruch negative pressure chamber (page 901), or by applying positive pressure (page 902).

Symptoms. When the pleura is opened during an operation or by an

* British Medical Journal, Nov. 27, 1897.

† Rudolph Matas, *Annals of Surgery*, April, 1899.

injury, the symptoms may be trivial and transitory, may be tolerably severe, may be extremely grave, and the patient may quickly die (Quénu and Longuet). Rudolph Matas sets forth the symptoms as presented by the French observers.*

The mild symptoms are a weak, slow pulse and irregular, noisy respiration.

The severe symptoms are slow pulse, slow and irregular respiration, and dyspnea, continuing after the anesthetic has been withdrawn.

The grave symptoms are cyanosis; collapse; small, weak pulse; shallow and noisy respiration; and spells of syncope. Death may occur suddenly from inhibition, or later from mechanical asphyxia (Matas).

Treatment.—Various plans have been adopted: suturing the opening in the pleura, plugging the opening; pulling the diaphragm into the wound in the

chest-wall and suturing it, and grasping the lung and suturing it to the wound. Whenever the pleura is to be widely opened, use a positive pressure apparatus, and when the operation is complete, suture the lung to the margin of the opening in the pleura with a continuous catgut suture. Parham, Keen, and the author have followed this plan, using the Fell-O'Dwyer apparatus, and the lung was kept from collapsing †

The Fell-O'Dwyer apparatus is shown in Fig. 491.

O'Dwyer's tube is introduced into the glottis as is the tube in intubation, and is attached to a bellows, the lung is inflated, respiration is maintained by the use of the bellows, and collapse, with all its dangers, is avoided. The modern positive pressure apparatus is better (page 902).

Contusions and Wounds of the Chest.—Contusions.

—A contusion may be trivial and limited to the superficial parts of the chest-wall; it may involve the muscles; it may be associated with fracture of the ribs or sternum or with visceral injury.

Symptoms.—In an ordinary contusion without visceral injury there are considerable pain, discoloration, and often

Fig. 491.—The Fell-O'Dwyer apparatus. This illustration shows an early model, since then the bellows has been improved by the addition of a strong wooden frame, which holds it steadily, and is provided with a long arm that acts as a powerful foot-piece for compressing the machine with the least amount of muscular effort.

much swelling. The patient prefers to lie upon the back and the respiration is abdominal. After a severe blow upon the chest there is great shock and may even be instant death. The condition of shock so produced is called *contusion of the chest*. After a severe blow upon the chest a limited area of

* Annals of Surgery, April 1899.

† F. W. Parham's paper on "Thoracic Resection for Tumors Growing from the Bone Walls of the Chest." Read before the Southern Surgical and Gynecological Association, November, 1898.

inflammation may arise in the pleura (*traumatic pleuritis*). Severe visceral injury is announced by positive symptoms. A *contusion of the lung* causes pain, cough, expectoration of bloody mucus, dyspnea, and possibly distinct hemoptysis. Over the contused region the percussion-note is dull and on auscultation crepitus is audible. A *traumatic pneumonia* always follows. This involves a limited area of lung tissue, but genuine croupous pneumonia may arise.

In **rupture of the lung** the physical signs are dependent on the extent and situation of damage. A minute rupture would not produce definite physical signs. If the lung is ruptured and the pleura is not, there will not be pneumothorax, but there may be cellular emphysema first becoming evident at the root of the neck. If the pleura is torn as well as the lung, there will be pneumothorax and hemothorax, the amount of hemorrhage depending upon the situation and extent of the injury.

Le Conte ("Annals of Surgery," March, 1908) points out five ways in which rupture may be caused: (1) *Bruising* (simply causes subpleural ecchymosis); (2) *bursting* (violent force, and a lung unable to empty itself of air is broken as an inflated paper bag is broken by a sharp blow). The question as to whether the glottis must be closed for such an injury to occur is not settled; (3) *penetration* by a green-stick fracture of a rib; (4) *compression* of the lung against some resistant structure; (5) *tearing*, when the lung has previously been adherent to the wall of the chest.

These five causes might be sententiously designated as bruising, bursting, puncturing, squeezing, and tearing.

The *symptoms* are shock, dyspnea, cough with or without bloody expectoration, rapid and irregular pulse, cyanosis, emphysema (appearing first over the region of injury if a broken rib penetrated the lung, and first at the root of the neck if the lung is ruptured, but the pleura is not), and in some cases pneumothorax and hemothorax (see Robt. G. Le Conte, *Ibid.*).

Rupture of the diaphragm causes pain, dyspnea, and often vomiting. The stomach or intestine may pass into the pleural sac. If this happens, there will be a tympanitic percussion-note over the displaced viscus and symptoms will vary with the viscus involved. Such a diaphragmatic hernia may become strangulated. (See page 1146.) In a case in the Jefferson Medical College Hospital, in which the stomach passed into the left pleural sac, there were persistent vomiting, violent pain in the chest and upper abdomen, great thirst, and displacement of the apex-beat. The condition may be confused with pulmonary rupture causing pneumothorax, but in rupture of the diaphragm nausea and vomiting are prominent features, whereas, in pulmonary rupture, if they exist at all, they are early and temporary; further, in rupture of the diaphragm the tympanitic percussion note is not found over the pleural apex but in pulmonary rupture with pneumothorax a tympanitic note is found all over the entire pleural cavity (Le Conte, *Ibid.*).

Treatment of Contusions of the Chest.—A contusion of the chest-wall is treated as directed in the section on Contusions (page 250), and the chest is strapped with adhesive plaster, as in the treatment of fractured ribs. In concussion of the chest the treatment for shock is applied. It may be necessary to employ artificial respiration for a time. If a diaphragmatic hernia is diagnosed, the abdomen should be opened, the displaced viscera restored to

their proper abode, and the diaphragm sutured. The diaphragm may also be reached by resecting several ribs and opening the pleural sac. In contusion of the lung cold is applied to the chest, and any inflammation which arises is treated according to general rules. In rupture of the lung the case may be treated expectantly, but dangerous and continued bleeding or pneumothorax may render surgical interference necessary. For pneumothorax paracentesis without suction is employed. If this fails, it may be repeated. If it fails again, resect a portion of a rib and put in a tube. If bleeding is dangerously profuse resect a portion of a rib and insert a drainage-tube into the pleural cavity.

Wounds of the Chest.—Non-penetrating wounds are not particularly grave, and are treated according to general principles, the chest being immobilized. Penetrating wounds are extremely grave, as viscera are apt to be injured. In such a wound an intercostal artery may be severed or the internal mammary artery may be divided. An intercostal artery is rarely divided unless a rib is broken. The surgeon should always examine carefully in order to determine whether an intercostal artery or the internal mammary artery has been divided, and, in doing so, should bear in mind the admonition of *Mata*—that is, the bleeding from these vessels may be internal, the blood collecting in the pleural sac. The pericardium or heart may be injured (page 461). A wound of the pleura is usually, but not always, associated with a wound of the lung. If the lung is injured, there are usually great shock, pain in the chest, dyspnea, and cough. In a large wound, damage to the lung will be indicated if air is sucked into the wound during inspiration and expelled during expiration, and blood is forced out of the wound by coughing. The lung may be visible or may protrude (*protrusion of the lung*). In a small wound it is often difficult and sometimes impossible to determine whether the lung has been injured. Pneumothorax with pulmonary collapse proves it has. Severe hemothorax strongly suggests it. Spitting blood does not prove it. In some severe cases there is no hemoptysis; in some slight bruises the amount of blood coughed up is large. Emphysema about the wound does not prove lung injury. An incised wound of the lung is apt to produce rapid death from hemorrhage, especially if the wound is at the root of the lung. A pistol-bullet or a sporting-rifle bullet is not usually productive of great primary hemorrhage; but infection probably follows, and secondary hemorrhage is apt to occur. The modern military-rifle ball passes through, rarely lodges, is aseptic, and often produces astonishingly little trouble. A pistol-bullet and an old-time rifle bullet may lodge or may perforate.

Treatment—Bring about reaction as previously directed (page 363).

An incised wound of the chest, if large, should be carefully inspected. If the wound is small, cut down layer by layer until the depths of the wound are reached. Disinfect the wound and arrest hemorrhage. If the pleura is not open, proceed according to general rules. If the pleura is found to have been opened, suture it with catgut, close the superficial wound, dress with gauze, and immobilize the chest-wall.

The above proceeding should be carried out whether it is or is not believed that the lung has been damaged, provided there is no pneumothorax and no violent hemorrhage. What course shall be pursued if the lung has been injured by a stab? If hemorrhage does not threaten life and there is no pneumothorax, the patient is kept at rest and observed. If pneumothorax occurs,

the pleural sac must be drained by means of a tube, because clots must be evacuated and infection should be anticipated. If hemorrhage into the pleural sac persists, active measures become necessary. The use of ice-bags and drugs is but waste of time. Some surgeons believe that the mere closure of the external wound leads to arrest of hemorrhage, blood accumulating and making pressure. It is true that hemorrhage often ceases after suturing or plugging a wound and strapping the chest, but it is not probable that it ceases because of these measures. Blood in the pleura usually remains unclotted for several or many days. Further, as Le Conte shows, as the blood is forced against the root of the lung, the right heart is engorged, the blood-pressure is raised, and the bleeding continues.*

Bleeding from the lung can often be arrested by inserting the end of a drainage-tube into the pleural sac. In cases where a drainage-tube is inserted into the pleural cavity and free drainage established, the pleura is immediately filled with air, and the muscles of respiration are kept from acting on the lung. The lung contracts by its own elastic tissue, as well as by the pressure exerted by the pneumothorax, and at the same time the presence of the air favors clotting in the severed vessels.† If the insertion of a tube fails, or if the bleeding is rapid and obviously seriously threatens life, several ribs must be rapidly resected and the bleeding part explored. In some cases the bleeding may be arrested by ligation, in some cases by packing a small wound with gauze, in some cases by the suture ligature. In a violent secondary hemorrhage following a gunshot-wound of the lung the author packed the entire pleural cavity with sterile gauze to obtain a base of support, and arrested the bleeding by carrying iodoform gauze directly against the oozing surface.‡ I did the same thing recently on a Chinaman suffering from a gunshot wound of the lung. The hemorrhage was arrested and he lived three weeks, dying finally from pericarditis. After directly arresting hemorrhage from the lung, turn clots out of the pleural sac and insert a drainage-tube. In a perforating wound inflicted by a bullet, reaction must be brought about, the wound dressed antiseptically, the chest strapped, and the patient kept quiet. If pneumothorax occurs, the pleura should be drained with a tube. If hemorrhage occurs, it should be met as directed above. In a wound in which the bullet has lodged, an examination should be made to see if the bullet is under the skin, and if it is, it is removed after the patient has reacted. It should always be borne in mind that a pistol bullet may be deflected by a rib or may pass from the front to the back part of the chest by making a burrow under the skin (*a contour wound*). If a bullet is lodged, no attempt should be made to remove it unless an operation must be done for bleeding, unless the bullet causes trouble, or unless it is felt under the skin. Under no circumstances conduct a long search for a bullet. If emphysema of the chest wall is moderate, strapping or a bandage will control it, if it is great, make multiple punctures and then a few pressure. In protrusion of a portion of the lung try to restore the protrusion, but if restoration is impossible or if gangrene seems likely to occur, ligate the base of the protrusion with silk and cut away the mass.

Occluding Pulmonary Embolism.—By this term we mean an embolism which completely blocks the pulmonary artery or some of its chief branches.

* *Annals of Surgery*, April, 1899.

† Le Conte in *Annals of Surgery*, April, 1899.

‡ *Annals of Surgery*, Jan. 1898.

Such cases occasionally follow a surgical operation. The clot is derived from a vein. The calamity is most apt to occur between the second and fourth weeks after an operation (Bartlett and Thompson, in "Annals of Surgery," May, 1908). If the pulmonary artery is completely blocked death occurs at once. If one branch only is blocked the patient may recover if the heart is sound and strong. If the artery proper is partly blocked, the patient has a period of suffering and dyspnea before death, but death is sure to occur from subsequent complete blocking.

Bartlett and Thompson (*Ibid.*) report 22 cases of occlusive pulmonary embolism, 20 of which were fatal. The greatest cause in a surgical operation seems to be varicose veins, especially about an abdominal or pelvic tumor.

The **symptoms** are sudden collapse, cyanosis or pallor with livid lips, the pulse at the wrist is absent or very rapid, and irregular. There are pain in the chest, intense dyspnea, dilated pupils, and early unconsciousness. The surgeon must bear in mind the danger of embolism and endeavor to prevent it in operations by handling and exposing viscera as little as possible by applying ligatures above all clots in veins and all varicosities, and removing the affected structures.

Treatment.—There is nothing to do medically.

Trendelenburg of Leipzig suggests surgical treatment ("German Congress of Surgery," 1908). He points out that death is not always sudden (in 7 cases out of 9 the victim lived from ten minutes to one hour), and advises opening of the pulmonary artery and removal of the embolus. It was tried three times. One died on the table; one died in fifteen hours from cardiac failure; one lived for thirty-seven hours and died of reactionary bleeding from the internal mammary artery.

Abscess of the lung may follow ordinary pneumonia. It is apt to follow aspiration-pneumonia. It is usually caused by streptococci or staphylococci, but it may result from pneumococci or colon bacilli. These germs may reach the pulmonary tissue by direct entrance from adjacent organs, by way of the blood or by way of the bronchi and alveoli. Osler tells us that pulmonary abscess may result from the aspiration of septic particles after "wounds of the neck, operations upon the throat," and suppurative lesions of the nose, larynx, or ear.* Aspiration-pneumonia may develop when there is difficulty in swallowing from any cause, when there is profound exhaustion, and when there is palsy or incoordination of any of the muscles of deglutition. Cancer of the esophagus may be a cause; so may perforation of the lung by an abscess, wound of the lung, impaction of a foreign body in the lung, suppuration about a focus of tubercle or a metastatic abscess. A pulmonary abscess may be of trivial size or it may be very large, involving an entire lobe. There may be one abscess, several, or many. When suppuration results from aspiration-pneumonia or blood-infection, there are usually multiple abscesses.

Symptoms.—The expectoration is not frequent, but is profuse, and during a paroxysm mouthfuls are coughed up in rapid succession. The expectorated matter is sour or very offensive in odor and contains fragments or shreds of pulmonary tissue, which can be identified as such by the microscope. The patient lies upon the diseased side in order to keep the pus

* See Osler's "Practice of Medicine."

from running into the bronchi and causing cough. When the cavity fills and pus reaches the bronchi, violent cough and expectoration begin, continue until the cavity is partly or entirely emptied, and then subside, perhaps for several hours. If the abscess-cavity is large and full of pus, an area of dullness on percussion can be mapped out. When the pus is coughed out and the air enters, physical signs of a cavity are clear. The x-rays often show the situation of such a cavity.

The course of abscess of the lung is usually acute. There are fever of the hectic type, rapid loss of weight, weakness and rapidity of circulation, dyspnea, pallor, sleeplessness, and great weakness. Gangrene may arise; empyema or pyopneumothorax may develop; very rarely the abscess breaks through the chest-wall; recovery may follow spontaneous evacuation or drainage by coughing up pus; death may result from exhaustion or secondary septic lesions. If operation is performed, from 50 to 60 per cent. of the patients will recover.

The treatment is purely surgical (*pneumotomy*). Make an incision over the cavity. Resect a portion of one or more ribs. Expose the pleura. If the two layers of the pleura are not adherent, suture them together and wait two days. If they are adherent, proceed at once. Search for the abscess with an aspirating needle. When the cavity is found, open into it with the cautery and insert a drainage-tube (page 908).

Gangrene of the Lung.—This term means the putrefaction of a devitalized portion of pulmonary tissue. The tissue is devitalized by the action of pyogenic micro-organisms. Gangrene may follow abscess, bronchitis, or pneumonia, or may be due to diabetes, to embolism of the pulmonary artery, bronchiectasis, tuberculosis, malignant disease, wounds, or the lodgment of foreign bodies. Gangrene may be circumscribed or diffused. There may be one cavity, small or large, or multiple cavities may form. The gangrenous area putrefies, softens, and the softened matter may be expectorated, a gangrenous cavity being formed. In the rare cases which undergo spontaneous cure the cavity is, after a time, surrounded by fibrous tissue and obliterated by granulations.

Symptoms.—Expectoration occurs only now and then, but at each seizure a great quantity of matter is brought up and this matter is extremely offensive. Occasionally there is no expectoration. The patient, as in lung abscess, lies upon the diseased side. The expectorated matter is mucopurulent, contains particles or shreds of pulmonary tissue, bacteria, and altered blood. The fetor of the pus is much greater than is the fetor of the pus of an abscess. The breath is very foul. Physical signs may indicate either consolidation or a cavity. There are hectic fever, great exhaustion, deathly pallor, and diarrhea. Pulmonary hemorrhage is not unusual, and complications spoken of in the article upon Abscess may occur (page 898). Recovery sometimes ensues, the cavity closing by granulation. Death may take place in a few days. Often the patient lives for weeks, being sometimes better and sometimes worse, dying finally from exhaustion or from the effects of a complication.

The treatment is to operate as for pulmonary abscess.

Treatment of Pulmonary Tuberculosis.—Surgical Treatment.—For the past decade surgical thought has been actively directed toward placing on a scientific footing operations for pulmonary phthisis. The

matter is still in a transition stage, and operations at present have a limited field of application, although Sonnenberg and others have reported cures. Baglivi, in 1643, endeavored to tap and inject tuberculous cavities. Hastings and Sturck did the same thing in the eighteenth century. Mosler, a number of years ago, attempted to treat cavities by introducing a trocar into the cavity and injecting permanganate of potassium solution through the cannula. Patients were not benefited by this procedure. The plan was revived by Pepper in 1874. The results are bad and the operation is dangerous. Hillier tried injection of corrosive sublimate into the lung parenchyma, but the effect of the injections was disastrous. Vidal advocates counter-irritation by the actual cautery and maintains that congestion improves nutrition. When the strength of the patient is well preserved and the pulmonary lesion is circumscribed and slowly progressive, it may be justifiable to perform an operation, open the cavity, and treat it directly (*pneumotomy*). That pneumotomy might be performed successfully was suggested to surgeons by observing that some patients recovered after sword thrusts into the lung. Fowler says it is not justifiable to operate if the disease has come "to a standstill." The same surgeon states that the only accessible region is bounded above by the clavicle, to the inner side by the mediastinum, to the outer side by the lesser pectoral muscle, and below by the second rib.* This operation does not cure any one, but it may cause distinct improvement when there is hectic from an ill-drained cavity containing the products of a mixed infection. In an advanced case there is usually more than one cavity, and then the operation is contraindicated. Before attempting it, be sure the case is advanced and not incipient and that the cavity is single. Locate the cavity by auscultation, percussion, and the x-rays. (See Willard, "Jour. Amer. Med. Assoc.," Sept. 20, 1902.)

Mauchaise says that pneumotomy is justifiable only in circumscribed tuberculous cavities without peripheral infiltration and in pulmonary abscesses.† Bronchiectatic cavities are usually multiple, they are exceedingly difficult to locate, and treatment by pneumotomy should not be attempted. In the treatment of pulmonary tuberculosis resection of the diseased area has been proposed (*pneumectomy*). Tuffier successfully performed this operation. Surgeons, as a rule, do not believe in pneumectomy. Reclus voices the general opinion when he says the operation is not required if the area of disease is very limited, as such a condition is frequently curable by medicinal means, and it does no good if the area of disease is extensive.

It has long been known that pneumothorax might benefit a tuberculous lung. Attempts have been made by Farlanini and Murphy to cure phthisis by the deliberate production of artificial pneumothorax. Murphy injected nitrogen gas into the pleural sac, and believes that the method is of great value. It is maintained that Murphy's operation occludes the lymph-channels, prevents bleeding, compresses the lung, favors the development of fibrous tissue and leads to healing of cavities. Every third or fourth week 120 c.c. of nitrogen gas are injected into the pleural sac. (See Willard in "Jour. Amer. Med. Assoc.," Sept. 20, 1902, Murphy's paper before Amer. Med. Assoc. in 1898.)

* See the very full and thoughtful article by George Ryerson Fowler on "The Surgery of Intrathoracic Tuberculosis," *Annals of Surgery*, Nov., 1896.

† *La Tribune medicale*, Sept. 21, 1893; *Revue de Chirurgie*, Nov. 11, 1895.

Lernke, in "Jour. Amer. Med. Assoc.," Oct. 14, 21, 28, 1899.) The operation is not dangerous, but its value is greatly diminished if there are adhesions. The more numerous the adhesions the less the usefulness of the method. Adhesions prevent pulmonary collapse. The method is valuable in hemoptysis.

Allis suggested that in extensive unilateral tuberculosis of the lung resection of a number of ribs will favor cure by permitting retraction of the chest-wall.* This operation is founded on the belief that the chief element in effecting a cure is the formation and contraction of fibrous tissue. Pulmonary collapse and abolition of movements favor the formation of fibrous tissue. In this operation the pleura is not opened. Quinke, Landerer, and others remove portions of ribs with periosteum along the axillary line. Some surgeons remove portions of ribs and periosteum from directly over the lesion. Freeman removes portions of ribs without periosteum and applies a truss to push in the chest wall ("Annals of Surgery," July, 1909). Friedrich, of Marburg, removes all the ribs from the second to the tenth inclusive and mobilizes the first rib (*thoracicoplasty pleuropneumolysis with subcostal apicectomy*). The pleura is not opened. He used to remove the periosteum, but does so no longer. He now leaves the periosteum so that after a time enough bone will reform to prevent lung bulging on coughing.

OPERATIONS ON PLEURA AND LUNGS.

Intrathoracic Operations Under Positive or Negative Air-pressure.—When under ordinary conditions the chest wall is widely opened the lung often rapidly collapses and the patient is placed in deadly peril (see *Acute Traumatic Pneumothorax* on page 893). The reality of the danger has to a great extent retarded progress in the surgery of the heart, lungs, and lower portion of the esophagus. Of late, however, methods have been devised for maintaining normal respiratory movements and preventing pulmonary collapse during operations which open the pleura. There are two forms of pressure apparatus and each form finds warm advocates. Negative pressure is the form that is advocated by Sauerbruch. In Sauerbruch's negative pressure chamber the lung is kept from collapse by suction exerted upon its exposed surface. Positive pressure is advocated by Brauer. Positive pressure keeps the lung from collapsing by distending it from within. The two methods act similarly in many respects. Clinical observations and numerous experiments seem to prove that "emphysema, persistent pneumothorax, difficulty of narcosis, and infection of the pleura are not dangers associated with the use of positive pressure as such" (Samuel Robinson and George Adams Leland, in "Surg., Gynecol., and Obstet.," March, 1909).

The Sauerbruch Chamber. This is an air tight cabinet. The sides are of boards covered with tin, the corners being soldered. The roof is of glass. The sides contain air-tight windows. There is one air tight door.

The room is lighted by electricity and contains a telephone. The larger chambers have a communicating room. Instruments which are wanted

* Allis, to State Med. Soc. of Penna. in 1891.

Surgery of the Respiratory Organs

placed in this room so that the surgeon may get them. The patient is placed outside of the cabinet and a tightly fitting rubber collar is placed around the neck. The body and legs are surrounded by a canvas cover. The interior of which is in communication with the external atmosphere. The chamber is sufficiently large to hold the patient, the surgeon, and the anesthetist. By means of an electric suction air pump, the valve of which is closed, negative pressure is obtained and is continuously maintained. The patient's thorax is exposed to the suction of negative pressure. The bronchioles are subjected to ordinary atmospheric pressure.

Fig. 492.—Sauerbruch's cabinet: Position of patient in chamber ready for operation under negative pressure.

even when a wide opening is made in the chest wall, the lung does not collapse. The operator does not suffer from the negative pressure.

The Positive Pressure Apparatus.—Numerous apparatuses have been devised.

This used to be done by the Fell O'Dwyer apparatus (Fig. 493). The larynx was intubated and bellows were used. It can be done with a mask, but is uncertain and difficult to use.

Brauer advocated the following plan: When the patient is anesthetized and the surgeon is ready to open the pleura, a glass chamber is placed over the patient's face and the air in the case is condensed by means of a small motor pump.

Bauer subsequently modified the head chamber so that the wrists of the anesthetist are admitted within it. Some surgeons have used compressed air by the nose, the mouth being sealed. Some have used a tube from the mouth. The trouble with this method in many cases is that it is not completely satisfactory tube has yet been made. As a general rule, it is better to give it by a well fitting face mask. A small motor pump is used for the air pump and thus we dispense with the trouble and use of bellows.

reservoirs Robinson and Leland* state that any positive pressure apparatus consists of four elements: (1) A supply of compressed air; (2) an anesthetizing segment; (3) a device for introducing air and ether into the respiratory tract; (4) a means of varying the resistance of exhaled air (Fig. 493).

Exploratory Puncture of the Pleural Sac.—Puncture often gives valuable information as to the existence of fluid in the pleural sac and as

Fig. 493.—Scheme of apparatus for the maintenance of distention of the lung by positive pressure (Robinson and Leland).

to the nature of the fluid. The operation must be performed with aseptic care, otherwise a serous effusion might be converted into a purulent effusion, and either a serous or a purulent effusion might be rendered putrid. A large hypodermatic syringe with a long and strong needle is used for exploratory puncture. A slender needle breaks easily and is unsafe. In order to prevent breaking of the needle impress upon the patient the absolute necessity of keeping quiet and avoiding any violent respiratory or general movement during the operation. It is not desirable to stick the lung, although harm rarely results from such an accident. If no fluid is found in the pleura on one trial, several other punctures should be made. What is known as a dry tap may be due to the entire absence of fluid, to encapsulation of fluid in a region not invaded by the needle, to the lodgment of the point of the needle in thickened pleura or in an adhesion, or to blocking of the lumen of the needle with coagula. Fowler points out that if a person has been recumbent for a long time, the upper layer of fluid may be clear while the lower layer is purulent.† The fluid should be collected in a sterile glass tube and subjected to a careful bacteriological study.

Paracentesis Thoracis.—The operation of tapping with a simple trocar and allowing the fluid to flow out through the cannula is no longer practised except in an emergency, when an aspirator cannot be obtained, or in an early stage of non-traumatic pneumothorax. An aspirator is a much better instrument.

Aspiration.—Aspiration consists in the introduction into the pleural sac of the tip of a hollow needle, the other end of which is attached by means of a rubber tube to a bottle from which the air has been exhausted. The fluid does not run out, but is sucked out, air is excluded, and bacteria do not enter the pleural sac. Fig. 379 shows a pneumatic aspirator. No anesthetic is required. The patient's skin, the instruments, and the surgeon's

* "Surg. Gynecol. and Obstet.," March, 1909.

† "Annals of Surgery," November, 1896.

hands must be thoroughly aseptized. The patient is given a little whisky, and, unless he is very weak, he assumes a semi-erect attitude, with the arm hanging by the side. The trocar is introduced in the fifth interspace, just in front of the angle of the scapula. The surgeon marks the upper border of the sixth rib with the index-finger, and plunges in the trocar just above the finger, thus avoiding the intercostal artery, which lies along the lower border of the rib above. He guards the needle with the index-finger to prevent its going in too far. The fluid is withdrawn rather slowly in order that the patient may escape syncope and violent cough. If the patient becomes very faint, the operation should be abandoned. All the fluid present should not be removed at one sitting—complete removal of a large effusion is not safe. The operation can be repeated if necessary. After withdrawing the cannula place iodoform collodion over the opening in the chest. In an early stage of non-traumatic pneumothorax perform paracentesis without suction. In non-purulent pleuritic effusion, if the lungs will not expand after tapping, perform thoracotomy. In some cases aspiration is followed by pulmonary embolism or embolism at a distance. Syncope is a not unusual result. Convulsions occasionally occur. In rare cases the sudden withdrawal of a large effusion is followed by *albuminous expectoration*, as was pointed out by Pinault in 1853. It usually begins from a few minutes to half an hour after aspiration. When this complication arises, the pulse is very weak, there are severe dyspnea, cyanosis, cough, and the expectoration of quantities of a yellow, frothy fluid. Riesman ("Amer. Jour. of Med. Sciences," April, 1902) demonstrates that the condition is due to pulmonary edema and not to puncture of the lung. The sudden withdrawal of fluid by aspiration relieves the pressure which was compressing the lung, the lung becomes congested with blood (*congestion by recoil*, Riesman calls it), the blood distends weakened vessels, and profuse transudation takes place into the air-cells. Most cases recover in a few hours or a day or two. Severe cases die from asphyxia. Terrillon collected 23 cases with 2 deaths. If albuminous expectoration arises, dry cup the chest and counterirritate with mustard plasters. Perform venesection. Give oxygen by inhalation. Administer atropin hypodermatically. Employ artificial respiration if necessary.

Thoracotomy is an incision into the cavity of the pleura. It may be merely an intercostal incision, or may be an opening into the chest after resecting a portion of a rib. Often in a child with empyema good drainage can be obtained by an intercostal incision, but in most children and in all adults a rib should be resected. The instruments required for rib resection and thoracotomy are a scalpel, a grooved director, forceps (hemostatic and dissecting), scissors, a periosteum elevator, retractors, a testotome or metacarpal saw, rongeur forceps, drainage-tubes, and needles.

If there is very little dyspnea, ether can be given. If there is considerable dyspnea, chloroform should be given. If there is severe dyspnea, no general anesthetic is admissible. In severe dyspnea the patient is using certain voluntary muscles to aid him in obtaining air. A general anesthetic abolishes the activity of the voluntary muscles of respiration, and so might cause suffocation. In such cases the operation can be done with fair satisfaction after

the injection of eucain or after infiltrating the superficial tissues of the chest wall with Schleich's fluid, or, what is better, preliminary aspiration can be performed. Aspiration will permit of the subsequent administration of a general anesthetic. The patient on whom thoracotomy is to be performed is placed supine, the diseased side being at or over the edge of the table. He must never be placed on the sound side, because he breathes only with that side, and pressure on it may be dangerous.

The arm of the diseased side should be elevated to a right angle with the body. If the surgeon desires to obtain only intercostal drainage, he should make a longitudinal incision about three inches in length at the upper border of the sixth or seventh rib, and the middle of this incision should correspond to the midaxillary line. This incision is carried, layer by layer, to the pleura. If, as will usually be the case, he wishes to remove a portion of a rib, he will make an incision about three inches in length directly upon the outer surface of the rib he wishes to remove, and the middle of this incision corresponds to the midaxillary line. Some surgeons resect a portion of the fifth rib, some remove a bit of the eighth rib, and Munro* shows that at the level of the eighth rib there is no danger of injuring the diaphragm. By many operators a portion of the seventh or eighth rib is removed in front of the line of the posterior axillary fold.

Fig. 494. — Resection of a rib (Esmatch and Kowaling).

I agree with Hutton that a portion of the sixth rib in the midaxillary line should be removed.† The reasons given by Hutton for the selection of this rib are: (1) It is over the portion of the lung which expands last. An empyema is drained only partly by gravity, and the fluid is really forced out and the cavity obliterated by lung expansion. If an incision is made anterior or posterior to this point, the expanding lung will block the drainage-opening, and a pus-cavity without drainage will remain in the midaxillary line. (2) Such an incision permits a patient to lie on his back without making pressure on the drainage tube.

The periosteum of the outer surface of the rib must be divided in the same direction as the superficial incision. The exposed rib is stripped of periosteum front and back by means of a periosteal separator, and with the periosteum at the lower border of the rib the intercostal artery is lifted out of harm's way. The rib can be divided by means of cutting forceps, a chain saw, or a Gigli saw. I prefer a costotome, as it accomplishes the section most rapidly. The usual method is to push a periosteal separator under the rib, and saw the bone in two places by means of a metacarpal saw (Fig. 494). An inch or more of the rib should be removed. The intercostal artery is ligated at each end of the incision, the periosteum is removed, and the pleura is opened. The object of removing the periosteum is to prevent the rapid formation of bone which might narrow the opening and interfere with drainage. The actual opening of the pleura is carried out in the same way in intercostal incision and after rib-resection. A grooved direc-

* Medical News, Sept. 2, 1897.

† See W. Menzies Hutton on "Empyema," in Brit. Med. Jour., Oct. 20, 1898.

tor is pushed into the pleural sac, and the opening is enlarged by means of the forceps and the finger.

The finger removes all masses of tuberculous material or aplastic lymph within reach. If the finger finds the lung firmly bound down by dense adhesions so that it cannot expand, simple rib-resection will not cure the patient, and Estlander's, Schede's, or Fowler's operation should be done. Some surgeons advocate immediate irrigation after opening an acute empyema, but this procedure is unsafe. It is true that in most cases irrigation does no harm, but in no case will it sterilize the cavity, and in some cases it is very dangerous. The pleura is very susceptible to the action of irritants. This is especially true of young children. It happens occasionally that the injection of the blandest fluid is followed by intense dyspnea, great shock, disturbances of respiration and circulation, convulsions, and even death (Quénu). The convulsions which occasionally follow pleural irrigation were called by de Cereville *pleural epilepsy*. In putrid empyema it is proper to irrigate. Irrigation will remove part of the actively poisonous putrid matter, and the retention of putrid matter is a greater danger than irrigation. It was formerly a common custom to make a counter-opening by cutting down upon the long probe pushed against the chest-wall after being introduced through the incision, but a counter-opening is of no particular use. A drainage-tube about two inches in length is introduced and stitched in place. The tube must not be long enough to touch against the lung. A safety-pin is clamped upon the tube to keep it from slipping into the chest. A tape should be fastened to each side of the tube and tied about the chest to prevent it from slipping out. Arrest bleeding, suture the skin, dress with gauze, wool-wool, and a binder, and have the dressings changed as soon as they become soaked at one point. Several times a day change the patient's position. At each change of dressings direct him to lie on the diseased side with the foot of the bed raised for half an hour. Healing takes place by ascent of the diaphragm, expansion of the lung, and retraction of the chest-wall. Expansion of the lung is favored by expiratory acts; hence cause the patient several times a day to blow through a rubber tube into a one gallon Woulff bottle filled with water. The water is blown into another bottle attached to the first by a tube. Remove the drainage-tube when the discharge becomes thin and scanty (about the eighth or tenth day, as a rule). If an empyema ceases to improve and remains stationary for months after it has been drained, firm adhesions exist. If after one year has passed a cavity still exists and there is a flow of pus, the surgeon must perform the operation of Schede, Estlander, Fowler, or Ransohoff.

Thoracoplasty (Estlander's operation) is employed in old cases of empyema in which drainage has failed, and in cases with retracted chest-wall, collapsed lung, thickened pleura, and cavities whose rigid walls will not collapse. The procedure recognizes the fact that after pus is evacuated, if the lung is adherent, it cannot expand to fill the space once occupied by fluid, and that the rigid chest-wall cannot fall in as a substitute for the lung. It seeks to destroy the rigidity of the chest-wall and to permit it to collapse and thus obliterate the cavity of the empyema. When the surgeon resects a rib and finds a cavity with uncollapsible walls, or a lung bound down with firm

adhesions, he should perform thoracoplasty. This operation causes the obliteration of the cavity by collapsing that portion of the chest-wall overlying it. The cavity is usually in the upper or central part of the pleural space. The instruments required are the same as those for resection of a rib. The position is the same as that for rib-resection. The length of the incision depends on the size of the cavity. The surgeon usually removes portions of the second, third, fourth, fifth, sixth, and seventh ribs. Make a transverse incision along the center of an intercostal space, and through this incision remove the ribs above and below by the method set forth on page 904 (the removal of six ribs will require three incisions). Instead of this incision, we can make a vertical incision or a U-shaped flap. Always take away the periosteum in order to prevent reproduction of the ribs. In cavities which are surrounded by firm adhesions, and in old cases in which the pleura is greatly thickened, irrigation is safe. If the cavity is small, it should be packed with iodoform gauze and allowed to granulate; if large, it should be drained by a large tube, the skin being sutured by silk worm-gut.

Fig. 495.—Incision for Schede's operation of thoracoplasty (Esmarch and Kowatzig).

Schede's Operation.—Schede showed that when the pleura is much thickened, even Estlander's operation will not permit the chest-wall to collapse and fill the cavity once occupied by the fluid. The instruments used are the same as for Estlander's operation. A U-shaped flap is made from the level of the axilla in front to the level of the second rib and between the scapula and spine behind. The lowest level of this incision corresponds to the lowest limit of the pleura (Fig. 495). The flap is loosened and raised and the scapula is lifted with it. The ribs from the second rib down and from the costal cartilages to the tubercles are removed, along with the intercostal muscles and the pleura. This is accomplished by cutting with bone-shears and scissors. Hemorrhage is arrested. The pleura is curetted. A drainage-tube or a piece of iodoform gauze is introduced, and the raw flap is laid against the visceral layer of the pleura. The superficial incision is sutured, except at the point where the tube of the gauze emerges. The mortality from Schede's operation is from 15 to 20 per cent.

Total Pleurectomy or Pulmonary Decortication (Fowler's Operation).—In the spring of 1893 de Lorme performed some experiments on dogs looking to the development of the operation. In October, 1893, George Ryerson Fowler, having no knowledge of de Lorme's investigation, operated on a man and cured a chronic empyema. The French surgeon's first operation was months later. Extensive rib-resection is practised. This is better than de Lorme's trap-door flap, which causes pneumothorax. The thickened pleura is removed from the chest-wall, lung, pericardium, and diaphragm, any sinus is extirpated, and all granulation tissue is taken away. Fowler

makes a report of 30 cases. Eleven cases were completely cured. In 17 cases the empyema was cured, but 6 of them had tuberculosis. There were 3 deaths. The combined statistics of Fowler, de Lorme, and Cestan show 35.7 per cent. cured, 19.7 per cent. improved, 33.9 per cent. not cured, and 10 per cent. died (Kurpjweit, in "Beitrage zur klinischen Chirurgie," Bd. xxviii, H. 3).

Dissection of the Pulmonary Pleura (Ransohoff's Operation).—

This operation can be employed when decortication is impossible, and it may be used as a substitute for decortication in certain cases. It is founded on the observation that if the thickened pleura over a shrunken lung is incised the cut widens with each respiration and quickly becomes a groove (Ransohoff, in "Annals of Surgery," April, 1906). The pulmonary pleura is divided by numerous parallel incisions one-quarter of an inch apart, and then similar incisions are made to cross these. An incision is also carried through the costal side of the angle of reflection of the pulmonary and costal pleura.

Pneumotomy for Abscess of the Lung. Give chloroform or use a local anesthetic. Place the patient recumbent with the shoulders a little raised. Make a U-shaped flap over the seat of disease. Resect a portion of a rib. If it is found that adhesions do not exist between the pulmonary and costal layers of the pleura, stitch these layers together with catgut and postpone further operation for forty-eight hours. If adhesions exist, proceed at once. Chloroform can be put aside when pleura is exposed. Fowler calls attention to the fact that lung tissue is so insensitive that the administration of an anesthetic can be suspended as soon as the pleura has been opened. Incise the agglutinated layers of the pleura, and pass an aspirating needle into the lung in various directions. When the abscess is located, open it with the cautery. Carry the Paquelin cautery slowly into the lung in the direction of the abscess cavity. The cautery knife should be at a dull red heat.

When the cautery opens the cavity of the abscess, withdraw the instrument and insert a drainage tube, and suture the flap of superficial tissue. If the abscess is not found after one or two punctures with the aspirating needle, abandon the attempt.

Tuffier explores for an abscess by what he calls *décollement of the parietal pleura*. He exposes the parietal layer of the pleura, passes his hand between this layer and the chest-wall, strips the pleura off over a considerable area, and is able to feel the lung below and thus determine its condition.

XXVI. DISEASES AND INJURIES OF THE UPPER DIGESTIVE TRACT.

Injuries and Diseases of the Face, Nose, Mouth, Salivary Glands, Tongue, Jaws, and Esophagus.—Wounds of the Salivary Glands. An aseptic wound usually heals and rarely results in a salivary fistula, although after healing it is not unusual for an encysted collection of saliva to gather under the skin. Such a collection of saliva, if it does not disappear spontaneously, can usually be gotten rid of by continued pressure. When a wound of a salivary gland is infected, a single fistula or multiple fistula may be left as a legacy. A salivary fistula is very annoying, because the saliva flows con-

stantly. A fistula usually heals spontaneously after a long time, but healing can be quickly brought about by touching the orifice with the Paquelin cautery.

Wound of Steno's duct is apt to cause a fistula, and the condition is often difficult to cure. In this condition, when the duct was cut across, the central end grows fast to the cutaneous surface. Fistula of Steno's duct may also be caused by obstruction and rupture of the duct and by suppurative or gangrenous processes.

In wounds of the duct the ends should be brought as near together as possible with catgut sutures which do not enter the lumen of the duct; an incision should be made through the mucous membrane to permit drainage of saliva if the mucous membrane is not already opened, and the skin should be sutured. In some cases the central end of the duct may be carried into the mouth and sutured to the mucous membrane. If, after an injury of Steno's duct, saliva gathers under the skin, make an incision through the mucous membrane, to give a route for the saliva to enter the mouth, and apply pressure externally. When a fistula forms, it may be cured by the cautery and pressure, but, if the peripheral portion of the duct is obliterated, which can be determined with a sound, an operation must be performed. Tillmanns advocates cutting out the external portion of the fistula by two elliptical incisions. A trocar is passed through the bottom of the wound in two places, about half a centimeter apart; a piece of stout silk is drawn through the holes and tied tightly and the superficial incision is closed. The silk cuts through and makes an internal fistula. Another method is to make an incision, find and isolate the central end of the duct, open the mucous membrane, suture the duct to it, and close the superficial wound.

Fig. 496.—De Guise's operation for salivary fistula. Farnatch and Kowalzig.

De Guise's operation is shown in Fig. 496. He threads a piece of silk through two needles and carries the needles into the mouth so that the silk will embrace a bit of tissue half a centimeter in length. The silk is tied tightly within the mouth, the ends are cut off, and the margins of the fistula at the surface are freshened and sutured.

Parotitis.—Mumps, or epidemic parotitis, is treated by the physician. In this condition the submaxillary and sublingual glands are usually involved as well as the parotid. In pyemia metastatic abscesses may form in the parotid gland. Great swelling arises, respiration is often embarrassed, and early incision is necessary. Parotid inflammation other than mumps is usually due to the passage of bacteria up Steno's duct, the source of the microbes being a bad condition of the mouth, particularly noma or stomatitis. Hence such inflammation is most common during the existence of acute infectious diseases and sepsis. Suppuration or even gangrene may occur. As a rule, only one gland is attacked, but both may be. It is a well-known fact that occasionally,

though very rarely, after an abdominal operation inflammation of the parotid gland occurs. The condition is more common in adults than in children. This form of parotitis may, of course, be due to septic metastasis and may be produced by trauma, but I am satisfied that most cases result from foul mouths, the infection ascending from the mouth along the duct. Oral cleanliness strongly tends to prevent the so-called "sympathetic" parotitis. In about one third of the cases the condition is not to be distinguished from mumps and is recovered from in seven or eight days. Mild cases seldom suppurate, and if they do, the pus flows down the duct and into the mouth. In nearly one half of the cases, according to Marchetti ("Epitome of Surgery," in "Brit. Med. Jour.," March 6, 1909), there is phlegmonous inflammation with necrosis and suppuration of the tissues and formation of a salivary fistula. In non-suppurative parotitis there are pain, tenderness, obvious swelling, and hyperemia of the skin, and it is difficult to open the mouth or swallow. When suppuration occurs, all of the above symptoms are intensified, the discoloration becomes dusky, the skin becomes shiny and edematous, the constitutional symptoms of pus formation exist, and there is usually delirium.

Treatment.—In the non-suppurative form apply an ice-bag over the gland for the first twenty-four hours and then substitute heat. Wash the mouth out frequently with an antiseptic wash and apply ichthyol and lanolin to the swollen region. In the suppurative form make several openings by Hilton's method, seeking for points of softening; apply hot antiseptic fomentations, wash the mouth frequently with an antiseptic fluid, and combat sepsis by appropriate constitutional treatment.

Salivary Concretions.—The saliva contains in solution certain salts which may deposit. Deposited on the teeth, they constitute tartar. Deposited in a salivary duct or the acini of a gland they constitute a calculus. The salts deposited are carbonate and phosphate of lime. A calculus may consist purely of these two salts or there may be a foreign-body nucleus. A calculus is a possible result of an inflammation which blocks, constricts, or roughens a duct or acinus and decomposes saliva. Small concretions are often passed. Concretions the size of a bean are retained. A concretion may attain the size of an English walnut. A concretion does not block a duct continuously, but does so now and then, causing swelling and tenderness of the gland. A retained calculus can be palpated by a finger in the mouth and a finger externally.

Treatment. A calculus in a duct is extracted by making an incision through the mucous membrane. If a very large calculus forms in the submaxillary gland, the gland should be removed through an external incision.

Harelip and Cleft Palate.—*Harelip* is a congenital cleft in the upper lip due to defective development. *Cleft palate* is a congenital fissure in the soft palate or in both the hard and soft palates. In harelip the cleft is usually complete, through the entire lip into the nostril, but in rare cases it may show only as a furrow in the mucous edge or as a split from the nostril partly into the lip. It is most common on the left side. In double harelip the central portion of the lip is often adherent to the tip of the nose. Double harelip may be free from complication, but is often associated with a malformation of the alveolus and palate. Median harelip is exceedingly rare. In cleft palate the septum of the nose is usually adherent to the palatine process

opposite the side upon which the fissure exists. In those rare cases of cleft palate double in front, the nasal septum is attached only to the premaxillary bone, and the premaxillary is not attached at all to the superior maxillary bone. In harelip there is frequently a cleft in the alveolus, and almost always flattening of the corresponding side of the nose. Harelip is often associated with cleft palate, talipes, and other deformities. It is a great deformity, and interferes with sucking, swallowing, and articulation.

Operation for harelip uncomplicated by cleft palate should be performed between the third and sixth months of life in a child in good health, free from stomach trouble, cough, or coryza, but operation is not advisable in the early weeks of life. Always, if possible, operate before dentition begins (seventh month). If the child is in poor health, postpone the operation until restoration has so far advanced as to render operation safe. While waiting for operation be sure the child is getting enough food. If it cannot suck, feed it with a spoon. If a cleft exists in the palate, we sometimes operate first upon the lip, because the pressure of the parts after the edges of the gap are approximated aids in the closure of the bony cleft. In other cases we operate first on the palate. Cleft palate interferes with sucking, deglutition, mastication, and articulation. In severe cases the food passes into the nose and excites inflammation. Loss of control of the palate-muscles always exists, and liquids and solids are liable to pass into the windpipe. Clefts in the hard palate should not be operated on until the second year, but should be operated upon then, otherwise speech will be permanently affected. Some surgeons refuse to operate until the tenth or twelfth year, but operation done this late will not correct speech-defect. The patient at the period of operation should be well and free from cough. In many cases the passage of food and drink into the nose can largely be prevented by the use of a diaphragm.

Operation for Harelip.—The instruments required are a tenotome and scalpel, toothed forceps, hemostatic forceps, scissors curved on the flat and pointed, straight blunt-pointed scissors, needles (straight and curved), silver wire or silkworm-gut and silk sutures, a mouth gag and tongue-forceps, a needle-holder and sequester-forceps, each blade protected by a rubber tube. Wrap the child in a sheet; place it in the Trendelenburg position, and rest the head upon a sand-pillow. The surgeon stands to the right side of the patient. Ether or chloroform is given. For *single harelip*, separate with the scissors the upper lip from the bone on each side of the cleft until approximation of the cleft can be effected without tension. If the premaxillary bone of one side projects more than its fellow, grasp it with sequester forceps and bend it back (Jacobson and Treves). Clamp the upper lip at each angle of the mouth to prevent hemorrhage. If the edges are of equal or nearly equal length, and if the gap is not very wide, perform Malgaigne's operation. This is performed as follows: a flap is detached on each side, the detachment beginning at the upper angle of the gap; each flap is detached above, but remains attached below. The flaps are separated from the bone, and are drawn downward so as to form a prominence at the vermilion border (Fig. 497). If the edges are pared so that in closure the vermilion border is even, when the parts are healed a gutter will be visible at the line of union. The edges are approximated by an assistant, and silkworm-gut sutures or silver wires are passed by means of a straight needle. Each suture goes down to the mucous membrane. The first suture

is passed through the middle of the lip, one third of an inch from the cleft. Three or four main sutures are passed through the thickness of the lip, and are tied and cut off. Two or three fine silk or catgut sutures are passed by a curved needle through the vermillion border of the lip and the mucous membrane of the mouth, and are tied and cut off. A small piece of gauze is placed over the lip and is held in place by straps of rubber plaster. After operation prevent the child crying by feeding it often and giving it small doses of laudanum. Heath orders two drops of laudanum in one ounce of distilled water, a teaspoonful to be given every two or three hours. About the sixth day one-half the sutures are taken out, and on the eighth or ninth day the remaining ones are removed. In many cases no further procedure is necessary, but if after some weeks the prominence at the lip-border does not shrink, it can be readily clipped away. Harelip-pins are not used at the present time, and are not needed if the lip is well separated from the bone. If the edges of the cleft are of unequal length, Edmund Owen's operation can be performed (see

Fig. 497.—McGuire's operation for harelip.

Fig. 498.—Incisions for double harelip (Chamarch and Kowaleg).

Fig. 499.—Mirault's operation for single harelip (Fismarch).

below, under Double Harelip), or we can perform Mirault's operation, as shown in Fig. 499.

In *double harelip* the operation is similar to that for single harelip. If the intervening piece is vertical and is covered with healthy skin, complete each operation as for single harelip, closing both fissures at once with silver wire in a strong, healthy child, closing them at intervals of three weeks in one not so lusty (Fig. 498). Excise the septum if it is deformed. The premaxillary bone should in most instances be removed, the skin over it being preserved. Sir Wm. Fergusson was accustomed to incise the mucous membrane and shell out this bone. The premaxillary bone can be forced back into line, being held, if necessary, by catgut suture of the periosteum; but if saved, it is liable to necrose and its teeth soon decay. Heath removes this bone two weeks before operating on the lip. If there is much hemorrhage after removal of the bone, arrest it with a hot wire or with Horsley's wax. Fig. 498 shows incisions for double harelip. Edmund Owen's operation is very useful (Figs. 500 and 501). In this operation very thick flaps are cut. The prolatum and invasive bone are removed. The flaps are cut as shown in Fig. 500, on one side by a line *ab*, and on the other side the piece *cde* is removed; *a* is brought to *e*, *b* is brought to *d*, *f* is brought to *c*, and sutures are applied (Fig. 501).

Operation for Cleft Palate.—It is true that during the early years of its growth a cleft diminishes in size and particularly if a harelip is closed; but to wait too long before we operate means permanent speech impairment. Bony clefts should be operated upon early in the second year. Clefts of the

soft palate only may be operated upon during the first six months of life. If both the hard and soft palates are cleft, close both at one operation. In an ill-nourished child in which the covering of the bone is obviously thin, it is best to postpone any operation upon a bony cleft until the end of the third year. I agree with Berry that operation is justifiable up to the age of twenty, but early operation is highly desirable. Edmund Owen has recently put forth a convincing plea for early operation.* He says he is operating earlier and earlier, and quotes Chilton as the gentleman who led him to do so. Owen maintains that if speech is to be improved, operation must be done early, and he formulates some very valuable rules for preparation and care. I have never been convinced that operation in early infancy is entirely safe and has any notable advantages. When one comes to treat congenital clefts of the lip, the alveolar process, and the hard and soft palate, the necessities one should seek to obtain are the surgical closure of the clefts, the establishment of the function of the involved tissues, the correction of the congenital deformity, and the prevention of postoperative or acquired deformity. There are few if any cases of cleft palate that cannot be successfully treated by surgical

Fig. 500.—Double harelip, the prolabium and alveolar bone having been removed (Owen).

Fig. 501.—The two sides of the lip drawn together and secured by sutures (Owen).

means and it is a very unusual thing for a case really to need any mechanical appliance, such as the obturator and velum.

In deciding upon the time for operating and the nature of the operation, the safety of the patient should be the first consideration. One must carefully consider his physical condition, especially with respect to nutrition. An operative method that has a greater mortality than is incident to minor surgery ought not to be selected, and no operation should be performed until the condition of the patient justifies it. Having considered the physical condition of the patient and the relative safety of different operative plans, a careful study of the individual case should be made; and in this study each of the four requirements above set forth must be attentively regarded. If we succeed in closing the cleft without establishing the function of the tissues, without correcting congenital deformity, and without preventing postoperative or acquired deformity, we leave the patient worse off than he was before, and perhaps renders subsequent satisfactory treatment impossible.

We should attempt to secure closure of the cleft with the least possible formation of cicatricial tissue. The simplest technique is the best, and we should endeavor to avoid all additional traumatism, such as incisions to re-

* *Lancet*, Jan. 4, 1896.

lieve tension and to permit of approximation. One should refrain from passing additional approximation sutures, from bruising the tissues by overextension or by traction-forceps, and from using large needles and coarse suture materials, which make large suture-cicatrices. The amount of scar tissue bears directly upon the functional result. In addition, when dealing with the lip, and especially with the soft palate, one must seek to avoid incisions that involve muscles, and particularly the nerve supply of muscles.

The periosteal-flap operation separates portions of the soft palate from the palatine bones. A large amount of cicatricial tissue is necessary to effect repair, and this mass of new tissue lessens the good functional results. In the periosteal-flap operation the repaired soft palate is anterior and inferior to the position secured by the osteoplastic method and, to that extent, interferes with the closure of the nasopharynx. Nevertheless, in my opinion, the operation which uses the soft tissues only is by far the safest and is the one I usually employ. In cases of complete cleft associated congenital deformities are especially manifest in the nose, lips, premaxilla, and maxilla.

To correct congenital deformities and to prevent postoperative or acquired deformities is the most neglected and the least understood phase of the subject; and it is a very complicated question to hope to make clear in a brief statement. The key to the difficulty is the normal contour of the face as established by the proper occlusion of the permanent teeth. In finding this out there is no better guide than the rules laid down by Dr. Angle in the latest edition of his *Orthodontia*. He maintains that every tooth must be held in its proper relation and occlusion; and that if any teeth are lost they must be replaced in order to establish or restore the proper expression and contour of the face. To comply with the foregoing requirements one should avoid any operation that would not maintain or would fail to replace the normal position of the premaxilla and the maxillæ and their future complement of teeth. If the premaxilla is only slightly in advance of its normal position, the early closure of the cleft of the lip will help to replace it. If, however, the premaxilla is far in advance of its normal position, it is hopeless to expect the pressure of a reunited lip to restore it to position. In such a case sufficient of the nasal septum posterior to the premaxilla must be resected, and the premaxilla must be carried back and sutured in position, but this operation should be done after the closure of the cleft soft and hard palates, and seldom at the same operation. If the cleft is unilateral in relation to the premaxilla and that bone is swung to the opposite side, and anterior to its normal position, the pressure exerted by an early repaired lip will often correct the condition. Until the deciduous incisors have erupted it is difficult to determine how far the intermaxillary bone really protrudes, and it is often surprising to observe how little correction is needed in what had appeared to be marked protrusion of the premaxilla in a unilateral or bilateral cleft. If in doubt about this point it is better to wait until the eruption of the deciduous incisors, when one may decide with certainty whether there is enough anterior protrusion to warrant the closure of the lip before operation on the palate. Early closure of the cleft of the lip brings very considerable pressure to bear, especially in double cleft or the typical harelip, as the lateral portions are comparatively short and the lip is usually quite tense. Sometimes this pressure is quite efficient, when exerted upon these cases of protrusion of the

premaxilla, which are frequent, and of lateral separation of the maxillae, which are infrequent, but when such pressure is exerted upon cases without protrusion or separation, it produces an unfortunate postoperative deformity, and one that is too frequently encountered. It causes the alveolar arch to lose its parabolic curve, and what should be an arch is frequently V-shaped or triangular, and not infrequently the cuspid teeth are closely approximated. One thus gets marked flattening of the anterior lateral region of the face or cheek, with loss of contour and position of the upper lip and apparent protrusion of the lower lip and chin. It is true that such a postoperative deformity can be corrected by modern orthodontic methods, but it is better to prevent it than to be obliged subsequently to correct it.

From the preceding remarks it is evident that it is to be regarded as advisable in many cases to close the cleft in the soft and hard palates before operating upon the lip. The best time for operating is just before the patient begins to employ articulate speech. In most cases the cleft in the alveolar process, including the floor of one or both nares, should be repaired separately, and subsequently to the repair of the hard and soft palates. A comparatively short time after operating upon the palate the lip may be repaired, and the lip also should be repaired before the establishment of articulate speech. An advantage in operating with the harelip still un-closed is that one can see better and work better during the operation on the palate, and can give the palate better local care after the operation. Unfortunately, however, many children with cleft palates are never brought for advice until they have cultivated articulate speech. It is always very difficult and often impossible to correct the manner of speaking that they have taught themselves. Only long training and much perseverance is of any avail. The earlier the operation is performed, the better will be the result—not only from the functional standpoint but also as regards the correction of existing deformity and the prevention of future deformity. So far as obtaining good surgical results go, there is practically no set age limit.

If operation is refused for cleft of the hard palate, if it offers no real hope, or if it is very dangerous, an obturator must be worn. An obturator is made by a dentist. In preparing a child for operation I follow Edmund Owen's rules, viz.: Have the child in the best condition, free from cough and stomach disorder. Operate in summer. Place the child under the charge of a nurse several days before the operation.

Operation for Suture of the Soft Palate (Staphylorrhaphy)—The operation of staphylorrhaphy, which is applied to clefts of the soft palate alone, is a comparatively easy procedure. In performing this operation the patient should be anesthetized and be placed in the Trendelenburg position, or else with the head hanging over the end of the operating table. The mouth is held open with Whitehead's gag, and an assistant holds an electric light and a reflector to illuminate the oral cavity. If the patient is not a young child, the operation may be done under cocaine, with the subject sitting erect in a chair and the surgeon sitting directly in front of him.

The surgeon should have at hand several knives of different shape. The double-edged, pointed knife is an excellent one for freshening the margins of the palate. Special forms of needle-holders have been devised for the purpose of carrying the needle. The heavy, curved, sharp-pointed bistoury is the best instrument for dividing the muscles of the palate; and a

sharp hook should be at hand, in order to catch the edge of the necessary.

The surgeon first of all separates the soft palate from the poster-

Fig. 502.—Longitudinal vertical section through the hard and soft palates. *a*, Before operation. *b*, Palatine mucoperiosteum detached and brought down. Blades of scissors introduced to cut attachment of soft palate to the bony palate and to the nasal mucous membrane. *c*, The same after the cut has been made and the soft palate thus brought down (Berry).

of the palate bones and the nasal mucous membrane (Fig. 503). This step is necessary in order that the edges may meet along the middle line (Berry). The edge of the cleft uvula is grasped with a pair of forceps, a sharp hook, and is pulled down to make it tense. This is then pared from below up to the piece being continued to the base to the apex of the cleft. This piece is severed from the other margin of the cleft is pared in the same manner. It is now advisable to divide the margins of the wound free from the palatine mucous membrane. These lateral incisions only relieve tension, but they do not paralyze the soft palate. Figs. 503 and 504 show the incisions as recommended by Berry.

Berry. These incisions divide the tendons of the levator palati and palatopharyngeus muscles, and temporarily paralyze the palate. The

Fig. 503.—Cleft of soft and part of hard palate. Shows exact situation in which the lateral incisions should be made (Berry).

Fig. 504.—Semi-diagrammatic view of left cleft palate. The septum nasi is at the palate on the (patient's) right side. The mucous membrane on the left side is to be detached and brought down to help in the closure of the anterior half of the cleft. Shows exact situation in which the lateral incisions should be made (Berry).

ment of palate function is not permanent, as the nerves to the muscles are not cut.

The sutures are inserted by means of a special needle-holder, so arranged that the needle may be directed in many different positions when grasped. The sutures are introduced from below upward, silkworm-gut being used for the uvula and the lower part of the velum, and silver wire for the balance of the cleft. Each suture, as it is passed, is so tied or twisted, and it is not cut off until the next suture is inserted, and thus serves as a handle. If there is too much tension to allow of the sutures being tied as they are inserted, all the sutures are passed and lightly twisted before one is tied.

Closure of Clefts in the Hard Palate (Uranoplasty).—As previously stated, the best time to perform these operations is during the second year of life. In some few cases we postpone the operation until the end of the third year. If the child learns to talk with the palate cleft, articulation will never be very greatly improved, even by operation. One should, therefore, try to operate before the child learns to talk. Even after the closure of the cleft the speech does not become entirely normal; in fact, as Berry says, it never becomes even very good. One should exercise the greatest care in forming the soft palate, because good articulation is largely dependent upon a well-formed soft palate (Berry, in "Brit. Med. Jour.," Oct. 7, 1905). The surgeon may be able to close the entire gap at one operation; or, owing to undue tension, he may be forced to close it but partly, completing the closure at some subsequent period.

The operation that, to my mind, is the best is one that uses the soft tissues alone—such a one as is advised by Berry. I have entirely abandoned the operation of wedging the bone over with a chisel. I am satisfied that it is far more dangerous than is the other method; it is more liable to fail; and, if it fails because of necrosis, it is difficult or impossible to cure the defect by a second operation. The essence of a successful operation, using the soft tissues alone, is, as Berry insists, the complete detachment of the soft palate from the posterior edge of the palate-bone (Fig. 502); because, if one fails to secure this, the edges of the gap will not approximate in the median line. One should also separate the soft palate from the mucous membrane of the nose (Fig. 502).

A second very important point is the imperative necessity of making incisions to the sides, to relieve tension, and to paralyze for a time the soft palate. The incisions, as recommended by Berry, are shown in Figs. 503 and 504. The cut is close to the teeth, and is taken as far posterior as the middle of the soft palate, at the junction of that structure with the lateral pharyngeal wall. In this cut there is some risk of dividing the anterior palatine artery; but hemorrhage from this vessel can be arrested by pressure. Berry insists that the incision need not go forward more than the level of one or two premolar teeth; or, in older children, to the first or second molars. The edges of the fissure are pared on each side, from the tip of the uvula to the top of the gap. Strips of the mucoperiosteum are lifted up on each side of the gap and shifted toward the cleft, and at this stage the posterior border of the soft palate is separated from the posterior border of the hard palate (Fig. 502).

The parts are sutured with silver wire, following the advice of Edmund

allowed to remain between two and three weeks.

Fergusson's Operation — In this operation the mucous edges of the bones are drilled for wires, and the sutures are inserted, but an incision is made on each side of the cleft down to the bone, each midway between the cleft and the corresponding alveolus, and divided on each side, by means of a chisel, to the full length of the bone, and the chisel is used as a lever to force each half of the bone together. The sutures are tied, and each lateral incision is plugged with iodoform.

Brophy's Operation — This operation is employed particularly in children under three months of age, and cannot be used when the child is older. In this operation the palate is closed before the harelip is touched. At this time, the bones are soft, and by leaving the harelip open, the surgeon has more room to work. The author of the operation states that when it is performed at this early age the palate-muscles do not atrophy, but develop, and that the patient does not form the evil habit of touching the nose.

In performing this operation the very strong-handled needles and forceps are necessary. The patient is anesthetized and put into the Trendelenburg position and a strong piece of silk is put through the tip of the nose as a traction-suture. The edges of the cleft in the hard palate are pared, and the edges of the bone being taken away with the paring. Then the edges of the soft palate are pared. The needle is threaded with strong silk, and is lifted; and the threaded needle is forced through the superior maxillary bone from without inward, starting just back of the malar process and above the palate. As the needle shows in the cleft the thread is caught with a pair of forceps, and the needle is pulled out, the loop of thread being in the cleft. Through a part of the opposite superior maxillary bone corresponding with this first point of entrance the needle is entered, and another loop is got into the cleft. The second loop is caught with the forceps, and when the former is pulled out, it carries the latter with it, and the thread now passes through both the superior maxillary bones and through the nasal septum as well. This thread is used to pull a piece of silver wire through. One other silver wire is introduced in the

deem it advisable to wait one day before doing so. After the palate heals the harelip is closed.

Carcinoma of the Lower Lip.—Cancer commonly arises in the lower lip, very rarely in the upper lip. Males suffer frequently, but females are not very often attacked. In some cases it seems to arise in smokers at the point on the lip where the pipe habitually rested. A short-stemmed clay pipe, which grows hot when it is smoked, is particularly apt to lead to the growth of cancer. The region of the lip which is most liable to cancer is the junction of the skin and mucous membrane. The growth may begin in a fissure or abrasion, may start in an eczematous area, but most frequently arises as an indurated area which quickly ulcerates. After a cancer has existed for a variable time the submental and submaxillary lymphatic glands become diseased. These glands are always involved within three months of the beginning of the cancer. In a case of my own they were found to contain carcinoma cells in less than three months after the origin of the carcinoma of the lip. This involvement cannot be detected by external manipulation in the earliest stages; hence it is not proper to conclude that the glandular involvement is absent simply because it cannot be palpated. It occasionally happens that glands enlarge because of septic absorption, and this enlargement may even precede carcinomatous involvement. From an operative point of view the glands should always be regarded as carcinomatous. If cancer is not operated upon, it destroys the lip, involves the glands of the neck extensively, the floor of the mouth, the periosteum and the lower jaw, and produces death in from three to five years. If the jaw is involved, the prognosis is bad and it is practically hopeless if the floor of the mouth is involved.

Treatment—The treatment consists in the early and thorough removal of the growth with the knife, and also in the removal of the fatty tissue and gland from the submaxillary triangles and from the submental region. The growth must be thoroughly removed—that is, the incision must be at least half an inch wide of the disease. For many years a favorite operation has been the V-shaped incision, the skin-edges being sutured by silkworm-gut, the sutures being passed almost to the mucous membrane and being inserted so as to compress the vessels when tied, and the mucous membrane being sutured with fine silk or catgut. The V-shaped incision should be used only for a very small and very recent growth. After the removal of the growth from the lip a vertical incision is made from the point of the V over the cricoid cartilage, and from the origin of this incision incisions are made in each direction along the under surface of the body of the jaw. The glandular area is thus exposed, and after the removal of the fat and glands the wound is sutured with silkworm-gut. Far better than the V-shaped incision is the operation devised by W. W. Grant, of Denver.* In this operation the growth is removed and cheiloplasty is performed.

Grant's Operation for Cancer of the Lip.—This operation gives a useful growth and a more natural looking lip than does the ordinary operation, and there is decidedly less tension on the suture line. Furthermore, the suture-line in a man is soon covered with a beard. The procedure has great advantages over the ordinary V-shaped operation, which greatly lessens the size of the mouth, making it what is known as a sucker-mouth; and the new lip is rigid and ugly.

* Medical Record, May 27, 1899.

In Grant's operation two vertical incisions are made, one on each side of the growth, and these are connected with a horizontal incision at the base (Figs. 505 and 506). Thus, a quadrangular gap is formed, which must be filled by flaps. An incision is made on each side from each inferior angle of the wound, obliquely downward and backward beneath the maxilla, on a line about midway between the angle of that line and the apex of the chin (Fig. 505). Its further extension is determined by the amount of lip removed and by the degree of glandular involvement.

Fig. 505.—Grant's method for removal of carcinoma of the lower lip. The incision

Fig. 506.—Grant's method for removal of carcinoma of the lower lip. Second step. The mass removed.

Fig. 507.—Grant's method for removal of carcinoma of the lower lip. Dissection preliminary to suturing.

Fig. 508.—Grant's method for removal of carcinoma of the lower lip. The wound sutured.

The submaxillary lymph-glands are removed through these incisions. The glands in the midline, however, beneath the chin may require a separate incision. If the lip is extensively involved, the cheek ought to be completely separated from the inferior maxillary bone to the middle of the masseter muscle (Fig. 507). When the glands have been removed, the triangular flaps are

brought together and united, first of all, in the middle line (Fig. 508). If the tension is marked, owing to the amount of tissue excised, it is wise to insert a traction suture, three-quarters of an inch from the center line, and tie it over pads of gauze covered with muslin. One thus prevents undue tension upon the sutures in the center of the flap. The stitches that unite the cheek posteriorly are inserted and tied, and the entire thickness of the cheek must be included. Silkworm-gut sutures are used. A drainage-tube is inserted in the posterior angle of the wound on each side. It is very useful to use also a T-drainage-tube as advised by Grant. This tube is about the diameter of a lead pencil and the cross-piece rests behind the incisor teeth or symphysis and beneath the tip of the tongue. This tube drains away all of the mouth secretions, saves the lines of incision from being constantly bathed in them, and renders very frequent changes of dressing unnecessary.

I have employed this operation repeatedly, and regard it as the most useful method we have for the purpose. Thorough removal of the carcinoma of the lip and of the related glands will cure from 60 to 70 per cent. of cases.

Carbuncle of the Upper Lip.—In contrast to carbuncle in other regions of the body, facial and lingual carbuncle is most common in young persons. The condition is due to staphylococcus infection and begins as a papule. Numerous pustules appear, and sloughing usually takes place. There may or may not be serious constitutional involvement. The condition is very dangerous, as thrombophlebitis may arise and track up into the cranium. I have known two persons to die from carbuncle of the lip.

Treatment.—Make a crucial incision, cutting away the corners and edges with scissors. Scrape out the carbuncle with a sharp and strong curet, swab with pure carbolic acid, pack with iodoform gauze, and dress with antiseptic poultices.

Tongue-tie (congenital ankyloglossia or adherent tongue) is a congenital shortness of the frenum, the tip of the tongue adhering to the floor of the mouth. It is due to the projecting portion of the tongue being incompletely developed from the tuberculum impar. "In many of the slighter cases the development has merely lagged behind, and will be completed as the child grows after birth" ("Diseases of the Tongue" by Henry T. Butlin. Second edition). The tongue cannot be protruded beyond the incisor teeth. Swallowing is interfered with, and later in life articulation is impeded. It is not very unusual in infants, but in the great majority of cases disappears as the child grows older. Persisting tongue-tie, Butlin says, is one of the rarest of conditions, and my experience is in absolute accord with this—in fact, I have never seen a single case. Many unnecessary or even harmful operations are done for a condition which, if let alone, will usually correct itself. Improper operation may result in fatal hemorrhage or in "swallowing of the tongue." The operation usually done is to tear up the frenum with a thumb-nail. This is unsurgical and makes a lacerated wound. A better way is to raise the tip of the tongue to make the bands tense, and then snip with the scissors close to the mucous membrane of the lower jaw. The slit in the handle of the grooved director was placed there to catch the frenum in, but a short frenum will not enter it (Butlin).

Ranula is a retention-cyst of the duct of the submaxillary or the duct of the sublingual gland. A ranula when first formed contains saliva, but after a

time the saliva undergoes a change, and in appearance comes to resemble mucus. *Mucous cysts* occur in the floor of the mouth, resulting from obstruction of the ducts of the *mucous glands of Nuhn and Blandin*. These glands lie on each side of the frenum of the tongue. Such a cyst is often spoken of

Fig. 309.—Ranula.

a *ranula*. A cyst of the *mucous glands* forms just back of the lower lip and lifts up the frenum. A true ranula appears upon the floor of the mouth on one side and pushes the tongue toward the opposite side. The treatment of a mucous cyst is by excision of a portion of the cyst wall and cauterization of the interior with pure carbolic acid, or by cutting a flap from the cyst-wall and stitching it aside so as to keep a permanent opening. Such an operation may cure a genuine ranula, but will often fail. In true ranula an external incision should be made, and

through this both the cyst and the gland should be removed. This plan is recommended by Mintz.*

Thyrolingual or Thyroglossal Cysts and Sinuses.—In early embryonal life the thyroid gland has a duct which passes from the thyroid isthmus to the foramen cæcum of the dorsum of the tongue. The duct may be lined with one layer, two layers, or several layers of epithelium, and there are mucous glands and lymph follicles in its walls, these structures being derived from the mucous membrane of the tongue. The wall of the duct presents numerous irregularly placed and irregularly shaped diverticula. It is known as the thyroglossal or thyrolingual duct. The duct runs from the base of the tongue down the mid-line of the neck. It is connected with the body of the hyoid bone, with the periosteum in front of the bone, and with the thyrohyoid bursa behind the bone. It passes to the upper portion of the front surface of the trachea, where it bifurcates, each branch passing to a lateral lobe of the thyroid gland. This fetal structure under normal conditions begins to atrophy in the fifth week and closes by the eighth week, the foramen cæcum marking its old orifice on the dorsum of the tongue. When the duct is obliterated, it becomes a cord of epithelium. In more than 30 per cent. of bodies the remains of this primitive passage can be found (Weglowksi, in "Zentrall. f. Chir.," 1908, xxxv, 2891). The duct may persist between the foramen cæcum and the hyoid bone, developing, it may be, into a *sublingual dermoid*. The portion behind and below the hyoid may remain and develop into a *subhyoid cyst*. The part inferior to the hyoid may persist, give origin to a cyst which ruptures and constitutes an incomplete *median cervical fistula*. The duct may remain open from the mouth and make, by bursting an opening in the neck, a *complete median cervical fistula*. A patent duct may exist for years and announce its existence by some acute inflammatory process. The small diameter of a cervical fistula renders probing to any depth impossible. Some have told us to determine if a fistula is

* Zeitschrift für Chirurgie, March, 1899.

complete by injecting quassia solution into the lower end. The patient will perhaps experience a bitter taste. If we inject a colored fluid we may see it if it runs from the mouth. I have never succeeded in doing either. Tumors may spring from the duct.

Treatment.—If a thyroglossal cyst or tumor arises on the dorsum of the tongue and if it is increasing in size and interferes with swallowing and speech, it must be removed through the mouth. A general anesthetic should be given. In some cases preliminary tracheotomy is necessary.

A cyst, tumor, or fistula about the hyoid bone requires excision, the patient being under the influence of a general anesthetic. A portion of the cyst wall adheres strongly to the posterior surface of the hyoid bone and must be carefully removed even if it is necessary to split the bone to accomplish it. In treating fistula the surgeon makes an elliptical incision of the skin about its orifice so as to free the fistula from the subcutaneous tissue. When traction is made upon the cutaneous end of the duct it will stand out clearly and can be dissected out (M. S. Seelig, in "Surg., Gynecol., and Obstet.," May, 1907). It is useless to try to cure a fistula by cauterization. A fistula requires the complete removal of its epithelial-lined walls. No lesser operation will cure. In one case I operated four times before securing success. In a recent case I divided the bone, removed the fistula, and sutured the bone with chromic gut.

Carcinoma of the Tongue.—This is one of the most dreadful forms of cancer. It is quite a common disease. In most of the cases I see it is far advanced when first brought to the surgeon. The only form of cancer which attacks the tongue is epithelioma. It is much more common in men than in women. It is a disease of adult life and is very rare before the age of thirty-five. It begins, as a rule, near the tip, on the side or at the base of the anterior two thirds of the tongue, as a warty growth, as an ulcer having at first a papillary structure, as a fissure which indurates, or as an indurated area which ulcerates. The cause of the growth may sometimes be traced to the irritation of a jagged tooth, or to the smoking of a pipe, or to holding nails in the mouth, as is done by those who nail laths. Cancer may follow a chronic inflammation—leukoplakia, for instance. Chronic ulcers are liable to become cancerous and any indurated ulcer has potentialities of peril and should be promptly removed. Fournier regards syphilis as an influential cause and states that in 184 cases of cancer of the mouth or tongue 155 had had syphilis. There has been no such proportion of syphilitics in my personal cases. In Whitehead's 104 cases only 7 had had syphilis. As in cancer of the lip, men are much more frequently affected than women. In most cases the disease spreads rapidly, produces early and extensive glandular involvement; disease of the floor of the mouth; dribbling of saliva; difficulty in masticating, swallowing, and talking, foulness of the breath; severe pain which usually radiates toward the ear, and often a fatal septic trouble. Cases not operated upon usually die within two years. There is a very rare form of carcinoma described by Wollfer, which grows very slowly or even remains latent for years.

One reason why cancer of the tongue grows so rapidly has been pointed out by Heidenhain, of Greifswald. The lingual muscles are contracting almost constantly, and as a result cancer-cells are forced along the lymph spaces to healthy areas.

Treatment.—A cancer of the tongue should be removed radically at the

tion the teeth should be scrubbed twice a day with a brush and mouth rinsed with hydrogen peroxid. The nares and nasopharynx be sprayed with peroxid of hydrogen and then with boric acid solution the second or third hour when the patient is awake.

In this disease not only the tongue but also the adjacent lymphatic glands must be removed. Cancer of the tip of the tongue, as a rule, first involves the submental and sublingual group of glands. Cancer of the anterior portion of the dorsum of the tongue first involves the lingual and submaxillary nodes. Cancer of the under surface of the tip of the tongue involves the submaxillary glands. Sooner or later the superior deep cervical nodes about the carotid bifurcation become involved in cancer of the anterior portion of the tongue. In cancer of the dorsum the submaxillary glands become involved as well as the superficial nodes. The lymphatic system of the base of the tongue is distinct from that of the balance of the tongue. It drains into the deep cervical groups.

It was my belief until recently that in a very recent and limited case the glands on the diseased side require removal, but that in the majority of cases the glands must be removed from *both sides* of the neck. Kuttner, of Tübingen, has convinced me that in any case the glands on both sides must be removed. Kuttner, of Tübingen, has demonstrated that lymphatic drainage from one side of the tongue may flow to glands on the same side of the neck, but also may flow to the opposite side of the tongue. Remove the involved glands by the "*block dissection*" of Crile. In a block dissection the sternocleidomastoid, the omohyoid, the jugular vein, even the pneumogastric and phrenic nerves on one side may be taken away. After a week or two the other side of the neck may be operated upon. It seldom requires a wide removal of structures. If the pneumogastric or phrenic were cut on one side they must be protected on the other. The jugular can be removed after a collateral circulation is established subsequent to removing the jugular of one side. Two operations are to be considered: partial removal and complete removal.

Partial Removal of the Tongue.—This operation is restricted to the removal of the diseased portion of the tongue and the lymphatic glands immediately adjacent to it.

Split the tongue back in the middle line with the scissors, and loosen the cancerous side from the floor and side of the mouth. Pass a stout silk ligature through the base of the tongue posterior to the cancer. Draw the organ out and cut off the diseased side in front of the ligature but back of the disease. Tie the vessels, remove the constricting and traction threads, and treat subsequently as in cases of complete removal.

Complete Removal of the Tongue (Kocher's Method).—Kocher recommends a preliminary tracheotomy in tongue-excision, but the Trendelenburg position renders this procedure unnecessary so far as fear of the passage of blood into the larynx and trachea is concerned. The instruments required are a scalpel, retractors, a dry dissector, hemostatic and dissecting forceps, a tenaculum, aneurysm-needle, tenaculum forceps, needles, sutures, and scissors. In this operation the patient is placed in the Trendelenburg position, the surgeon standing to the side. Ether or chloroform is given. Ligate the lingual artery on the side opposite to the one where the main incision is to be made. Remove the glands on that side and suture the wound. An incision is then made on the side opposite to that on which the artery was ligated. This incision passes from behind the lobe of the ear, along the anterior edge of the sternocleidomastoid to about the middle of the margin of this muscle. From this point the incision is carried to the level of the hyoid bone and then to the symphysis menti, along the anterior belly of the digastric muscle (Fig. 510). The flap is dissected and turned up; the facial and lingual arteries are ligated; "the submaxillary fossa is evacuated" (Treves); the sublingual and submaxillary glands are removed; the mylohyoid muscle is divided; the mucous membrane is incised close to the jaw, and the tongue, caught with tenaculum forceps, is drawn through the opening. The tongue is split in the middle with scissors, and the near half is removed, bleeding is arrested, the remaining half of the tongue is cut through, and the vessels are tied. Stitch the mucous membrane of the stump to the mucous membrane of the floor of the mouth with catgut sutures.

Kocher does not suture the skin-wound; many surgeons do suture it and employ drainage tubes. I follow the suggestions of

Treves as to after-treatment. Some hours after the operation, when oozing has ceased, dust the mouth-wound with iodoform. The patient, as soon as possible, is propped up in bed, and he must not swallow the discharges if it can be avoided. The mouth, every half hour, is sprayed with jeroxid of hydrogen and washed with a carbolic solution (1 : 60). Every three hours after washing the floor of the mouth and the stump the parts should be dried with absorbent cotton and dusted with iodoform. For twenty four hours after the operation nothing is given by the mouth except a little cracked ice, the patient being fed per rectum. At the end of twenty-four or forty eight hours some liquid food is given from a feeding cup. The patient will soon learn to swallow, but if he cannot swallow easily, he is fed with a tube. Treves, in his clear and positive directions for after treatment, states that nutrient enemata

Fig. 510.—Kocher's excision of tongue (Esmarch and Kowalew).

are to be continued until sufficient nourishment is taken by the mouth. The mouth should be flushed by irrigation, and must be washed immediately after taking food; that morphin is to be avoided, and that the patient usually leave the hospital in from seven to ten days.

Whitehead's Operation.—Whitehead removes the entire tongue from within the mouth by the use of scissors. He passes a ligature through the tip, cuts the frenum, draws the tongue strongly forward, and separates by a series of clips with the scissors. The lingual arteries are tied as cut. The stump should be kept under control, as regards hemorrhage, by a stout silk ligature passed through the remains of the glosso-epiglottidean fold and retained for twenty-four hours."*

Heath has shown that if the forefinger be passed to the epiglottis and used to "hook forward" the hyoid bone, the lingual arteries are stretched and portions of the tongue can be removed almost without bleeding. It is rarely desirable in Whitehead's operation to remove the glands and the tongue at one séance. To do so increases shock and the danger of death. The rule of procedure set forth by W. Watson Cheyne † is eminently wise. This rule is as follows: If glandular involvement is trivial or not detectable, it is perfectly proper to remove the tongue first, and after a week or so remove the glands. If the glandular involvement is marked, growth in the glands will be much more rapid than growth in the tongue. In such a case the glands should be removed before the tongue, because, if the tongue is removed before the triangles are cleared, in the week or two of waiting the case may become inoperable. In the majority of cases clear out the triangle before removing the tongue, doing the other operation in one or two weeks when the wound in the neck is healed. If the disease in the mouth is far advanced, do both operations at one séance.

Stricture of the Esophagus.—*Fibrous or cicatricial* stricture is due to the healing of an ulcer, and results from traumatism, chronic inflammation, syphilis, tuberculosis, chronic ulcer, prolonged vomiting, variola, gout, or to swallowing a corrosive substance or a boiling liquid. It is commonest in the young, and is apt to be situated opposite the cricoid cartilage, at the tracheal bifurcation or near the cardiac end. Cicatricial strictures are usually single, but may be multiple. Stricture following impaction of a foreign body is located at the seat of impaction unless the tube has been injured by efforts at extraction, in which case multiple strictures may exist (Maylard). Strictures which result from swallowing boiling fluid or corrosive liquid are usually very extensive, and may be multiple. Syphilitic stenosis is due to the healing of a gummatous ulceration, but there is nothing characteristic in this kind of stenosis. Tuberculous stenosis is extremely rare.

Symptoms of Cicatricial Stenosis.—The condition may occur at any age. The chief symptom is difficulty in swallowing, at first slight, but becoming more and more pronounced until swallowing is almost or quite impossible. The dysphagia is first manifested to dry solids, then to all solids, and finally to liquids. In some cases vomiting occurs after swallowing. If the stricture is high up, the vomiting is almost immediate, if it is low down, the vomiting is delayed, especially if the canal is dilated above the stricture. From time to time the patient vomits independently of taking food, the ejected matter being saliva. The vomited matter is not bloody. The patient feels weak and

* "American Text-book of Surgery."

† The Practitioner, April, 1895.

hungry, becomes exhausted and emaciated, and suffers from flatulence, gastralgia, and constipation.

There is occasionally slight uneasiness or even pain in the region of the stricture, possibly "about the epigastrium or between the shoulder-blades" (Maylard). The stricture may be located with a bougie and by auscultation over the spine on a line with the supposed obstruction. While a patient is swallowing water, the arrest of the fluid at the seat of stricture may be audible. Even if the fluid passes, it will be delayed for a time and the duration of deglutition is thus prolonged. In order to determine the time of deglutition put the ear just below the angle of the left scapula, put a finger on the patient's Adam's apple, and hold a watch in the other hand. Have the patient take a drink of water. Count the time from the moment the Adam's apple begins to rise until the fluid is heard to gurgle into the stomach (Ogston's method). It ordinarily requires four seconds for food to pass from the mouth into the stomach (Maylard). If food is retained for some time before it is ejected we may be able to locate the seat of obstruction by the x-ray. An emulsion of bismuth is swallowed and a skiagraph is taken. The bismuth is seen on the plate as a black mass extending above the seat of constriction. The bougie can be passed until it reaches the block and a skiagraph may be taken with the bougie in position.

In a case reported by Seelig ("Surgery, Gynecology, and Obstetrics," Sept., 1908) the patient was directed to swallow a fine gold chain as this is as ordinary wrapping twine. The chain was about two feet long. If a diverticulum exists the chain will fill the sac and a skiagraph will show the position of the diverticulum. If no diverticulum exists the plate will show the chain nearly in the middle line of the body.

The history of the case is of much importance in diagnosis. The surgeon must inquire about impaction of a foreign body, or swallowing of acid or alkalies, or boiling fluids; and must examine for evidence of syphilis. If there is no history of injury, syphilis, tuberculosis, variola, or prolonged vomiting, and the patient is over forty years of age, the indications point to cancer rather than cicatricial stenosis. The easy passage of a bougie when the patient is anesthetized shows that spasm is the cause, and not organic disease. Narrowing due to external pressure is marked by positive symptoms of the causative disease.*

Treatment. Thiosinamin is given by some physicians, but I have never seen it accomplish the slightest good. Telleky† recommends it in old scars without inflammation. He makes a 15 per cent alcoholic solution and injects from one-half to one syringe-ful at a dose, throwing the fluid beneath the skin between the scapulae. He uses twenty doses in the course of two weeks. Gradual dilatation through the mouth is a method employed for at least a time in almost every case. It is the method of choice when it can be carried out, and usually it can be carried out. Begin with the largest bougie which will easily pass. Warm the bougie, oil it, pass it gently, and hold it in position for several minutes, prolonging the time of retention of the bougie as treatment progresses. Pass an instrument every second or third day, gradual

* See the excellent article in Maylard's "Surgery of the Alimentary Canal."

† Wien. klin. Woch., Feb. 20, 1902.

increasing the size. If the stenosis involves a considerable portion of the esophagus, gradual dilatation will almost certainly fail to cure.

Symonds advocates the insertion of a tube through the stricture and leaving it in place until there is decided dilatation, and then replacing the tube with a larger instrument. The patient is fed through the tube. Gradual dilatation from below has been practised in cases where a bougie could

Fig. 511.—Esophageal instruments: A, B, Forceps; C, horsehair probang; D, cannula-catcher; E, esophageal bougie.

not be passed from the mouth. A gastrostomy is performed, and after the fistula has become sound the patient is made to swallow "a shot to which is attached a silk thread" (Maylard). The silk thread is brought out through the fistulous orifice and is attached to a bougie, and the dilating instrument is pulled up through the esophagus. *Forcible dilatation* can be employed through the mouth or through a gastrostomy opening, by means of bougies, tents, or divulsing instruments. *Electrolysis* is used by Fort and others. Some surgeons perform *internal esophagotomy* through the mouth with a special instrument. A fibrous stenosis in the region of the cricoid cartilage which is not cured by gradual dilatation should be treated by the operation of *external esophagotomy*. In this operation the stricture is divided by a longitudinal incision; "funnel shaped retraction of the cut portion is caused by adhesion to the external tissues divided, and it lessens future contraction."¹⁰ If dilatation fails in the case of a stenosis above the line of the aortic arch, the esophagus may be opened above the stricture (*external esophagotomy*), a tenotome is introduced through the wound, the stricture is cut and well dilated by the passage of instruments. This operation is known as Gussenbauer's combined esophagotomy.

¹⁰ W. J. Mayo, Jour. Amer. Med. Assoc., July 29, 1899

If a stricture is impassable from above, the stomach should be opened and retrograde dilatation be carried out. Billroth showed years ago that a stricture impassable from above may be passable from below. This is because the esophagus above the stricture is basin shaped and immediately below the stricture is funnel shaped (Abbe). If a fine bougie is carried from the stomach to the mouth it is used to carry a piece of string through the same route, and

Fig. 512.—Abbe's method of cutting esophageal strictures.

this string is used to pull bougie after bougie through the stricture. A firm, non-dilatable stricture in the thoracic portion of the esophagus can be treated by Abbe's method (Figs. 512 and 513). He performs a gastrotomy, sutures the stomach to the abdominal wound to prevent contamination of the peritoneum, and seeks for the esophageal opening by two fingers passed within the stomach. Abbe points out that finding the orifice would seem much more easy than it is. In a recent case I found it only after a prolonged search, the

Fig. 513.—The bougie engaged in the stricture while the string-saw is being used.

entire esophageal region feeling smooth to the touch. Abbe says that "this surface is maintained by the circular sphincter muscle layers, and it is not until a moment's pressure of the finger at the right place causes them to yield that it slips upward into the esophagus" ("Med. Record," Nov. 30, 1907). He then passes a long filiform whalebone bougie from the stomach into the mouth, ties a piece of braided silk to the bougie, withdraws the instru-

ment, and leaves the silk in place. One end of the silk emerges from the mouth and the other end from the gastrotomy wound. In some cases he opens the stomach and also opens the esophagus above the stricture; one end of the string comes out of the esophagotomy wound and the other end out of the gastrotomy wound. A large dilating bougie is then passed from the stomach into the esophagus and pushed as forcibly as is safe into the lumen of the stricture. The string is used as a string- or bow-saw, and the stricture is divided, the dilating bougie being pushed firmly upward while the saw is being used. If this is not done the saw will not cut. Only stretched tissue will be divided. When the stricture has been divided, the silk is withdrawn, full-sized bougies are passed, a temporary gastrotomy is usually made, and the wound or wounds are sutured.

An operation devised by A. J. Ochsner is thus described by Mayo: "The anterior wall of the stomach is drawn out of a left oblique incision through the abdominal coverings; a small opening is made into the stomach sufficient in size to introduce the finger. A whalebone probe, to the tip of which a silk string guide has been tied, is now passed through the esophagus either from above or retrograde, as in the Abbe method. With this guide a loop of silk is drawn out of the gastric incision in such manner as to leave the guide in place or a third string. Into this loop a small soft rubber drainage tube three feet or more in length is caught in the middle by traction on the ends of the double thread through the mouth; this loop of rubber tube is drawn through the stomach and made to engage in the stricture.

"The greater the amount of traction, the smaller the stretched rubber tube, until it is sufficiently reduced in size to enter the stenosed portion. By alternating the direction of the pull the tube is drawn out by its free end and in by the silk loop. Increasing sizes of tubes can be employed, and, if necessary the third string can be used as a string-saw, after the Abbe plan of procedure." In a very severe case of stenosis gastrostomy is performed to keep the patient from starving. In a case of fibrous stenosis in charge of the author it was found impossible to insert any instrument from above or from below. Gastrostomy was performed by Kader's method. The patient was fed through the artificial opening and the esophagus was thus put at rest. Two weeks after the operation it became possible to pass a bougie from the mouth. The gullet was gradually dilated to its normal caliber and the gastrostomy wound was closed. This case demonstrates that a stricture of the esophagus, like a stricture of the urethra, may become temporarily impassable from inflammation, edema, and spasm; but, after the part is put at rest, will again permit the passage of an instrument.

Carcinoma of the Esophagus.—Cancer causes obstruction of the esophagus. It arises in those beyond middle life, and is far more common in men than in women. The disease may begin at any portion of the gullet, but is least often met with in the central portion (Maylard, Rutlin). Epithelioma is the usual form, but scirrhous or encephaloid may occur. Cancer soon ulcerates, involves adjacent parts, and affects the deep cervical and posterior mediastinal glands.

Symptoms of Cancerous Stenosis. The patient is over forty years of age, is usually a male, and presents the same difficulty of swallowing met with

in cicatricial stenosis. The vomited matter is apt to contain blood; the use of the bougie causes bleeding; there are generally decided pain and very great emaciation. The seat of obstruction is located by the bougie and by listening over the spine while the patient is attempting to swallow water. The stomach is the seat of pain; the mouth is dry, and there is often great thirst. As the disease infiltrates, the involvement of adjacent regions produces other symptoms. Dyspnea may result from tracheal pressure. Pleuritis, pericarditis, or pneumonia may arise.

Treatment.—The disease is of necessity fatal, and treatment is only palliative. Complete excision is scarcely feasible. The patient should be put upon a soft, bland diet, small quantities being given frequently. When trouble is experienced in swallowing the bland and soft food, pass a soft bougie every third or fourth day. When the patient becomes entirely unable to swallow soft food, we may insert a Symonds tube or do an esophagostomy (if this can be performed below the stricture), or perform gastrostomy. In every doubtful case of esophageal stricture give a course of iodid of potassium before performing any operation.

Spasmodic Stricture of the Esophagus (*Esophagismus; Hysterical Stricture*).—By this term is meant a spasm of the circular muscular fibers of the gullet, which is most common near the larynx or the cardia. This condition not unusually arises in a hysterical individual, in which case it will be associated with the stigmata of hysteria, especially globus hystericus. In some cases evidences of hysteria are wanting, although the patient is neurotic and ill-nourished, and the condition is due to a reflex irritation. A spasm of the muscular fibers of the esophagus may be clonic or may be tonic. A clonic spasm may arise during vomiting or from some reflex cause; it may affect one part of the tube for a time and then shift to another, or may develop only in one particular region. Globus is a spasm which moves upward. Tonic spasm is in one fixed place. Most reflex spasms are tonic and result from cancer of the liver, cancer of the stomach, tonsillitis, glossitis, pharyngitis, or inflammation of the epiglottis (A. L. Benedict, in "Am. Jour. Med. Sciences," August, 1904). Spasmodic stricture may also arise during pregnancy and as a result of laryngeal ulceration. I have seen two instances due to cancer of the stomach. In one of these cases the esophageal spasm entirely disappeared after the performance of pylorotomy. It occasionally occurs in tetanus, and sometimes in epilepsy.

Symptoms of Spasmodic Stenosis.—It arises suddenly in a hysterical or neurotic individual. It may last for a time and suddenly pass away, or may persist for a long time. The difficulty in swallowing is irregular, rarely interfering seriously with nourishment, and sometimes solids are taken more readily than fluids, and *vice versa*.

There may be regurgitation; but if it occurs, it does so at once on swallowing food. Examination with a bougie detects the obstruction. If the bougie is held firmly against it, in most cases the spasm will, after a time, relax suddenly or gradually and let the instrument pass. A medium-sized instrument or a large instrument may not pass until the patient has been anesthetized, but in every case a bougie can be passed after an anesthetic has been given.

Treatment.—The systematic passage of bougies. Occasionally the passage of an instrument but once will cure a case. The general health must be

improved, and in persistent cases it may be necessary to use electricity within the esophagus, employ cold locally, and administer the bromids.

Diverticula of the Esophagus.—Maylard tells us that these pouches may be due to one of four causes—they may be congenital; may be due to stricture; may be caused by pressure from within, upon a weak spot of the wall; may be due to traction from without, by the healing and contraction of an area of inflammation. To these another cause should be added, muscular weakness resulting in dilatation.

Symptoms.—When the diverticulum is in the neck, a lump forms during deglutition, and this lump may be obliterated by pressure. Food will pass into the stomach only when the diverticulum is full. A bougie cannot be passed unless the pouch is full of food, at which time it may pass or may not. Sometimes it enters the pouch. This latter symptom, the variability in the passage of the bougie, is the evidence relied on for diagnosis in intrathoracic diverticula. By listening with a stethoscope fluid may be heard to pass into the pouch. After a patient swallows an emulsion of bismuth or food mixed with subnitrate of bismuth a diverticulum may be skiagraphed. When a bougie is passed as far as it will go a skiagraph should be taken with the bougie in position. The plate may show that the instrument is so much deviated to the side that it must be in a pouch. If a fine gold chain is swallowed it may fill up the pouch, and if it does, a skiagraph will indicate the diverticulum. The opening of the pouch may be seen by means of an esophagoscope.

Treatment.—Extirpation and suture, as performed by von Bergmann, Hearn, and others. For five days after operation no food is given by the mouth.

Injuries of the Esophagus from Within.—Injuries of the internal surface are more common than injuries from without. Burns and scalds are among these injuries. Wounds may be inflicted by foreign bodies. Injuries of the gullet cause pain on swallowing, and a severe injury induces bleeding, the blood being both coughed up and vomited. A severe wound may involve a large vessel and cause violent or even fatal hemorrhage. If the larynx or trachea is involved, there will be "cough and expectoration of blood, mucus, and food" (Maylard). The pleural or pericardiac sacs may be perforated.

Treatment.—Feed only by the rectum. Give morphin hypodermatically. Do not feed by the mouth for ten days, and even then give only fluid food and jelly. Symptoms are met as they arise. After burns by caustic, administer the antidote; give large drafts of water and wash out the stomach. From two to four weeks after a caustic has been swallowed and after a burn or scald the use of sounds should be begun, and sounding should be persisted in for a considerable time to prevent contraction.

Injuries of the Esophagus from Without, Other Structures not being Seriously Involved.—Such injuries are rare. Esophageal injuries, as a rule, are associated with serious damage to adjacent structures. These injuries may be due to stabs or to bullets. Besides the obvious external signs of the injury there will be difficulty in swallowing, cough, bloody expectoration, or vomiting; and mucus or the contents of the stomach may run out of the wound.

Treatment.—Suture the wound, and feed by the rectum for ten days.

Foreign Bodies Lodged in the Esophagus.—These accidents occur especially in children and lunatics, and women are more apt to suffer from them than men. A list of various bodies which have been swallowed will be found in Poulet's elaborate treatise. There are three regions where a foreign body is especially apt to lodge—viz, opposite the cricoid cartilage,

Fig. 514.—Author's case of whistle in esophagus removed by external esophagotomy.

at the level of the diaphragm, and at the point where the left bronchus crosses the gullet. Small and sharp bodies may lodge anywhere.

Symptoms.—The symptoms are variable, if the body is large, there will be pain and difficulty in swallowing, and, in some cases, dyspnea from pressure upon the trachea or bronchus. Occasionally the dyspnea is such a prominent feature that it misleads the physician into the belief that the foreign body is lodged in the air-passages. Death may actually result from asphyxia. In

Fig. 515.—Author's case of jackstone in esophagus removed by external esophagotomy.

some other cases the symptoms are very slight. If the body is sharp, there will be hemorrhage and severe pain. The blood may be hawked up, or may be swallowed and vomited. A patient may grow accustomed to a foreign body and cease to notice it; but, on the contrary, the foreign body may produce inflammation, and may even ulcerate into the windpipe, the pleura,

the pericardium, or the aorta. In many cases of impaction a patient makes violent efforts to hawk and produces aphonia. There may be violent retching. Even after a foreign body has been removed by swallowing or otherwise a sensation is apt to remain as if it were still lodged. The diagnosis is made by the history, the detection of the body by external manipulation, by feeling it with an esophageal bougie, and, if bone or metal, seeing it with the fluoroscope or obtaining a skiagraph.

Treatment.—The surgeon should learn, if possible, the size, shape, weight, and nature of the foreign body, and should locate its point of impaction. The exact point of lodgment of bone or a metallic body is determined by the x-rays.* An anesthetic is given before manipulating in a child, a nervous woman, or a lunatic, and is *sometimes* necessary for a man. If the foreign body is soft, external manipulation may succeed in altering its shape, so that it may be swallowed or ejected. If the foreign body is hard, external manipulation may shift its position. It is usually impossible to reach the foreign body through the mouth by means of the fingers (when the body is in the rear of the pharynx it may be pulled forward or pushed down). Sharp foreign bodies may be entangled and carried down when the patient eats mush, bread, or boiled potatoes. The administration of emetics is an old plan which occasionally succeeds, but which is too unsafe to be employed. Maylard says that when a mass of food is impacted it is occasionally possible to soften and disintegrate the mass by administering a mixture containing pepsin. The horsehair probang is a very useful instrument (Fig. 511, C). It may be used to push a body downward into the stomach, or to catch the body and pull it up. When this instrument is withdrawn, it opens like an umbrella. Maurice H. Richardson has shown that in an adult the diaphragmatic opening is about fourteen and one-half inches from the incisor teeth, a point to be remembered in deciding whether to push down or pull up the impacted article. Esophageal forceps (Fig. 511, A, B) are valuable in some cases. The coin-catcher (Fig. 511, D) is a useful instrument. Créquy's plan of removal is to take a tangled mass of threads, tie a stout piece of string about the middle of it, coat it with sugar, and have the patient swallow it. It may pass the foreign body; if it does so, on withdrawal it may entangle the object and extract it. To remove a fish-hook with line attached, the following plan may prove successful, stick the line which projects from the mouth into a metal catheter, carry the catheter down to the hook, and push the hook out. It is not proper to allow a foreign body to remain in the esophagus until it causes ulceration. Neither is it proper to make prolonged efforts to extract it through the mouth. Such efforts may do great harm, and if one careful and consistent effort fails, an operation should be performed. If the body is lodged anywhere above the lower third of the esophagus, external esophagotomy is performed, and usually on the left side. Through this wound the foreign body is extracted. The cut is made on the left side, between the trachea and larynx in front and the carotid sheath behind, the center of the incision being opposite the cricoid cartilage. After the foreign body is extracted the mucous membrane is sutured with chromicized catgut, and the superficial structures are closed with silkworm gut after a drainage tube has been inserted. The patient is fed by the rectum for eight or

* See cases of White, Keen, Alfred Wood, MacIntyre, Taylor, and others.

ten days. When a foreign body is lodged in the lower portion of the tube, the stomach is opened and the body extracted by this route (Richardson). In White's case of jackstone in the gullet gastrostomy was performed. A string was tied about some rolls of gauze, the string was passed by means of a whalebone from the stomach into the mouth, and the body was entangled and drawn out.

Surgical Invasion of the Mediastinum.—The posterior mediastinum has been entered in order to remove a foreign body from the bronchus and to extract a set of false teeth wedged in the esophagus. The same method can be followed to reach suppurative processes in the mediastinum, abscesses of the lung otherwise inaccessible, and diverticula and carcinomata of the lower end of the gullet. Nassilov resects ribs close to the spine. The portion of the esophagus above the aortic arch can be reached after partial resection of the third, fourth, fifth, and sixth ribs of the left side. The inferior portion of the esophagus can be reached after resecting portions of the lower third or fourth ribs on the right side (Binnie's "Operative Surgery"). The anterior mediastinum may be entered to remove a bullet, to drain an abscess, to reach a wound of the heart or lung, and to explore for the cause of symptoms. I explored the anterior mediastinum after rib resection, found a bullet imbedded in the aorta, and allowed it to remain. The patient recovered. M. H. Milton* splits the sternum and separates the two pieces.

Invasion of the mediastinum is much safer if the operation is performed in the Sauerbruch chamber or with the aid of positive pressure within the bronchi. Either of these plans will prevent pulmonary collapse if the pleura is opened.

* Lancet, March 27, 1897.

XXVII. DISEASES AND INJURIES OF THE ABDOMEN.

Diagnosis of Intra-abdominal Emergencies.—The exact diagnosis is always difficult and is not unusually impossible. What a surgeon must try to determine, and what he usually can determine, is whether he is dealing with a trivial and temporary derangement for the relief of which an operation is entirely unnecessary, or whether he is confronted with a grave calamity which imperatively demands immediate surgical aid. We can decide that a calamity exists, but the exact nature of the lesion is often doubtful until operation is performed. Every operation in such a case is exploratory. Before the diagnosis of a calamity is made morphin should not be given, because it allays the pain, relieves the anxiety, causes the disappearance of rigidity, lowers the pulse, abates shock, and hence veils the real situation, so that the most discerning surgeon will probably be misled. If shock is profound, diagnosis is usually impossible, unless shock is due to hemorrhage, and immediate operation during shock is not to be thought of except to arrest bleeding. If excessive and continued hemorrhage is suspected, immediate operation is indicated. If it is not suspected, the patient should be covered with blankets and surrounded with hot water bags, atropin should be given hypodermatically, and hot salt solution should be administered by rectum, subcutaneously, or intravenously. Suprarenal extract is a valuable remedy to maintain blood pressure in shock (Crile). When the patient reacts, and he usually will react, an attempt is made to make a diagnosis. It is perfectly proper to give a single hypodermatic injection of morphin (gr. $\frac{1}{4}$) after the effort has been made to diagnose the condition. The danger of deluding the surgeon is past and the drug abates pain, lessens peristalsis, relieves mental anxiety, and is distinctly beneficial. Before the morphin was given the surgeon came to a conclusion as to the necessity for operation. After the morphin has been given, if an operation is indicated, it is performed as promptly as circumstances admit. Whenever it is esteemed consistent with safety, the patient ought to be removed to a hospital for operation.

Contusion of the Abdominal Wall without Injury of Viscera.—

In some cases of contusion of the abdominal wall only the parietes are damaged, in other cases the viscera or the abdominal tissues are injured. Contusion may involve the skin alone, or may involve the skin, muscles, and peritoneum. In *simple contusion* there is considerable shock if the injury is severe. There is pain, increased by respiration, motion, pressure, and attempts at urination or defecation. When tenderness appears some days after the accident there is usually deep-seated injury. Extensive ecchymosis may appear. Even after a severe contusing force has been applied there may be no discoloration, and it may happen that after a slight force there is much discoloration. There is great ecchymosis in anemic persons, victims of hemiplegia, in obese individuals, opium eaters, and drunkards. In severe cases the tissues are pulvified and sloughing inevitably ensues. Abscess occasionally follows contusion. The prognosis after abdominal contusion is always uncertain.

Treatment of Simple Contusion.—In treating simple contusion place the patient at rest in a supine position, with the thighs flexed over a pillow; obtain reaction from the shock. Give morphin if pain is severe. After shock has passed off it is advisable to place an ice-bag over the seat of injury. If much blood is extravasated into the abdominal wall, aspirate and apply a binder. After twenty-four hours apply local heat by means of the hot-water bag, employ an ointment of ichthyol, and move the bowels, if necessary, by salines. Regard every contusion as serious, and watch carefully for the development of signs of internal hemorrhage or visceral injury.

Muscular Rupture from Contusion. In this injury there are severe shock and pain (increased by respiration and movement). Separation between the fibers of the muscle is distinct at first, but it is soon masked by effusion of blood. Such injuries may cause death, or may lead to hernia. The rectus is the muscle most apt to rupture. The rupture is due to sudden contraction rather than to the direct effect of a blow.

The treatment is the same as for simple contusion. Always apply a binder. A hernia is returned and a compress is applied over the opening through which it emerged. If strangulation occurs, operate at once.

Injuries with Damage to the Peritoneum or the Viscera.—**Rupture of the Peritoneum.**—The peritoneum may be involved in an abdominal contusion. It may rupture even when there is no visceral injury or muscular contusion. The uterine peritoneum, the parietal peritoneum, the visceral peritoneum, or the mesentery may rupture. Rupture of the peritoneum causes intra-abdominal hemorrhage.

The treatment consists in opening the abdomen, arresting the hemorrhage, and bringing about reaction.

An injury to the peritoneum creates a point of least resistance, and at such a point peritonitis may develop. The peritonitis is usually local, but may become general. After any severe intra-abdominal injury the symptoms of peritoneal shock appear (*peritonism*), and the patient may rapidly die. In the condition of peritonism the temperature is subnormal; the extremities are cold; the face is pallid and sunken; the pulse is small, weak, and very frequent; the respiration is shallow and sighing; there is great thirst, the patient is restless and turns uneasily, and there is rigidity and distention. Vomiting almost always occurs. In some cases there is regurgitation rather than vomiting. The abdomen is the seat of a violent, persistent pain. The patient is fearful of impending death. As the symptoms develop in a grave case they will point to one of two conditions—hemorrhage or peritonitis.

In *intra abdominal hemorrhage* the subnormal temperature and other evidences of shock persist. Vomiting ceases, but nausea exists. The patient is uncontrollably restless and tosses about in bed. The thirst is great. The abdomen is rarely rigid. Fainting spells occur. Blood examination shows a marked fall in the percentage of hemoglobin. Percussion demonstrates the existence of an effusion which alters its position as the patient's position is altered, and which gradually increases in amount. Dulness is first met with in the loins. Digital examination of the rectum or vagina may aid in diagnosis because in hemorrhage blood gathers in the rectovesical pouch. If peritonitis develops, the vomiting becomes worse, the pain intensifies, and the abdomen grows rigid and distended.

sible that some of the cases were not positively instances of rupture. Nevertheless, the lesion, for reasons previously stated, is not nearly so dangerous as rupture of the intestine. Another reason for the greater danger of intestinal rupture is that fecal matter is much more poisonous than the gastric contents. Laparotomy has lessened the mortality of rupture of the stomach. Petry and also Eisendrath mass together operations for rupture of the stomach and rupture of the intestine. Petry finds the group mortality to be 52.3 per cent., and Eisendrath finds it to be 52.5 per cent. Statistics referring to the stomach alone should show a lower death-rate.

Rupture of the Intestine without External Wound.—In a great majority of cases the damage is produced by direct violence. In some few cases the force is indirect (falls on the feet or buttocks, blows on the back or loin). The injury may result from *oscillation* or from *compression* (the younger Senn). The common cause is undoubtedly compression of the gut against the pelvis or vertebral column, but it is certain that a gut containing fluid may be ruptured purely by violent shaking or oscillation. If oscillation produces the damage, the rupture is on the portion of gut furthest from the mesentery; if compression is the cause, any part of the bowel may suffer. Rupture is most apt to occur if the belly is relaxed. It is predisposed to by adhesions, disease of the wall of the bowel, and irreducible hernia (the younger Senn). Most ruptures are complete. In a very few cases the tear extends only through one or two of the coats and the rupture is incomplete. A contusion of the gut may be followed by rupture several days after the injury. A complete rupture usually permits leaking of feces, but in very rare cases a small opening is plugged up by pouting mucous membrane. Leaking may be delayed from a rupture because intra-abdominal pressure may for a time keep the opening pressed against a section of sound gut (the younger Senn). The amount of damage to the belly wall does not convey any notion of the amount of visceral injury. The belly wall may be severely injured and the viscera escape. With only a slight contusion of the wall there may be extensive visceral injury. Homer Gage* collected 85 cases; in 75 the injury was due to direct force, and in 32 of these the force was inflicted by the kick of a horse or of a man. In one of my cases it was due to the kick of a horse, in one to the kick of a man, and in one to a crush inflicted by a cart-wheel. The victims in the majority of reported cases were young men, probably because young men are most apt to be exposed to violence. In 78 collected cases (Gage) the situation of the injury was specified: The duodenum, 10; jejunum, 20; ileum, 42; large intestine, 6. Curtis found the large intestine injured in 4 cases out of 113, and Poland, in 5 cases out of 64. In many cases there is more than one tear, and sometimes many tears exist. Both the large and small intestines may suffer. Chavasse collected 106 cases in which the ileum or jejunum suffered, 19 in which the large intestine did, 7 in which the duodenum did, 7 in which both the large and small intestine were involved, and 1 case in which the rectum was ruptured (quoted by the younger Senn in "Am. Jour. Med. Sciences," June, 1904). As Makins points out, the portion of gut most apt to be injured is a portion hanging low in the pelvis, because a loop in this situation is most easily squeezed against bone by a blow on the belly. The mesentery may be lacerated (in 7 per

* Annals of Surgery, March, 1902.

cent. of cases, according to Gage; in 16 per cent., according to Curtis). The symptoms of rupture of the intestine are profound shock, tympanites, abdominal pain, and rigidity, rapidly followed by peritonitis if the patient survives. In some cases pain is referred to the back. Vomiting comes on soon after the accident, the vomited matters being possibly at first bloody and later stercoraceous. The respiration is thoracic, the tongue is dry, and great thirst exists. The pulse, which is slow at first, becomes small and rapid and of high tension. Blood in the stools rarely appears early enough to be of diagnostic value, and there may be diarrhea or constipation. The respiration is costal. Dyspnea exists. There may be no marked symptoms for an hour or two or for many hours. Cases are on record of people with ruptured intestine returning to work perhaps for hours. Holland's patient had no symptoms for twenty-four hours, although the jejunum was ruptured. Poland's patient ruptured the duodenum but walked one mile. The escape of gas into the peritoneal cavity may cause the diminution or disappearance of liver-dulness. After anesthetizing the patient, hydrogen gas insufflated into the rectum will come from the mouth if there is no perforation in the stomach or the intestine; if a perforation exists, tympanites is much increased, and the area of liver-dulness may disappear. To apply *rectal insufflation of hydrogen*, generate the gas in a bottle by means of zinc and sulphuric acid, catch the gas in a large rubber bag, and attach the tube from the gas reservoir to a tip which is inserted in the rectum. Give the patient ether to relax the abdominal muscles, direct an assistant to press the anal margins against the rectal tip, and when the patient is unconscious, turn on the stopcock and press upon the reservoir (the elder Senn).

It has been suggested that ether vapor, mixed with air, can be used instead of hydrogen gas.* In this method a little ether is poured into the bottle of an aspirator, the valves are opened, one tube is carried into the rectum, the other tube is attached to a bicycle pump, and by working the pump the ether vapor is driven into the bowel. If there is perforation, tympanites is notably increased. Most surgeons regard the rectal insufflation test as unsatisfactory and often dangerous. Personally I am not inclined to use it. Its application requires considerable time, it must of necessity increase fecal extravasation, and, as Le Conte† says, it "so distends the intestines that it may be impossible to return them to the abdominal cavity until they have been emptied of gas."

Treatment of Rupture of Intestine.—If symptoms point to dangerous hemorrhage, and in any case in which the patient does not seem to be reacting, but is rather getting worse, operate at once. If in doubt as to whether or not rupture exists, make every endeavor to bring about reaction, and explore. Reaction is brought about as previously directed. Asepticize and anesthetize. Perform a laparotomy, making the incision in the middle line and below the umbilicus; note if gas escapes when the peritoneum is opened or if fecal material or an inflammatory exudate flows out; check hemorrhage; start at a fixed point and conduct a careful search to find the rent. When the rent is found, it should be closed by Halsted sutures if possible. It is only a small rupture, however, which can be so treated. Most large tears

* Emerson M. Sutton, of Geneva, in *Jour. Am. Med. Assoc.*, July 23, 1898.

† *Am. Jour. Med. Sciences*, Dec., 1901.

make resection necessary. Because of the frequency of multiple lesions the surgeon must not be sure he has finished his work when he finds and closes one tear, but he must determine by careful search that no other tears exist. The surgeon notes if there is injury of the mesentery and if the circulation of any portion of the bowel is interfered with. If there is serious impairment of circulation in any part of the bowel-wall, perform intestinal resection, followed by end-to-end approximation or lateral anastomosis. In some cases of rupture the patient is so severely shocked that it is impossible to do a resection with any hope of the patient living. In such a case stitch the ruptured portion of gut to the belly wall. The opening in the gut becomes a fecal fistula, and if the patient survives, can be subsequently closed (Senn). The same procedure is proper if the bowel is distended and paralyzed. After closing the opening in the bowel or resecting flush the abdominal cavity with hot saline solution, and wipe the peritoneal fossae and the space between the liver and diaphragm with gauze. Finney eviscerates, wipes out the abdominal cavity, and wipes the intestines as he restores them. This is justifiable if the operation is done soon after the rupture, but not in later cases, in which lymph has gathered on the bowel. Whatever method is used to cleanse the abdomen, remember that infectious material is apt to accumulate between the liver and diaphragm and in Douglas's pouch. Drainage is to be used. Suprapubic drainage is most advantageous. Place the patient semierect and employ continuous proctoclysis of normal salt solution as directed for peritonitis. The value of operation for intestinal rupture is conclusively demonstrated. Curtis collected 116 cases which occurred before 1887. Not a case was operated upon, and every patient died. Homer Gage collected 85 cases since 1887: 45 were not operated upon and every one died; 40 were operated upon and 17 recovered. Eisendrath collected 40 cases operated upon. Nineteen recovered and 21 died (52.5 per cent.). The mortality of cases not operated upon is, according to Eisendrath, at least 93 per cent. The sooner after the injury operation is performed the greater the chance for success. The younger Senn points out that in operations done within four hours the mortality is 15.2 per cent.; in those done between five and eight hours it is 44.4 per cent.; in those done between nine and twelve hours it is 63.6 per cent., and in those done later it is 70 per cent.

Identification of the Small Intestine and of the Large Intestine.—

In abdominal operations it is frequently imperatively necessary that the large intestine be recognized with certainty or the small bowel be positively identified. The size of the tube will not always aid in this recognition, as a small intestine may be distended enormously and a large intestine may be contracted to the size of a finger because of obstruction above. The longitudinal muscular fibers of the large bowel are accentuated in three portions: these accentuations constitute the three longitudinal bands which begin at the cecum and terminate at the end of the sigmoid flexure of the colon. Each band is composed of a number of shorter bands, the shortness of these constituent bands permitting the sacculation of the large intestine. Longitudinal bands and sacculation are not met with in the small gut, their presence or absence being a means of identification in many cases; but when the colon is much distended, the bands cannot be seen distinctly and the sacculation disappears. From the large intestine only spring the appendices

through a smaller incision, and that will diminish handling of structures, tends to increase the chances of recovery. For the writer suggests a method of bowel-identification which rests on that each bowel has a posterior attachment, that the origin of the mesentery differs according to the bowel it supports, that a single finger can find the origin of the peritoneal support of any section of the bowel if the origin being known, the portion of the bowel it supports is readily deducible. In an exploratory operation, for instance, the finger is in contact with the bowel: to determine whether it is a large or a small bowel, first if the structure is movable or is firmly fixed; next, pass the finger behind the bowel and let it find its way posteriorly. If dealing with the small bowel the finger will reach the origin of the mesentery between the second lumbar vertebra and the right sacro-iliac joint; if dealing with the large bowel, the finger will reach the origin of the mesocolon at a point where the colon is fixed posteriorly and to the side."*

Location of a Loop of Small Intestine (Figs. 516, 517, 518). Monks points out a plan by which, in most instances, we can learn with approximate accuracy what portion of the small intestine we may have exposed. (Annals of Surg., Oct., 1903). He learns first by observation of the position of the vessels. Opposite the upper portion of the bowel there are primary loops only with perhaps an occasional small secondary loop. As the ileum descends "secondary loops become more numerous, larger, and approach the bowel more closely than the primary loops in the upper part," and about the middle of the ileum these secondary loops first become a "prominent feature." As the ileum descends further, the primary loops become smaller, secondary loops become more numerous, and tertiary loops appear. Opposite the lower portion of the ileum the loops are not definite in arrangement, but form a network. Monks points out that opposite the upper bowel the loops when put gently on the stretch, "are straight, large, and regular, and give off branches to the mesentery," and are about 5 cm. long. One-third they are usually less than 1 cm. long, are smaller, are not so straight, are not so regular, and give off numerous mesenteric branches. Monks further shows that fat impairs the translucency of the mesentery.

Fig. 516.—A loop of intestine the middle of which is exactly three feet from the end of the duodenum. The gut is of large size. The mesenteric loops are primary, and the vasa recta large, and regular in distribution. The translucent spaces (lunettes) between the vessels are extensive. Below, the mesentery is streaked with fat. The veins which had a distribution similar to the arteries, are for simplicity omitted from this and from the subsequent drawings. The subject from which the specimen was taken was a male of forty years, with rather less than the usual amount of fat. The entire length of the intestine was twenty-three feet (Monks).

Fig. 517.—A loop of intestine at six feet. As compared with Fig. 516 the gut is somewhat smaller. The vascularity of the intestine and mesentery is less. Secondary loops are a prominent feature. The vasa recta are smaller. The lunettes are also present, but are not so large as in Fig. 516. The subject was a male of about thirty-five years, with an average amount of fat. The entire length of the intestine was twenty feet (Monks).

intestine is pulled downward we can determine if "the line of resistance from above is from the median line of the body or from the left or right of it."

Fig. 518.—A loop of intestine at twelve feet. The vessels are smaller. The primary loops are lost in the fat, but secondary and even tertiary loops are visible. The vasa recta are shorter, more irregular, and branching. The specimen came from the same subject which furnished Figs. 516 and 517 (Monks).

Fig. 519.—A loop of intestine at twenty feet. The gut appears to be thick and large. The mesentery is quite fat and opaque, and large and numerous fat cells are present. The vasa recta, which are complicated, are seen with difficulty, and are represented by more numerous in the fat. The subject was a stout woman and the entire length of the gut was twenty-four feet. (Monks.)

This resistance of the mesentery indicates to which point the loop is attached, and hence what portion of bowel the loop comprises. I have used these observations of Monks repeatedly to great advantage.

Rupture of the Liver (page 1014)

Rupture of the Gall-bladder and the Bile-ducts (page 1014).—Rupture of the gall-bladder or the ducts is most apt to happen from injury when gall-stones exist. Peritonitis, general or local, is almost certain to follow such a rupture. Besides those symptoms common to all severe abdominal injuries, there is often intense jaundice.

Treatment.—Suture the laceration or make a biliary fistula.

Rupture of the Spleen (page 1046).

Rupture of Mesenteric Arteries.—The symptoms are those of hemorrhage. The superior mesenteric artery, the inferior mesenteric artery, or branches of either or both may be damaged. If branches of the superior mesenteric artery are divided near the bowel, gangrene of the bowel will result, but wound of a branch far from the intestine does not cause gangrene. The last branches are terminal arteries, hence the gangrene. The branches of the artery divide and form arcades arranged concentrically and the terminal arteries come from the peripheral arcades. In wounds of the vessels far removed from the gut anastomosis prevents gangrene (Labastie, in "Archives Générales de Chirurgie," Jan. 25, 1908). In most cases in which there has been rupture of mesenteric arteries, death from hemorrhage rapidly occurs. If the victim should not die of hemorrhage he is in danger of gangrene and peritonitis. Aldrich* reported a case in which death occurred on the seventh day. The treatment is immediate laparotomy. If the wound is found close to the gut the portion of gut supplied by the cut vessel should be resected. If well removed from the gut simply ligate the vessel (Labastie, *Ibid.*). In a wound near the root of the mesentery perform extensive resection of the gut and remove also a portion of the mesentery.

Rupture of the Kidney (page 1278).

Rupture of the Ureter (page 1280).

Wounds of the Abdominal Wall.—Non-penetrating wounds are to be treated on general principles. They are sutured with great care and are firmly supported externally. Ventral hernia may follow a large wound.

Penetrating Wounds. The symptoms of penetrating wounds of the abdominal wall are usually those of shock and hemorrhage, and later of septic peritonitis. Emphysema is apt to occur and viscera may protrude, and often do in the case of a large incised or lacerated wound. Extravasation of contents of intra-abdominal viscera is very apt to occur, and is sure to occur if the viscus was distended when injured. Normal urine and normal bile may do little harm, but if either excretion is septic, disastrous consequences are certain to ensue. If intestinal contents escape, septic peritonitis is certain to occur. Bleeding is usually profuse and prolonged, because spontaneous arrest of hemorrhage from any vessel of considerable size will rarely take place within the abdomen.

Treatment.—The surgeon endeavors to discover promptly if a wound of the abdominal wall is or is not penetrating in character. This fact may be proved by protrusion of viscera, by the appearance of stomach-contents

* Annals of Surgery, March, 1912.

in the wound, or by a flow of bile, urine, or feces from the wound. If none of the above indications exists, and if there are no signs of serious hemorrhage, the wound should be irrigated with hot salt solution, and should be dressed with gauze, and every effort should be made to bring about reaction; otherwise operation should be immediate.

When reaction is obtained, the wound should be enlarged layer by layer until it becomes obvious whether or not the peritoneum is open. Madelung, of Strassburg, points out that incision layer by layer will be of no use in settling the question of penetration if the wound is in the chest, the buttock, the perineum, or the back of a fat individual.* If after incision layer by layer it becomes evident that penetration has not occurred, the wound should be closed and treated on general principles. If it becomes evident that it has occurred, the abdomen should be opened at the point of penetration, and a thorough exploration of intra-abdominal structures should be made in order to determine injury and be able to treat it properly.

In a case still doubtful after incision by layers, do an exploratory laparotomy in the middle line. It is impossible to affirm from the appearance of the wound and from the symptoms that visceral injury has not occurred; hence in every penetrating wound in civil practice perform exploratory laparotomy.

In every case in which it is evident that penetration has occurred, laparotomy is necessary in order to detect and correct intra-abdominal injury, and to clean the peritoneum by flushing with hot salt solution. If viscera protrude, they must be washed off with hot salt solution and covered with hot sterile pads, and after the patient has reacted, the wound should be enlarged, the condition of the contents of the abdomen investigated, hemorrhage arrested, wounds properly treated, and the viscera returned.

It is customary to flush the belly with hot salt solution, some of the fluid being allowed to remain. This proceeding mechanically cleanses the peritoneum, removes blood-clots, and strongly combats shock. It is not absolutely necessary to flush out the belly unless a considerable hemorrhage has occurred or feces or stomach-contents have been extravasated. If extravasation of stomach-contents or feces has occurred, not only should flushing be practised, but evisceration should be carried out; the fouled intestine should be wiped off with gauze pads wet with hot salt solution, and be wrapped in hot moist towels; the peritoneal fossæ should be rubbed with gauze pads and the space between the liver and diaphragm should be carefully wiped.

A wound of the stomach should be sutured; a wound of the bowel may be sutured, or resection and anastomosis or resection and end-to-end suturing may be required. Visceral injuries are treated by appropriate means. In a punctured wound or a gunshot-wound of the intestine rectal insufflation of hydrogen gas when the abdomen is open may disclose the situation of the injury, but evisceration is usually practised instead.

After the completion of intra-abdominal manipulations the surgeon restores any protruding bowel.

Drainage is required when the contents of the stomach or the intestines have escaped, when hemorrhage is severe, or when the liver, pancreas, kidney, or spleen is found to be damaged. The peritoneum may be sutured with a con-

* Annals of Surgery, Sept., 1897.

tinuous suture of catgut, and the muscles, fascia, and skin with interrupted sutures of silkworm-gut, or through-and-through sutures of silkworm-gut may be used. Active stimulation and artificial heat are needed immediately after the operation to combat shock. In many cases intravenous infusion of hot normal salt solution is of great value. It may be given both during and after operation. Enteroclysis, or high rectal injection of hot saline fluid, is useful. So is hypodermoclysis, or the subcutaneous injection of hot salt solution. The after treatment consists of the semierect position, continuous proctoclysis of salt solution, avoidance of food by the stomach for forty-eight hours, and the administration of brandy and water from time to time. For two days the patient should be fed by the rectum. On the appearance of the first sign of peritonitis, forty-eight hours or more after the operation, give a saline cathartic. It is not wise to purge during the first forty-eight hours after the operation, unless a Murphy button was used. When there is no sign of peritonitis, a purge should not be given until the fourth day. After forty-eight hours liquid food can usually be given by the stomach. Solid food may be given after seven or eight days, but the patient must not leave his bed until the wound is firmly united, because of the danger of ventral hernia. A support should be worn for a long time. E. D. Fenner* reports 39 stab wounds of the abdomen operated upon in the Charity Hospital of New Orleans. There were 9 deaths (23.07 per cent.).

Gunshot-wounds of the Abdomen.—The bullet may penetrate from the front, the side, the back, the chest, or the perineum. If a bullet has penetrated, it may or it may not have produced visceral damage. A pistol-bullet or the bullet of a sporting-rifle usually does; a projectile of a modern military rifle may not or may produce wounds which can be recovered from without operation. A urinary examination should be made promptly to see if blood is present.

In gunshot-wounds of the belly shock is usually due to hemorrhage, and in civil practice certainly prompt operation is indicated. The incision is made through the belly even when the shot entered the back. In some cases the opening is made through the wound; in others it is not; but in every case the wound is explored and cleaned. The incision should be long enough to permit of thorough work. After opening the abdomen our first duty is to arrest hemorrhage, our next is to look for perforations of the viscera and mesentery and close them. If the anterior wall of the stomach is perforated, close the opening and examine the posterior wall through an opening made in the gastrocolic omentum. If a posterior perforation is found, close it and insert posterior drainage into the lesser peritoneal cavity. As a rule, an intestinal perforation can be closed, but occasionally a portion of the intestine requires resection. If the bullet is encountered it is removed, but a prolonged search for it should never be made. Finally the abdominal cavity is cleansed, drainage is provided for, and the abdominal wound is closed. In one of my fatal cases the bullet entered the rectum low down and was not found. In a case of mine with 6 perforations of the small intestine recovery followed operation.

E. D. Fenner† reports 113 gunshot-wounds of the abdomen operated upon in the Charity Hospital of New Orleans; there were 78 deaths (69 per cent.). In a series of 14 cases operated upon by Vaughan the mortality was 64 per cent. ("Am. Jour. Med. Sciences," Feb., 1906).

Military surgeons have shown that wounds inflicted by the modern hard-

* *Annals of Surgery*, January, 1902.

† *Ibid.*

jacketed projectile are not so apt to involve fatal hemorrhage and disastrous complications; in fact, such wounds are often recovered from without operation, and sometimes with an entire absence of serious symptoms. Again, it is difficult or impossible to treat such cases as in civil practice, even were it desirable. In fact, in military practice the results are slightly better from expectant treatment, whereas in civil practice the reverse is true. Still, even in war, if conditions permit, operation should be performed if there is hemorrhage or obvious visceral injury, or if septic peritonitis develops. Treves says that in the Boer War only 40 per cent of cases of gunshot wounds of the abdomen not operated upon died, but, as pointed out by Hildebrandt, many cases die on the battle-field and while being taken to the hospital, hence the mortality is much higher. In the war between China and Japan the mortality from gunshot-wounds of the abdomen is said to have been about 77 per cent.

Gunshot-wounds of the Pregnant Uterus.—It is rarely that both walls are perforated, as the force of the bullet is greatly lessened by the uterine contents. As a rule, there are severe shock and hemorrhage, and occasionally amniotic fluid flows from the wound of entrance. The intestine may also be injured. As a rule, labor pains come on soon after the injury. Gellhorn* has collected 18 cases. In this series there were 12 recoveries. The proper treatment early in pregnancy, if the wound is small, consists in emptying the uterus and closing the wound. A large wound, or any wound late in pregnancy, demands the Porro operation—removal of the uterus, ovaries, and tube.

Omental Cysts. Cysts may spring from the outer surface of the omentum (escaped ovarian cysts, lymphatic cysts, dermoids).

True omental cysts arise within the cavity of the great omentum. There are 20 cases on record (Edwin M. Hasbrouck, in "Annals of Surgery," August, 1908). In 50 per cent. of cases the patient is an adult, but half of the reported cases were under ten years old. (Some of these were of congenital origin.) Hasbrouck (Ibid.) points out that the condition is much more common in females than in males, that there are no characteristic symptoms, that the condition begins as omental endothelioma between the two surfaces of omentum which fuse because of inflammation and form a closed sac, that hemorrhages are apt to occur into the cyst, and that operation shows a mortality of 6 per cent. The operation performed is extirpation.

Mesenteric Cysts. These rare cysts are divided into (1) embryonic, (2) hydatid, (3) cystic malignant disease (Dowd, "Annals of Surgery," 1908). A great majority of mesenteric cysts are embryonic. Moynihan believes that embryonic cysts arise from "rests" from "the Mullerian or Wolffian organ—ducts, or from the ovary," which are included between the folds of mesentery. These rests undergo cystic degeneration. Mesenteric cysts grow and pass along between the layers of mesentery until they reach the gut and then compress the gut and push its wall ahead of them.

Such a cyst may contain embryonal material, bloody fluid, serous or chylous fluid, or lymph. In Harry C. Deaver's report of a case ("Annals of Surgery," May, 1909) it is shown that in 40 cases there were 24 females and 16 males, that the size varies from that of a split pea to enormous dimensions, that there may be a pedicle form in front of the vertebral column or from

* St. Louis Med. Review, Dec. 7 and 9, 1901.

intestinal wall; that the sac wall may be exceedingly thin or as much as 1 cm. in thickness; that in some cases large veins are present on the surface of the cyst; that adhesions to the abdominal viscera are common; that intestinal obstruction may occur (kinks, volvulus, intussusception); that cysts are most commonly found in relation with the lower end of the ileum; and that there are no characteristic symptoms except perhaps the rapid body wasting mentioned by Moynihan. Moynihan points out that the cyst fluctuates and is most prominent toward the navel, that it is very mobile, especially transversely (we should add if not anchored by adhesions), and that the cyst is surrounded by a resonant zone and crossed by a resonant band.

Treatment.—Incision and drainage if there are numerous and firm adhesions. Enucleation whenever possible. Resection of the involved portion of gut with the cyst in some cases of multiple cyst (Harry C. Deaver, *Ibid.*).

STOMACH AND INTESTINES.

Foreign Bodies in the Stomach and Intestine.—Foreign bodies of considerable size are rarely taken into the alimentary canal except by children, insane people, or drunkards. Small bodies (bits of straw, fragments of bone, etc.) are frequently swallowed. Most foreign bodies swallowed are passed with the feces, but some lodge. Any body which can pass the esophagus is not too large to pass through the intestines. Lodgment is an accident, not an inevitable consequence—an accident which is due to the shape and size of the body. A foreign body may lodge in the stomach. In some cases there are no symptoms. In other cases symptoms are violent. The severity of the symptoms depends upon the shape and character of the body.

In some cases it is possible to feel the body from without. A metal body in the stomach will deflect a magnetic needle held over the viscus (Polaniou). Many foreign materials can be skiagraphed. A body of small size may pass through the entire canal and emerge without having done any harm, but it may lodge and may cause perforation. If perforation occurs, the foreign matter may become encysted, for instance, in the mesentery, may cause an abscess or may cause general peritonitis. A fish-bone may cause an anal abscess. An epiploic appendix may cause saccululation of the bowel, perforation may take place in this sac, an *epiploic abscess* resulting, which may attain considerable size and may be mistaken for carcinoma (J. Bland Sutton, in "Lancet," Oct. 24, 1903). It is not wise to attempt to recover a foreign body from the stomach by inducing vomiting. In some cases gastrotomy is necessary. When a small or sharp foreign body has been swallowed and has not caused perforation, abscess, or obstruction, the usual treatment is as follows: a purgative should *never* be given to expedite the passage of a foreign body, because increased peristalsis means increased danger of impaction or of perforation. Endeavor to encrust the foreign body, and thus lessen the danger of perforation, by feeding with bread and milk only for several days, and at the end of this period give a mild laxative. An exclusive diet of mush or of mashed potatoes has been suggested. Suet dumplings may be given. Pain is relieved by opium. A foreign body rarely lodges in the duodenum, but may lodge lower down, and may cause ulceration, perforation, abscess, or intestinal obstruction. Operation is necessary in such cases.

Volvulus of the Stomach.—This condition is very unusual. Ten cases are on record (Streit, in "Am. Jour. Med. Sciences," June, 1906). One-third of the cases are associated with diaphragmatic hernia. The symptoms come on suddenly with sudden abdominal pain, distention, and collapse. There is nausea, but the patient can neither vomit nor belch. In the upper left abdomen there is a tender, tense, and tympanitic area. The rotation of the stomach may be on its vertical or on its longitudinal axis. An hour-glass stomach may undergo twisting on its vertical or longitudinal axis. Berg operated successfully for volvulus of the stomach. He opened the abdomen, relieved distention by tapping the stomach with a trocar, and then easily corrected the twist. The gastrohepatic omentum should be shortened by Beyer's operation (page 1091).

Carcinoma of the Stomach.—Innocent tumors and sarcomata occasionally attack the stomach, but they are infinitely rare in comparison with primary cancer. This disease is unusual before the age of forty, and is practically never seen before the age of thirty. It is more common in men than in women, the proportion being as 5 to 4. In a very few instances cancer has been found to have arisen from an ulcer. The forms of cancer which may arise in the stomach are the spheroidal cell growth (either the hard form known as scirrhus or the soft form known as medullary or encephaloid), the cylindric cell growth or adenocarcinoma, and colloid (due to the myxomatous degeneration of either a spheroidal cell or a cylindric cell carcinoma). Scirrhus more than any other form produces constriction of the pylorus and more seldom than any other form produces hemorrhage. It may spread for a considerable distance along the submucous coat, muscular coat, and subserous coat without apparent involvement of the mucous membrane wide of the primary focus of disease. In some cases scirrhus is limited to the pyloric region, in others it is a limited tumor of some other part of the wall of the stomach. In the condition known as "leather-bottle stomach" a scirrhus has invaded the entire stomach wall and the wall of the viscus is thick and rigid.

Medullary cancer and adenocarcinoma produce hemorrhage. Both of these forms most often arise in the pyloric region. Medullary cancer may remain limited, but, as a rule, a cauliflower growth arises and eventually fills the stomach and portions of the mass may slough away.

Adenocarcinoma is apt to spread along the mucous membrane instead of "infiltrating the deeper layers" as other forms are prone to do ("Cancer and Tumors of the Stomach," by Samuel Fenwick and W. Soltan Fenwick). Spheroidal celled carcinomata are twice as common as cylindric celled and medullary cancer is about as common as scirrhus.

Cancer may be limited to the body of the stomach (either curvature or either wall), the pyloric end or the cardiac end, but it may involve two of these regions, or almost the entire stomach, or, being multiple, may be found in many parts. Sometimes there is a primary cancer on one wall, and another quite due to contact, in a corresponding point of the opposite wall (contact cancer). All forms of carcinoma most frequently begin in the region of the pylorus. In many cases of gastric carcinoma adhesions form between the stomach and the liver, colon, or diaphragm. Even in cancer of the pylorus the duodenum is seldom invaded. Medullary cancer not unusually passes into the esophagus. It is usually fatal in from four months to two years, and

most patients die within one year. In 60 per cent. of cases the pylorus is involved. In over half of the cases of cancer of the pylorus there is no important lymphatic involvement (McArdle). In investigating any gastric disorder follow Mayo's advice and study the history, the size and situation of the stomach, determine the existence and situation of pain and tenderness, the presence of a tumor, and if the passage of food is interfered with.

Symptoms.—Examine with care a patient in whom cancer is suspected. In unusual cases it produces no symptoms until it has lasted for some time and has attained a large size (latent cancer). In nearly all cases it does produce symptoms. The disease comes on gradually, usually with indigestion and physical weakness. The patient has persistent dragging pain, which is increased by eating and pressure, and attacks of vomiting are frequent. After a short time the patient becomes very weak and exceedingly anemic, and it is often possible to feel a tumor in the stomach. Blood examination shows diminution of red corpuscles and hemoglobin and perhaps absence of any increase of leukocytes after a full meal. The vomiting of gastric cancer is at first only occasional, but as the case progresses it becomes more and more frequent. Vomiting soon after eating occurs when the cardiac region is involved; vomiting an hour or so after eating occurs when the pyloric end is involved. When the body of the organ is the seat of disease, vomiting may be absent. The vomited matter is often mixed with a small amount of altered blood (*coffee ground vomit*). In most cases occult blood is found in the feces, especially if hydrochloric acid is absent from the stomach contents. These symptoms associated with "coffee-ground vomit" and lactic acid in the stomach contents are strongly indicative of cancer (Wm. J. Mayo, in "Surg., Gynec., and Obstet.," May, 1908). A *test-meal* is given and important conclusions are sometimes derived from the presence or absence of hydrochloric acid and lactic acid. It is my custom to have the stomach washed out and then have Ewald's test-breakfast given. This consists of one roll of white bread (35 gm.), 400 gm. of H₂O, and 400 gm. of tea without milk or sugar. In one hour the stomach is emptied by means of a tube and a pump or a tube and abdominal compression, and the material is examined. If the result of the test seems out of accord with the other symptoms, repeat the process (L. Boas, in "Berlin. klin. Woch.," No. 440, 1905). In most cases free hydrochloric acid is not found in the stomach contents, but lactic acid is found and Oppler's bacillus can often be detected. There may be red blood-corpuscles in the fluid. If the cancer is not ulcerated, free hydrochloric acid will probably be found; if it is ulcerated, it will usually be absent*. Free hydrochloric acid may be absent from the stomach because of atrophy of glands, cessation of secretion, or neutralization by the products of the cancerous area. Free hydrochloric acid may be absent when cancer does not exist. I have noted its absence in two cases of cicatricial stenosis of the pylorus.

It may be absent in cancer of the esophagus, advanced Bright's disease, cancer of the duodenum, febrile conditions, and amyloid disease. The constant presence of considerable quantities of hydrochloric acid is strong evidence against the existence of cancer of the stomach. If cancer arises from ulcer, free hydrochloric acid is apt to be present for a considerable time.

* Reissner, in *Munchen. med. Woch.*, Dec. 3, 1901.

Distend the stomach with gas or fluid and map out its a tumor. A tumor can usually be felt if it involves the anterior wall, and a large tumor of the pylorus can be palpated. In regions the tumor can rarely be felt.

Cancer of the cardiac end interferes with the entrance into the stomach, and in such a case the stomach is shrunken and not dilated immediately above the growth. In cancer of the pylorus the stomach is partially or completely arrested as it passes to emerge from the stomach becomes much dilated. The vomited matter rarely contains recognizable fragments of the growth, but if the stomach has been irrigated may contain pieces which are cancer (Rosenbach).

In cancer of the stomach the general course of the tumor is upward but there are occasional deviations to below or above normal. In the urine contains albumin, indican, acetone, and in cancer of the stomach produces spasm of the esophagus in two cases. Cancer of the stomach is apt to involve the lymph-glands, or organs or other structures, especially the liver is involved in 30 per cent. of the cases (Welch). There is enlargement of the suprasternal glands of the left side is usual and early, but in cancer of the pylorus 60 per cent. of the cases show distinct lymphatic involvement. In many doubtful cases of cancer of the stomach is justifiable.

Treatment.—The medical treatment consists in milk-morphin and of lavage if the pylorus or body of the stomach is involved. Form lavage as follows: The tube for lavage should be long enough to reach about three feet out of the mouth when the other end is in the stomach. It should be flexible, should have an opening in the stomach opening on the side about one inch above the stomach-end, and should be greased with glycerin. The patient sits down, throws the head back, and the tube is directed to take deep breaths. The tube is carried into the pharynx, the patient is ordered to swallow it, and the tube is thus taken into the stomach. Fluid is poured into the funnel-like end of the tube, and when the funnel empties itself of the fluid the funnel is lowered and the fluid is poured out. This proceeding is repeated till the fluid becomes clear. To use is a solution of bicarbonate of sodium, a teaspoonful to the quart of warm water. Lavage should be practised before meals and sometimes also at bed-time.

The indications for operation are well set forth by Murphy: progressive aggravation of symptoms in spite of a rigid medical treatment, loss of gastric mobility, progressive diminution of gastric stasis, progressive diminution of free hydrochloric acid in the gastric juice under forced feeding, progressive reduction of hemoglobin under, and moderate leukocytosis.

Surgical treatment aims to remove the growth or to relieve the obstruction at one of the orifices of the stomach.

* John B. Murphy, in Chicago Med. Recorder, June, 1900.

In cancer of the body of the stomach, if the growth is not extensive, excision may be performed, if it is extensive, it is useless to attempt it unless the growth is absolutely non-adherent. Conner, of Cincinnati, attempted total excision in 1883, but the patient died on the table. In 1897 Schlatter, of Zurich, successfully removed the entire stomach. Brigham, Richardson, Macdonald, Boeckel, De Carvalho, Bardelichen, Haine, Gallet, Dollinger, Ferry, Ribera, and others have successfully removed the entire stomach and attached the esophagus to the small intestine (*complete or total gastrectomy*). In these cases digestion was satisfactorily performed after removal of the stomach. Very rarely will cases be found suitable for such a radical proceeding. The case suitable for this treatment is one in which the entire stomach is involved in the growth, in which there is no obvious glandular involvement, and in which the stomach is not adherent, but is freely movable. Herbert J. Patterson ("The Hunterian Lectures for 1906") collected 27 cases of total gastrectomy for cancer: 10 died and 17 recovered. If a small portion of the fundus is left the operation is called *subtotal gastrectomy*. H. J. Patterson (Ibid.) collected 20 cases of subtotal gastrectomy for cancer with 6 deaths. In limited cancer of the body of the stomach perform *partial gastrectomy*. In cancer of the cardiac orifice of the stomach the surgeon usually keeps the passage open as long as possible by the frequent passage of a tube, and through this tube introduces liquid food. Sometimes a small tube is introduced and permanently retained. When it becomes difficult to introduce a tube, *gastrostomy* may be performed. As a matter of fact, in most cases gastrostomy is done as a last resort, and it is scarcely worth doing in cancer of the cardiac end of the stomach. It is far more useful in cancer of the esophagus. In cancer of the pylorus, limited in extent and without lymphatic involvement, *pylorectomy* may be performed; but in cancer which has widely infiltrated the coats of the stomach and has involved the lymphatic glands, *gastro-enterostomy* is performed as a palliative measure, the patient during the rest of his life subsisting upon liquid or semiliquid foods and submitting to frequent irrigation of the stomach to remove food-residue. In cases of irremovable and far advanced cancer it is often best to refuse to operate and to deliberately create the opium-habit in the patient.

The most successful of all the above operations are pylorectomy and partial gastrectomy. The mortality is large. In H. J. Patterson's series of cases the mortality was 28 per cent. There are in literature 43 cases which have survived three years or over (Macdonald). Mayo reported 21 gastro-enterostomies for cancer with 4 deaths. The greatest prolongation of life was nineteen months. His experience makes him question if the operation is worth doing in malignant disease.

Sarcoma of the Stomach. Of recent years it has been proved that sarcoma is more common than was once supposed. There are over 60 cases on record. It can occur at any age, but is more usual in early life than is carcinoma. It has been estimated by Wm. T. Howard* that 37.7 per cent. of cases are under the age of forty, and 11.44 per cent. are under the age of twenty. The pylorus is involved in about one fourth of the cases. In most cases the posterior wall and greater curvature are involved. Howard says there is a diffuse growth in 21.31 per cent. of cases and that the cardiac end is

* Jour. Am. Med. Assoc., Feb. 8, 1902.

involved in only 4.9 per cent. of cases. Sarcoma arises in the submucous coat. Any form of sarcoma may arise. It causes stenosis in less than one-tenth of the cases. There is no sex predisposition in sarcoma, as there is in cancer.

Symptoms.—A tumor forms, grows rapidly, and often attains a large size, and not unusually actually causes a projection of the abdominal wall. If it ulcerates, there will be hematemesis, but it often does not ulcerate, and bleeding is much rarer than in carcinoma. Not unusually this growth arises in a person under forty, and sometimes in one of less than twenty years of age. Stenosis is uncommon. The liver is involved secondarily in only 11.47 per cent. of cases (Howard), metastases are more rare than in carcinoma, free hydrochloric acid is usually absent from the gastric contents, and microscopic examination of washings from the stomach may detect fragments of sarcoma. Certain diagnosis is impossible without exploratory incision. Howard estimates the average duration of life to be from nine to ten months.

Treatment. If the liver is free and if there are no metastases, partial gastrectomy or complete gastrectomy may be advisable. If pyloric stenosis should arise, gastro-enterostomy may be performed.

Ulcer of the Stomach. Ulcer of the stomach is a condition due to digestion of a portion of the stomach-wall by very acid gastric juice, the destroyed portion having been the seat of lowered vitality. The reason for the lowered vitality of the gastric mucous membrane is uncertain. Thrombosis has been suggested as a cause, but it is rare in gastric ulcer. Embolism is assigned by some as a cause, but emboli are seldom found on pathologic examination. It has been asserted that menstrual disorders may be responsible for ulcer, that tight lacing may be, and that habitually bending over (as in making shoes) may be a cause. The Mayos are of the opinion that the grinding action of the pyloric portion of the stomach may be an exciting cause of ulcer of that region. Some assert that mental anxiety, alcoholism, and syphilis may be causal (Alderson). Ulcers due to syphilis and tuberculosis are not peptic ulcers.

Robson believes that gastric ulcer is septic in origin and that oral sepsis is responsible for its origin in most cases. "Mild sepsis leads to gastritis and hyperchlorhydria, which in its turn provokes and keeps up ulceration" (A. W. Mayo Robson, in "Keen's Surgery," vol. iii). Some observers blame direct damage to the mucous membrane by traumatism or the swallowing of corrosive liquid. The question of cause is involved in uncertainty. What does seem to be certain is that anemia predisposes to the formation of very acid gastric juice (*hyperchlorhydria*) and to ulceration. In some cases chlorosis is associated with ulcer.

Ulcers are far more common in females than in males, and are more frequent in young women than in those of middle or advanced age. The acute round ulcer is vastly more common in women. The chronic indurated ulcer is most frequent in men. Men about forty and women between twenty and thirty are particularly liable. There is usually a single ulcer, but in one fifth of all cases there are two or more, and when there is an ulcer on the anterior wall, it is not uncommon to find one exactly opposite on the posterior wall ("a kissing ulcer" Moynihan calls it). The Mayos divide ulcers into two clinical forms—the *indurated* and the *non-indurated*. In the indurated ulcer all the coats of the stomach are involved and the mass of scar tissue indicates

an effort at repair. The most common situation for this form of ulcer is the region of the pylorus (Wm. J. Mayo, in "Jour. Am. Med. Assoc.," Oct. 21, 1905). The non-indurated ulcer involves the mucous coat only and may be of microscopic size, and even a microscopic ulcer may cause death from hemorrhage (Wm. J. Mayo). These non-indurated ulcers exhibit no sign, or almost no sign, on the outer surface of the stomach, and may not be detected even when the stomach is opened by the surgeon. The non-indurated ulcers are divided into the *mucous erosions* of Dieulafoy, in which the superficial epithelium only is involved, and the true round fissured *peptic ulcers* (Wm. J. Mayo, in "Jour. Am. Med. Assoc.," Oct. 21, 1905). Both conditions are rare. Ulcers are also divided into *acute ulcers*, which progress rapidly and produce definite symptoms, and *chronic ulcers*, which are usually chronic from the beginning, but which may exhibit acute exacerbations, and may have periods of great relief or apparent cure (Wm. J. Mayo, in "Med. Record," August 6, 1904). The most common seats of ulcers are the posterior wall and lesser curvature, especially in the pyloric region; in fact, 80 per cent. occur in the pyloric region. An ulcer may heal or may perforate. Only 2 per cent. of ulcers on the posterior wall perforate, as they tend to form adhesions to adjacent structures (Alderson). Ulcers on the anterior wall are unusual, do not tend to form adhesions, and are apt to perforate. It is not uncommon to have ulcer of the first portion of the duodenum associated with gastric ulcer. Gastric ulcer is at least four times as frequent in England as in the United States. In 2830 autopsies made in the Philadelphia Hospital there were 40 gastric ulcers, and in 3763 autopsies made in four Philadelphia institutions there were 51 gastric ulcers—a percentage of 1.35 (see A. P. Francine, in "Proceedings Phila. Co. Med. Soc.," March 31, 1905).

Symptoms.—In an acute ulcer the symptoms are often typical; there are pain, tenderness on pressure, slight or distinct unilateral muscular rigidity, vomiting, hemorrhage, and hyperchlorhydria. In a chronic ulcer the symptoms may be clear, may be misleading, may be variable, and in some cases even absent (*latent ulcer*). In ulcer dyspepsia usually exists. It is usually but not always acid dyspepsia and is associated with much flatulence. In most cases, though not in all, food aggravates the condition. There is a gnawing sensation (*hunger pain*) when the stomach is empty, and may be actual pain. The taking of food may temporarily relieve pain, while as quantities of gastric juice are poured out to digest the food the pain increases. If hyperchlorhydria disappears (as it may do from chronic gastritis and does do from gastric dilatation following pyloric obstruction), pain may not be increased during digestion. In ulcer of the cardiac and lesser curvature gnawing uneasiness is but briefly or not at all relieved by taking food and pain develops immediately or almost at once. In ulcer of the pyloric region the gnawing uneasiness may be distinctly relieved by taking food, but in two or three hours pain is apt to become severe. In ulcer the pain is paroxysmal. It is at times very violent in the epigastric region, and also passes to the back, being located between the eighth and ninth dorsal vertebrae.

In gastric ulcer it is usual to find distinct or severe tenderness developed by epigastric pressure, and tenderness is associated with more or less rigidity. In ulcers of the anterior wall tenderness is most acute. In many of these patients vomiting occurs about two hours after eating. The vomited matter, as a rule,

contains much hydrochloric acid. Vomiting often relieves of the gastric contents after the administration of a test meal in 80 per cent. of the cases hyperacidity. Obvious hemorrhage occurs in less than one-half of the cases, and from 3 to 10 per cent. actually die of hemorrhage. Wm. J. Mayo states that "most of hemorrhages from the stomach are from chronic ulcer with ulcer history" ("Surg., Gynec., and Obstet.," May, 1908). Blood is brought up with food, and is then black and clotted, or may be in large amount. Blood may be present in vomited material in such small amount that its presence is observed only by the demonstration in the feces of minute quantities of blood, which is important diagnostically. It may be demonstrated by the guaiac test. For two days before this test the patient must eat sausages, or fish. Blood in the stools does not prove the presence of ulcer. It may come from any spot from the mouth to the anus. Mayo says ("Surg., Gynec., and Obstet.," May, 1908): "The presence of blood in the stool affords proof as to the fact that there is a hemorrhage, but never be lost sight of that it bears with it no evidence as to the intestinal origin. The patient may have bleeding gums or some slight abrasion in any part of the many feet of mucous membrane exist between the lips and the anus. If occult blood is found by the test, it must be corroborated by others, as some unsuspected sources may give rise to the reaction."

"As a matter of fact, hemorrhage from ulcer is by no means a frequent occurrence. The base of the ulcer is clean and free from debris, so that bleeding may be infrequent. Careful examination of the stools for several days may be necessary to detect its presence."

In hemorrhage from an acute ulcer a pint or two may be vomited, and such a patient presents all the general symptoms of hemorrhage. In some cases blood from the stomach is passed in the stool in part or wholly. A very large hemorrhage may occur, and may never be repeated, or a large hemorrhage may be followed by several others, the first of three or of a series. In a great many cases after the first hemorrhage there is no further bleeding or there are subsequently only small hemorrhages. Small hemorrhages may occur indefinitely, and eventually in a large hemorrhage. In chronic ulcer in which hemorrhages recur over a long period the condition is due to the erosion of the mucosa or to the erosion of small vessels which retract because they are imbedded in fibrous tissue. A large hemorrhage may be due to the erosion of a large vessel, but is often due to the existence of a great number of erosions of the mucous membrane, perhaps so numerous that blood seems to pour from every part of the surface. It is usually stated that in a sudden acute violent hemorrhage there will probably be no history of antecedent stomach trouble. It is of the opinion that "a single hemorrhage from a patient with no previous gastric symptoms is probably not due to ulcer" ("Surg., Gynec., and Obstet.," May, 1908). It may arise from rupture of veins in the stomach or from blood from hemoptysis being swallowed.

In a chronic ulcer it is sometimes, though seldom, possible to palpate the indurated area.

Constipation generally exists. There is usually very marked anemia aggravated and, some think, occasionally caused by continued loss of blood. Indigestion aggravates anemia and also may cause it. There is loss of weight. There is often a tender area in the back a little to the left of the ninth and tenth dorsal spines. A triangular area of hyperesthesia is often found in the left epigastric region (Head).

If the ulcer does not cicatrize, but progresses, causing pain and hemorrhage, the patient becomes thinner, more anemic, weak, and even exhausted.

It is certain that many cases of gastric ulcer are unrecognized; in fact, as Habershon says, diagnosis is rarely made unless hemorrhage exists, and in certain latent cases both vomiting and bleeding are absent. It is believed by some that latent ulcers are even more common than are ulcers causing symptoms. Hall ("Am. Jour. of Med. Sciences," May, 1900) says: "Rather than look too narrowly for exactly this or that evidence, we should take the broader ground that ulcer probably exists in most patients complaining of persistent indigestion, even though not of an acid character, if pain, tenderness, vomiting, and rigidity, or two or three of these phenomena be present, and even though hyperacidity be not proved."

A gastric ulcer may cicatrize and thus be cured, but the cure of the ulcer may prove the ruin of the stomach by producing stenosis of one of the stomach orifices or hour glass contraction of the body of the stomach. An ulcer may perforate and does so in about 15 per cent. of cases (Robson). A *perforation* may be *acute*; that is, the ulcer suddenly breaks open when the stomach contains food or liquid, and the contents of the stomach are poured into the free peritoneal cavity. A *subacute* perforation occurs when the stomach is empty or nearly empty. The opening is small in size, there is no escape of stomach-contents or the escape of only a small amount, and the opening may be quickly closed by adhesions to an adjacent surface of peritoneum or a piece of omentum. If a certain amount of stomach-contents is extravasated, it is usually surrounded by adhesions or tracks slowly toward the pelvis. In what is known as a *chronic* perforation the break takes place usually in the posterior wall into a box of preformed adhesions, the extruded gastric contents are circumscribed by these adhesions, the general peritoneal cavity is not invaded, but circumscribed suppuration is inaugurated.* This condition is known as *perigastric abscess*, and the subphrenic form is the commonest. In such a case the abscess may break into the pleural cavity or even into the lung. I recently operated on a girl of sixteen and found a perigastric abscess and a perforation of the anterior wall near the pylorus, and this condition was tuberculous. A fistula persisted for months, but finally healed.

Perforation is usually brought about by muscular effort and is most common after a full meal. The real cause is spasm of the pylorus which causes tension of the stomach walls and keeps the viscus from emptying. Pyloric spasm is very common in sufferers from ulcer. In acute perforation food is the most active cause, in chronic perforation, muscular effort. "The severity of the symptoms depends upon several conditions: the previous state of health, the size and number of the perforations, the condition of the stomach, whether full or

* See paper by B. G. A. Moynihan, Brit. Med. Jour., Jan. 31, 1903.

almost empty, the bacterial virulence of its contents, vomiting."* The situation of the ulcer has some influence. "If in the fundus, at the cardiac end, or in the body of the stomach, infection of the whole peritoneal cavity rapidly follows; if at the pylorus or in the first portion of the duodenum, the inflammation is confined to the right side of the abdomen, owing to the hillock of the mesocolon at the pyloric end of the stomach" (Moynihan, *Brit. Med. Jour.*, Jan. 31, 1903). In such a case the fluid may gravitate to the right iliac region and the condition may be mistaken for appendicitis. In subacute gastric perforation I operated, believing that it was a simple ulcer. Alderson calls attention to the fact that the sudden collapse may be mistaken for poisoning, and he cites the death of Orleans, in 1670.

Acute perforation can usually be certainly diagnosed early. Such an emergency has usually, but not invariably, been preceded by positive and prolonged symptoms of gastric disorder, and violent epigastric pain, greatly increased by swallowing, and by pressure. This pain may radiate through the abdomen. The chief tenderness is in the region of the stomach, and after perforation does not of necessity correspond to the site of the ulcer. The collapse is usually profound. In some cases death occurs before rupture, but, as a rule, reaction occurs and peritonitis develops. Rupture. When it does occur, it does much harm by ejecting gastric contents into the peritoneal cavity. This is very unusual. Board-like rigidity exists, and it is confined to the upper portion of the abdomen. The area of liver-dulness is diminished or obliterated. If a patient with acute perforation is operated upon, he will soon exhibit the symptoms of peritonitis. Subacute perforation causes less violent symptoms and is usually preceded by a long history of gastric disorder. There is in the beginning severe but not prolonged pain, which gradually abates. Moynihan points out that there may be several days before the perforation. Peritonitis develops. Gibbon says, the chief symptoms are often pelvic. Cullen says, the signs and symptoms of perigastric abscess.

Treatment.—Medical Treatment of Non-perforated Ulcer.

It is necessary to abandon stomach feeding for a time. Give nothing whatever by the mouth and give an enema of salt solution every six hours. This is preferable to a nutritive enema. Every time a nutritive enema is given a flow of gastric juice is secreted from the stomach (see W. Pasteur, in "*Lancet*," May 21, 1904; and W. Moynihan, in "*Lancet*," Nov. 10, 1906). During this treatment the patient is comfortable and is not unbearably disturbed by hunger. At the end of a week or ten days pancreatinized or peptonized milk may be given by the mouth, or else nutritive enemata are substituted. When the patient is given for a few days before stomach feeding is resumed, the feeding has been abandoned the patient is placed on a diet of easily digestible pancreatinized milk, and lavage is given twice a day.

* Moynihan, in *Brit. Med. Jour.*, Jan. 31, 1903.

Carlsbad salts are given (Ziemssen); to others silver nitrate, bismuth subnitrate, or oxalate of cerium. If pain is severe, opium may be required. Many cases are apparently cured by medical treatment. Russell's statistics show that 40 per cent. of cases were reported cured under medical treatment, but no one knows how many of those reported cured again gave evidence of the disease or later perished of hemorrhage or perforation. Further, 18 per cent. of the 500 London Hospital cases under medical treatment died.

Surgical.—Following the Mayos, we would not advise surgical treatment in acute ulcers unless complicated by hemorrhage, perforation, or obstruction; or in chronic ulcer, until careful medical treatment has failed. Operation is indicated for chronic ulcer when a mechanical cause is responsible for retention and stagnation of stomach contents, and in certain cases of hemorrhage. Operation is also indicated in chronic ulcer with frequent exacerbations, but the surgeon must be very chary of operating upon neurotic women with gastropexia, unless, of course, there is a positive indication (Wm. J. Mayo, in "Jour. Am. Med. Assoc.," Oct. 21, 1905).

In a chronic ulcer if the patient grows worse in spite of careful dietetic and medical treatment, if hemorrhage has been profuse or if there have been frequent distinct hemorrhages, if the pain is violent, or if tenderness is marked, open the abdomen and inspect the stomach. An ulcer with indurated edges is easily found. The form, called by the Mayos the non-indurated ulcer, gives no evidence or little evidence of its existence when the outer coat of the stomach is felt and inspected (Wm. J. Mayo, in "Jour. Am. Med. Assoc.," Oct. 21, 1905). Even when the stomach is opened, no ulcer may be found. According to Mikulicz, in some mucous ulcers there is a very little thickening, and, according to Moynihan, the mucous coat may be a little adherent to the muscular coat, so that it does not slide easily. An enlarged gland in a portion of the omentum may be a sign of ulcer (Lund). An indurated ulcer may be removed by an elliptical incision in the long axis of the stomach, the coats being sutured by the usual method, and gastro-enterostomy being also performed. In some cases gastro-enterostomy alone leads to the cure of chronic ulcer. The Heineke-Mikulicz operation is not satisfactory in ulcer. Finney's gastro-duodenostomy is not advisable if there is an unhealed ulcer, because food still passes over the ulcer after its performance (Wm. J. Mayo).

Operation for Gastrorrhagia (Hemorrhage from the Stomach).—Rydygier proposed in 1882 to operate for hemorrhage. The first operation was done by Mikulicz in 1887, and the first successful operation was reported by Roux in 1893.

In an acute and violent hemorrhage threatening life the proper course to pursue is somewhat uncertain. It is not proper to operate if there has been but one hemorrhage, because the chances are that the bleeding will not be repeated. Again, the chance of arresting such a hemorrhage by operation is, on the whole, poor. The danger of waiting after one hemorrhage is not so great as the danger of immediately operating, because collapse antagonizes renewed hemorrhage, but adds enormously to the risk of an operation. In over 90 per cent. of cases the hemorrhage ceases spontaneously. In over 18 per cent. of those dying of hemorrhage death is so rapid that operation is impossible (Savariaud). If the bleeding is from a distinct ulcer, we may succeed in excising the ulcer or in ligating the bleeding point. Roux, of Lausanne,

saved a patient by excising an ulcer and ligating the blood vessels on each side of it. As a rule, however, the bleeding is not fatal but from a multitude of excoriations. In the light of this we may lay down the following rule. Do not operate for ulcer. Simply bring about reaction by gentle means, let the patient give suprarenal extract by the stomach. If the bleeding is in comparatively trivial amounts, do not operate, but if it is severe, advise operation. In cases of ulcer in which bleeding persists, operation is indicated. In operating for a severe ulcer, the surgeon opens the abdomen while hot salt solution is being given. The stomach is opened, the clots washed out, and a search is made for the source of the blood. If it is found that the blood comes from an area which may be extirpated, ligated, or cauterized with the cautery, advise surrounding it with a purse-string suture. Otherwise, simply perform gastro-enterostomy, which is of service in giving rest to the dilated stomach, the hemorrhage being prevented by the tension of the gastric walls and the rest secured by the formation of a hemostatic clot. Gastro-enterostomy is of most service in pyloric and in duodenal ulcer. If the ulcer is well above the pylorus, it may be excised if possible. As a rule, it will be found that the vessels of the ulcer are varicose. Excision is indicated because otherwise excision is impossible "the main blood vessels leading to the ulcer are ligated and the peritoneum and muscular coats drawn up over the ulcer" (in "Surg., Gynec., and Obstet.," May, 1908). If it is found that the bleeding comes from a multitude of excoriations and that the patient is in a condition which expresses it, "weeping blood," we can do nothing but gastro-enterostomy, which in such a condition is of uncertain value.

Operation for Perforation.—In acute and subacute perforation, having all proper means taken to bring about reaction, the abdomen is being sterilized and while either intravenous saline enemata, external heat, atropin hypodermatic, or any of these, is advised to wait until reaction was established before operating, I do not believe such advice erroneous. To delay after an acute perforation for what may never come. Open the abdomen at the point of tenderness, or, if there is no such point, open it in the middle of the right side to the right of the midline. When the abdomen is opened, look for an escape of odorless gas, and food or fluid may be seen escaping into the peritoneal cavity. The perforation is sought for and found in the anterior wall. When found, it should be buried in the wall, a portion of which must be inverted by two layers. I do not believe that excision or paring the edges is indicated in a case of perforated ulcer. If no perforation is found, make an opening into the lesser peritoneal cavity (between the stomach and omentum), explore the posterior wall, and close and suture. In addition to closing the perforation, gastro-enterostomy is usually indicated in order to drain the viscous, give it rest, and prevent recurrence of ulceration. But, as a matter of fact, the patient is usually too severely shocked to require operation justifiable, and I agree with Gibbon that such

performed only when there are multiple ulcers or when there is pyloric constriction (John H. Gibbon, in paper before the Tri-State Med. Assoc. of Virginia and the Carolinas, Feb. 23-24, 1904). After closing the perforation the abdominal cavity is irrigated with hot salt solution and the space between the liver and diaphragm is sponged out with a gauze pad wet with hot salt solution. If the case is operated many hours after the perforation, or if the peritoneum was badly soiled, drainage *must* be used, but even in other cases it is safest to use it. Drainage is obtained by means of a strand of iodoform gauze passed to the suture line in the stomach. In cases with much extravasation, especially if the extravasation has reached the pelvis, a suprapubic opening is made and a tube inserted. After the patient has reacted from the shock of the operation he should be placed in a semi-erect position to direct the flow of infective material to the pelvis, and continuous proctoclysis should be employed as in peritonitis (page 1006). The treatment of chronic perforation is the treatment of perigastric abscess, and consists of incision and drainage. Of late, a number of cases of acute and subacute perforation have been successfully operated upon. Moynihan estimates that 35-40 per cent. of acute perforations recover after operation. T. Crisp English ("Lancet," Nov. 28, 1903) reported 42 consecutive gastric perforations operated on in St. George's Hospital. Twenty-two recovered.

Cicatricial stenosis of the orifices of the stomach results from the healing of an ulcer, the swallowing of a corrosive substance, or traumatism from a foreign body. Constriction of the *cardiac orifice* is indicated by gradually increasing difficulty in swallowing. After a time the esophagus above the stricture dilates or pouches; the fluid food passes into the stomach, but the solid food lodges in the esophageal pouch and is soon regurgitated. The site of the stricture is located by a bougie, and by having the patient swallow while auscultating over the esophagus and cardiac end of the stomach. If the constriction be malignant, the patient will be found to be beyond middle life, the vomit is occasionally bloody, emaciation is rapid and decided, and occasionally the supraclavicular glands are enlarged. A tumor of the cardiac end of the stomach can seldom be palpated. If the constriction be cicatricial, the history will indicate the cause. Constriction of the *pyloric orifice* causes retention of food and dilatation of the stomach. Dyspeptic symptoms will be found to have been long present. A tube passed into the stomach permits of the injection of fluid so as to fill the stomach. When the fluid runs out, it contains portions of undigested food, which was perhaps eaten days before, and measurement of the liquid shows that the capacity of the stomach is enormously increased. If hydrogen be forced through the tube, the outline of the distended stomach is at once made clear. The usual method of distending the stomach is by a Seidlitz powder: two solutions are made; the bicarbonate solution is swallowed at once, and the tartaric solution is taken afterward in small amounts at a time. Percussion over the distended stomach indicates the size of the viscus. It is well to remember that dilatation of the stomach can occur without cicatricial stenosis when gastric ulcer exists. The cause in such a case is pyloric spasm or perhaps the atonic condition which may result from anemia and neurasthenia.

In malignant disease of the pylorus a tumor may often be palpated; there

that the vomited matter in congenital stenosis of the pylorus never contains any bile whatever, for obvious reasons—the pylorus is shut and the bile cannot enter the stomach. A child in this condition receives little or no nourishment, becomes quickly emaciated, and soon dies. Some of these children die in a month; others, in several months; and a few may live for five or six months. It may be possible, in these cases, to palpate a thickened pylorus; and the outlines of the dilated stomach can probably be made out. The most common symptom is gastric peristalsis. In Bunts' table gastric peristalsis was present in 84 per cent., and tumor in 69 per cent. of cases. The intestines are very much collapsed, and the child is, of course, very much constipated. Cases have recovered after lavage carried out daily for some weeks and careful breast feeding. A trial should be given this method unless the condition of the patient demands immediate relief. The delay in employing surgery in hopes of lavage succeeding must never be so long that the patient emaciates. If his condition does not soon show signs of improvement, operation is indicated. Some of the cases reported cured by medical means may have been instances of pyloric spasm. The operation for this condition is usually gastro-enterostomy. The mortality after the operation is apparently over 50 per cent. It is superior to pyloroplasty because it enables us to at once feed the exhausted child.

Perigastric Adhesions.—That perigastric adhesions are frequently responsible for stomach pain and digestive difficulty is undoubted. Such adhesions often arise in cases of protracted ulceration of the stomach or duodenum. A common cause of perigastric adhesions is gall-stone disease. Tuberculous peritonitis causes dense adhesions. In some cases the adhesions are traumatic, in some they are due to syphilis, in many the cause is uncertain (Fred. D. Bird, "Intercolonial Med. Jour. of Australasia," Dec. 20, 1900). Adhesions may cause blocking or kinking of the pylorus, or may glue the stomach to the parietal peritoneum or to some adjacent viscus. In Fenwick's table of 123 cases he finds that the adhesions usually cause the stomach to adhere to the pancreas or to the liver. The formation of adhesions in cases of gastric ulcer is, in many instances, conservative, serving to prevent perforation or to limit extravasation if perforation of the stomach-wall occurs.

Symptoms.—The symptoms are variable. In some cases the adhesions produce little or no trouble; but in the majority of cases they cause definite symptoms, and sometimes the condition becomes one of absolute disablement. The symptoms may be due to blocking of the pylorus, a condition that is followed by gastric dilatation. They may be due to dragging upon the adhesions, when the stomach contracts during digestion, or when peristalsis occurs in an adherent piece of intestine.

The usual symptom is pain, frequently of a violent character. The pain comes on in paroxysms, and recurs over and over again, it may be during years. H. Hale White* points out that in these cases there is usually some pain persisting which is now and then increased into violent paroxysms; and that the only other condition that produces persistent pain with violent exacerbations is cancer. In *adhesion-dyspepsia*, however, there is no distinct loss of weight; the condition may exist in youth, as well as in middle age or old age; it is

* Lancet, Nov. 30, 1901

not increased by taking food; and it very rarely can a history of antecedent gall-stone disease or of ulcer be possible to make the diagnosis without exploratory operation. In cases the condition may sometimes be diagnosed by the presence of these attacks of violent pain, there is no tenderness, the adhering and matting together with inflammatory products a palpable mass. In doubtful cases of chronic and dilated stomach an exploratory operation should be performed, if adhesions then become manifest.

Treatment.—In some cases simply dividing an adhesion, in other cases it is necessary to make extensive separations, covering the raw surface with omental grafts. In cases about the pylorus gastro-enterostomy is usually the procedure.

Bilocular Stomach (Hour-glass Stomach).—

In some cases are congenital, but the writings of Mayo Robt. L. Patterson cause us to gravely doubt if it is ever congenital. In called congenital cases ulcers are found, or ulcer scars (scars) are demonstrable. The advocates of a congenital origin say they are secondary to the narrowing, and that ulceration tends to be at the seat of constriction. Beyond doubt, a very great number of cases of bilocular stomach result from adhesions produced by an ulcer. In hour-glass stomach with a large opening between the pouches may be no symptoms. When the opening is small, it resembles those of pyloric stenosis. The sac toward the cardia is dilated.

Symptoms.—The diagnosis of cancer is often difficult. If gastritis may have caused free hydrochloric acid and if of fermentation are usually found. The patient vomits bringing up food which was eaten a day or two before, retained in the stomach and not digested. Occasional vomiting. There is pain and the patient is harassed by eructations. Emaciation is pronounced. Cumston says that if belly distention of the stomach may make the condition that if water is thrown into the stomach, only a part of the stomach is emptied as much as possible by a tube, a splint is elicited in the stomach because the pyloric pouch is not dilated. Death is torsion on the axis.*

Treatment.—The diagnosis becomes certain only by operation, and exploration also enables the surgeon to decide to what operation should be performed. Cumston suggests:

1. In rare cases resect the stricture and suture the ends.
2. If there is trivial ulceration or a slight scar, do gastro-enterostomy upon the constriction exactly similar to pyloroplasty.
3. The best operation in most cases is gastrogastrostomy, i.e., anastomosis of the cardiac pouch to the pyloric pouch, if the pyloric pouch is small. Then do gastro-enterostomy.

* Cumston, in Med. News, Dec. 1902.

Other operations are:

4. Gastroduodenostomy.
5. Gastrojejunostomy.
6. Gastrolisis.*

In malignant disease resection (partial gastrectomy) is indicated. After gastropasty recontraction is common, but I do not believe in the operation. Gastro-enterostomy is unsatisfactory. The ordinary operation drains but one pouch. Weir and Foote advised a double gastro-enterostomy, tapping each sac. In most cases gastrogastrostomy followed by gastro-enterostomy is the best procedure.

Chronic Dilatation of the Stomach.—A dilated stomach, roughly speaking, is one which can contain more than 1.5 quarts (Ewald). Some few cases of dilatation result directly from atrophy of the muscular coat, brought about by drinking quantities of liquid, especially beer; chronic catarrh of the stomach; and conditions such as cancer, tuberculosis, diabetes, etc. The common cause of dilatation is constriction of the pylorus. In order to force food by the pyloric narrowing more force is necessary than is required in a normal state of affairs and the stomach muscle hypertrophies. This muscular hypertrophy is compensatory, and dilatation does not occur so long as the muscle is efficient. But finally the pyloric opening becomes so narrow that compensation fails, the stomach-contents accumulate, and the stomach dilates.

Symptoms of Dilated Stomach.—There is annoying hunger unless cancer exists. Thirst is complained of. At intervals of a day or two the patient vomits enormous quantities, and portions of food may be identified which were eaten several days before. The vomited matter is sour and foul-smelling, contains numbers of yeasts and much fermentative acid. Free hydrochloric acid is often absent. In some cases vomiting occurs two or three hours after each meal. The patient suffers from foul gaseous eructations. There are progressive emaciation, constipation, scantiness of urine; sometimes cramp in the legs, belly, and arms; tetany may occur; insomnia is the rule; cardiac palpitation occurs, and there is dyspnea, particularly at night.

Physical Signs of Dilated Stomach.—The epigastric region is hollow and the left side of the abdomen is more prominent than the right. The outline of the greater curvature of the stomach can be distinguished. If the stomach contains air, percussion gives a tympanitic note; if it contains fluid, a dull note. When it is partly full of fluid, by altering the position of the patient we can show by percussion that the fluid changes its position. In a doubtful case give a light meal in the evening, and in the morning, before the patient has eaten, introduce a tube and remove any material contained in the stomach. The presence of undigested food points to dilatation.

To Test the Motor Power of the Stomach.—*Klemperer's Test.* Wash out the stomach. Introduce 100 c.c. of olive oil by means of the tube. After two hours withdraw the oil. The stomach cannot absorb oil, and if the amount withdrawn is subtracted from the amount introduced, the difference is the amount which passed the pylorus. If the condition is normal, not more than from 20 to 40 c.c. should be found in the stomach after two hours.

* Med. News, Dec. 7, 1902.

The Salol Test of Ewald.—Salol is not decomposed in the intestine is broken up into phenol and salicylic acid, absorbed and salicyluric acid soon appears in the urine. If the intestine, salicyluric acid will not appear in the urine, the intestine more slowly than normal, salicyluric acid a longer interval than when there is no pyloric block to re of the stomach. In a normal person salicyluric acid is in from three-fourths of an hour to an hour after swallow. In stenosis of the pylorus it appears much later. The test The bladder is emptied and the patient is given three containing 5 gr. of salol. The patient is directed to pass water until he has done so four times. Each sample voided is cyluric acid by adding neutral chlorid of iron. If salicyluric a violet color is noted.

To Test the Absorptive Power of the Stomach.—The power of the stomach can be tested by giving the patient a 15 gr. of iodid of potassium. Normally the drug should appear in saliva in from ten to fifteen minutes. When absorption is not appear for an hour or longer. In order to test for it, mix with the saliva and touch the moist paper with a drop of If iodine is present, a blue color develops.

While the diagnosis of dilatation of the stomach can be the determination of the cause may require an exploratory

Treatment.—Cases not due to pyloric obstruction are treated by lavage, regulated diet, use of an abdominal belt, etc., and other agents called for by symptoms.

In all cases where there is pyloric obstruction, in many and in cases in which medical treatment fails, exploratory is indicated. In dilatation without pyloric obstruction some gastroplasty. If pyloric obstruction exists, the surgeon pyloroplasty, pyloroplasty, or gastro-enterostomy, the depending on the condition discovered. If gastroptosis exists, Beyer's operation may be performed.

Acute Dilatation of the Stomach.* This condition occurs in the course of chronic dilatation or when no previous dilatation. Its clinical features were described by Brinton in 1859. He furnished us with the first comprehensive description of the condition. The cause is uncertain, and is a subject of active investigation at the present time. It is said to be due to degeneration of the stomach in the course of specific fevers, to paresis arising in the course of shock and to the drinking of a quantity of effervescent liquid. It is a fatal sequence of abdominal operations, particularly operations on the bladder and bile ducts. The surgeon sees it in the course of shock from operations in which a general anesthetic was used and in cases of spinal curvature.

One set of observers maintains that the condition is brought about by constriction of the duodenum, the constricting cause being

* See Kelling, in *Archiv f. klin. chir.*, 1901, lxiiv, Albrecht, in *ibid.*, 1890, clvi; Conner, in *Am. Jour. Med. Sciences*, March, 1907.

mesentery and the superior mesenteric artery and the duodenum being squeezed against the vertebral column (Rokitansky, Albrecht, Robinson, and Kundrat). Codman believes that normally in man there is more or less tendency to such constriction on standing erect or lying down and that a trivial increase of the constriction which may be brought about by various causes may completely obstruct the duodenum ("Boston Med. and Surg. Jour.," 1908). Conner collected 18 fatal cases shown by necropsy to be due to mesenteric obstruction (Lewis A. Conner, in "Am. Jour. Med. Sciences," March, 1907).

Another set of observers assert that acute dilatation is due to lesion of the nerve trunks or nerve centers, resulting in paresis of the muscle of the stomach wall and spasm of the pylorus. The cause of the nerve lesion is variously held to be hyperacidity of gastric secretion, the absorption of the toxins of fermentation, the secretion of chloroform into the stomach, the overdistention of the viscus with ether vapor, and the enormously great secretion of fluid into the stomach.

As Conner says (*Ibid.*), the theory of pyloric spasm being causative is untenable because in most cases vomited matter contains bile and in two-thirds of the cases the duodenum is certainly involved in dilatation.

It seems certain that some cases of gastric dilatation are associated with mesenteric constriction of the duodenum, brought about by the intestines descending into the pelvis. The constriction inaugurates the dilatation and is aggravated by the dilatation. Conner points out that the intestines enter the pelvis as a result of dorsal decubitus, a long mesentery, and a gut nearly empty of gas and feces, and is favored by relaxation of the belly wall ("Jour. Am. Med. Assoc.," March, 1907).

Symptoms.—The most frequent and prominent is violent vomiting, usually inaugurating the symptoms and continuing throughout the illness, although occasionally it ceases for some time before death. The amounts vomited are large and often enormous. The vomitus is thin and of a green or black hue, usually contains bile and sometimes a little blood, but very seldom feces.

In most cases, but not in all, there is epigastric or umbilical pain and tenderness. Distention is the rule. Rigidity is rare. In many cases there is no passage of gas or feces, but in some diarrhea exists. There is great thirst, there may be hiccup, and delirium may arise before death. The temperature is nearly always normal or below normal. There is seldom visible gastric peristalsis (Conner, *Ibid.*), and splashing sounds are obtainable over the stomach.

Collapse arises early and quickly becomes profound. Tetany occasionally occurs. A case of my own died of acute gastric dilatation after an operation for stone in the kidney. He suddenly developed attacks of violent and profuse vomiting, rapidly went into collapse, lividity developed and hiccup arose, and he died in forty-eight hours.

A case may die in less than twenty-four hours or may die after ten days or more. Conner's group of cases show a mortality of 72.5 per cent. Fluid cannot reach the small intestine, and as none is absorbed from the stomach and little from the duodenum, the tissues starve for the want of it (Laffer, in "Annals of Surgery," April, 1908). The condition is frequently diagnosed acute intestinal obstruction or peritonitis from perforation.

Treatment.—When the stomach has dilated greatly and when collapse is profound, treatment is usually of no avail. When an early diagnosis is made treatment is often of the greatest value. The stomach must be at once emptied by the use of a tube and the treatment be repeated at intervals of a few hours. Neither food nor drink should be given by the mouth. Saline enemata and perhaps nutritive and stimulating enemata should be given. The patient should at once be placed upon the belly and kept there until the condition abates, in the hope that this posture will relieve duodenal constriction.

Gastro-enterostomy has been employed, and is advocated by Mayo Robson. Byron Robinson had a successful case. I would be disposed to employ it in spite of the reported failures. In a number of cases the stomach has been opened and washed out without benefit. Petit opened the abdomen and discovering a kink at the junction of the duodenum and jejunum, he raised the jejunum and sutured it to the transverse colon and the patient recovered (Conner, *Ibid.*).

Not until we know definitely the cause or causes of acute dilatation of the stomach will we be able to lay down with precision and accuracy the treatment which is indicated. There is much difference of opinion as to the causation of the condition and widely different methods of treatment are advocated by various surgeons.

Gastroptosis.—In this condition the stomach has undergone displacement downward, the greater curvature in many cases being but little above the pubic symphysis and the lesser curvature being between the ensiform cartilage and the umbilicus. This condition is far more common in women than in men, and is especially common in women who have had many children. It may be produced by tight lacing and may follow mobility of the right kidney, of the liver, or of the spleen. It is often associated with enteroptosis and is particularly prone to arise in the anemic and tuberculous.

Symptoms.—There may be no symptoms for a long time, but sooner or later dyspepsia arises because the stomach cannot empty itself. The stomach becomes atonic, its secretions are scanty and altered, and while the viscus may be normal in size or even shrunken, it is usually dilated. The malposition can be made out by percussion when the stomach is distended with air or with fluid.

And by the x rays after the patient has drunk a pint of a solution of mucilage of acacia containing subnitrate of bismuth. The bismuth lines the stomach and intercepts the x-rays and a radiograph shows the outlines of the stomach and hence its size and position. The pylorus descends to the umbilical region, which it does not do in dilatation. In dilatation the pylorus is but slightly lower than normal, but the lower border of the stomach is notably depressed.

When a patient with gastroptosis stands erect the bulging is most prominent in the region of the umbilicus and the epigastrium is deepened.

Gastroptosis is not infrequently associated with chlorosis.

Treatment. Lavage, regulation of diet, improvement of the general health, and the wearing of an abdominal binder. If medical treatment fails and the condition is producing grave impairment of the general health, it may be necessary to perform a surgical operation. Gastro-enterostomy is advocated by some on the ground that the unpleasant symptoms result from stag-

nation of gastric contents. Good results have been reported by this plan. The operation of Depage is unphilosophical. Duret's operation is objectionable (page 1090). Beyea's operation is usually preferred (page 1091).

Intestinal Obstruction (Ileus or Enterostenosis).—Intestinal obstruction is a condition in which fecal movement is mechanically impeded or prevented. It may be either *partial* or *complete*. *Acute obstruction* is due to a sudden narrowing or occlusion of the lumen of a portion of the intestine. *Chronic obstruction* is due to a gradual narrowing of the lumen of a portion of the intestine, and it may at any time become acute. If obstruction to circulation in the wall of the bowel occurs, the condition becomes one of strangulation. In acute obstruction the stagnated intestinal contents become charged with powerful poisons which act most harmfully on the musculature of the intestinal wall, and, after absorption, attack the heart and nervous system. The inaugural shock is due to the production of the block, the later increasing depression is due to absorption of poisons. Gas forms in great amount in the intestine and produces distention. Distention impairs the circulation in the wall of the intestine and embarrasses respiration by pushing up the diaphragm. Intestinal obstructions are classified* as follows.

1. *Strangulation by bands or in apertures*, the commonest form, is due to peritoneal adhesions, but the band may come from the omentum. Strangulation by bands or in apertures usually involves the ileum and sometimes the colon. This form of obstruction is identical with hernia, except in the absence of an external protrusion. Obstruction may take place by *Meckel's diverticulum* (page 973), a structure due to persistence of the vitelline or omphalomesenteric duct, coming off from the ileum from 12 to 36 inches above the ileocecal valve, and present in about 2 per cent. of persons. The vitelline duct should be obliterated in the eighth week of fetal life. If it persists the individual possessing it is in constant and serious danger. The mortality of a series of cases of obstruction due to Meckel's diverticulum is enormous. A Meckel's diverticulum usually has no mesentery, is from 3 to 10 inches long, and arises from the convex side of the gut. It may hang free or may be attached to the umbilicus by its tip or by a fibrous cord formed by the obliterated tip. In some cases it remains open at the umbilicus (page 308). In other cases a cord runs from the umbilicus to the gut or the tip of the diverticulum or is adherent to another portion of the intestine. The diverticulum may become strangulated, may enter a hernial sac, may ulcerate or perforate like an appendix (W. Sheen, in "Bristol Medico-Chir. Jour.," Dec., 1901, gives an admirable account of "Some Surgical Aspects of Meckel's Diverticulum"; see also article on "Obstruction of the Bowels by Meckel's Diverticulum," by James E. Moore, in "Journals of Am. Med. Assoc.," Oct. 4, 1902, and on "Abdominal Crises Caused by Meckel's Diverticulum," by Miles F. Porter, in "Jour. of Am. Med. Assoc.," Sept. 23, 1905). Strangulation of the diverticulum may take place beneath an adherent appendix, a Fallopian tube, a portion of mesentery, or the pedicle of an ovarian tumor, or it may take place in an omental or a mesenteric aperture. Gangrene, inflammation, or twisting may occur. Obstruction may be due to invagination of the diverticulum into the bowel. H. Tyrrell Gray collected 39 cases of invagination and added one of his own, 40 in all ("Annals of Surgery," Dec., 1908). Gray shows that

* After Treves, in "Heath's Dictionary."

enteric axis or on the axis of the bowel itself, or two intestinal twisted together. Volvulus is commonest in the sigmoid flexure and may occur in a hernial sac.

3. *Intussusception* is the invagination of a portion of bowel into the lumen of an adjacent part of the gut. One-third of all cases of obstruction are due to this cause (Treves). Most cases of obstruction in childhood are due to intussusception. Pitt reports that in St. Thomas's Hospital, 1900 inclusive, there were 115 cases of intussusception, and 66 were under fifty years of age. Gibbon's patient was fifty eight. Morrison had a case due to polypus, and the patient was six years of age. Males are twice as liable as females. During the peristalsis a localized circular constriction forms and the invagination passes through the constricted area. The great relative frequency of intussusception in childhood is due to the greater mobility and irritability of the large bowel (Treves). The irregular and localized spasm is due to bulky material within the gut, and according to Rushmore ("Annals of Surgery," August, 1907) the starting point of invagination is obstruction. If peristalsis alone the cause the condition would be far more common than it is. The diarrhea of children. There are four chief varieties: the *ileo-cecal*, in which the ileum and the ileocecal valve pass into the cecum and colon; the *cecal*, in which the large intestine is prolapsed into itself; the *ileal*, in which the ileum alone is involved; and the *ileocolic*, in which the ileum prolapses into the ileocecal valve. Other forms are *diverticular* (with a diverticulum) (due to reversed peristalsis), *Merkel's diverticulum*, *ileo-appendiceal*. The first variety is vastly the most common. In Rushmore's table of "Annals of Surgery," August, 1907) the location was definitely stated in 140 of these were ileocecal and 31 were ileocolic.

4. *Stricture of the intestine*, which may be either cicatricial or congenital.

5. *Obstruction by Tumors of the Bowel and by Foreign Bodies*. Tumors may be innocent or malignant. Foreign bodies include, besides the natural contents of the gut, stones that have been swallowed, gall-stones and enteroliths or calculi. Foreign bodies are apt to lodge in the lower portion of the large intestine.

of mechanical obstruction by a large stone which entered the intestinal canal by ulceration, but that there are three other possible conditions, viz.: Local peritonitis in the gall-bladder region causing paralysis of the bowel; volvulus of the small intestine due to biliary colic or to ulceration of a gall stone into the gut; obstruction coming on "after the original cause has disappeared" and due to adhesions without or obstruction within the gut.

6. *Obstruction by tumors, etc., outside the bowel*, among the causes of which are retroflexion or retroversion of the womb, especially in pregnancy, cysts or tumors of the kidneys, ovaries, uterus, etc., movable kidney, and enlarged spleen. Obstruction from any of the above causes takes place in the rectum or the sigmoid flexure.

7. *Obstruction from fecal accumulation* is due to paresis or paralysis of the bowel and the diminution or abolition of peristalsis. Obstruction may follow an abdominal operation. Paresis or paralysis arises in the colon. Treves mentions among the rare forms of obstruction kinking of the bowel, adhesions matting the bowels together or compressing the gut, and shrinking of the mesentery.

In addition to the seven groups previously mentioned, we should consider *post-operative intestinal obstruction* and *obstruction from embolism or thrombosis of the mesenteric vessels*. Obstruction of the mesenteric vessels is liable to occur when the aorta is atheromatous, and usually causes gangrene of the intestine.

Symptoms of Acute Obstruction. Severe colic comes on suddenly, the pain varying in intensity, but at no time entirely ceasing. In a suddenly arising intraperitoneal accident, whether it be perforation, acute obstruction, or acute strangulation, there is at first shock, from which the patient usually reacts for a time. In obstruction there is constipation, which soon becomes absolute, not even gas being passed; vomiting is early—first of the contents of the stomach, next of bilious matter, and finally of feces (*stercoraceous vomiting*); the abdomen becomes distended and tender. After reaction from shock some fever may be noted, but in any unrelieved case collapse soon arises; the temperature becomes subnormal; the face, Hippocratic; the pulse, rapid and feeble. The amount of urine passed is very small. In obstruction of the upper third of the ileum true fecal vomiting cannot occur. If obstruction is high up in the small intestine, tympanites does not occur. The tongue is dry, the mind is clear, and muscular cramp may occur. Intestinal peristalsis above the obstruction may be detected through the abdominal wall. According to Elsberg gangrene occurs in only 13 per cent. of the cases. Tapping is more apt to cause pain than is pressure, in peritonitis pressure is more apt to cause pain than tapping (Battle). In intestinal obstruction (post-operative and primary) there is a leukocytosis of from 15,000 to 30,000 (Blood-good, in "Johns Hopkins Hospital Reports," vol. vii).

Symptoms of Chronic Obstruction.—At intervals there arise attacks of pain which become gradually more frequent and severe, and are linked with vomiting and constipation, the vomiting not being stercoraceous and the constipation not being absolute. Between the painful seizures the patient complains of constipation alternating with fluid diarrhea, distention of the belly, some abdominal uneasiness, anorexia, and dyspepsia. The attacks recur with increasing frequency and severity, and acute obstruction may arise or the patient may be worn out by pain, vomiting, and want of food.

with great distention of the umbilical region, means obstruction of the small intestine or the cecum. Distention of the entire abdomen and of the flanks with tenesmus, with less violent symptoms, less rapidity of progress, means obstruction of the large intestine. A test for obstruction in the large intestine is an injection by a fountain-syringe: if six quarts can be introduced, there is no obstruction in the large intestine; if less than four quarts can be introduced, there is probably obstruction in the large intestine. The location of a sound in the rectum is generally useless and is often unsafe. In most cases the seat of the lesion and the cause of the obstruction can be determined only by exploratory laparotomy.

The determination of the causative condition is always difficult and is often impossible. *Intussusception* is the common cause in children. In most cases the child was previously healthy. It begins with violent abdominal pain, but although the patient is pale, there is seldom shock at first. Between the seizures of pain the patient often appears to be in good health with a normal temperature and an almost normal pulse. A sausage-shaped mass can usually soon be felt somewhere over the large intestine, but it may be in the right iliac fossa or in the left iliac fossa, but usually over the transverse colon. Osler reports that a mass was palpable in 66 per cent of the cases and in over one-third of the cases it was noted the first day. It begins as early as three hours after the onset of pain. It may shift its position from day to day, by hour, and it may disappear after having been obvious. It may be felt only when an anesthetic is given. Rectal examination gives no information in the early cases or cases involving only the small bowel. In late cases it may perhaps be felt in the rectum. Tenesmus exists, and bloody mucus is passed in most cases. The abdomen is rarely distended or tender until late in the case and at this period there may be shock or sepsis. Vomiting occurs, but is seldom stercoraceous. In *obstruction from bands, internal hernia, etc.*, there is a record of antecedent peritonitis, of a traumatism, of a violent pelvic pain. The attack is sudden in onset, is fierce in character, is usually excited by violent exercise or the taking of food. Vomiting is frequent and intractable, and it soon becomes stercoraceous; pain is violent and

tion is negative; abdominal distention and tenderness are early and pronounced; peristalsis above the volvulus is vigorous, collapse is not so rapid nor so grave as in obstruction from bands and internal hernia. *Obstruction by a foreign body* may sometimes be inferred from the history of some such body having been swallowed. The obstructing body may occasionally be felt during palpation or may be discovered with the x-rays. Abdominal distress may exist for days or weeks before obstruction occurs. Vomiting is late and is rarely severe, but pain, tenderness, and distention are marked. In *obstruction from gallstones* there will be a record of one or more attacks of hepatic colic. Pain is early and acute, and vomiting is invariable and usually becomes stercoraceous. In *obstruction from fecal accumulation* chronic obstruction evolves into acute obstruction, pain and vomiting are late or even absent, and the doughlike mass of feces may be felt by rectal examination or by abdominal palpation. In some cases the fluid elements of the feces pass, but the solid elements agglutinate to the walls of the bowel (the *diarrhea of constipation*). *Obstruction from stricture or from pressure* comes on acutely after a prolonged period of disturbance, during which period attack after attack of temporary obstruction, complete or partial, takes place. A history of blood or pus in the stools would indicate *tumor of the bowel*; a history of blood or pus having been absent would indicate pressure from without. In *functional obstruction* there is no local pain, no tenderness, no tumor, no tendency to collapse, but simply distention and absolute constipation, and possibly non-fecal vomiting occurring in a neurotic or hysterical subject. A *phantom tumor* due to a local distention of the intestine from limited muscular spasm disappears under ether. *Obstruction of the mesenteric vessels* causes colicky abdominal pain, but early in the case there is no tenderness, rigidity, or distention. Pain in the loin and back is often complained of (McArthur, in "Annals of Surgery," vol. xxxiii). Moderate vomiting may occur and there may be blood in the vomitus. There is great restlessness, usually collapse, and frequently bloody diarrhea, or, at least, bowel washings may be bloody. Cardiac disease can usually be demonstrated and albuminuria is common. Obstruction may follow an abdominal operation (*postoperative obstruction*); it may arise a day or so after operation; it may arise in ten or twelve days after operation; it may not arise for weeks or months (Legeve). It may be due to some cause at the seat of operation (adhesion of the bowel to a raw surface, volvulus, catching of the intestine under adhesions, etc.). It may be due to some cause distant from the seat of operation (displacement of intestine, bands, etc.). It may arise from paralysis of a portion of the bowel, which may or may not be due to sepsis.* It may be due to thrombosis of a mesenteric vessel. The symptoms of *postoperative thrombosis of the mesenteric vessels*, according to A. E. Maylard,† are as follows: Abdominal pain, perhaps colicky in character, gradual or acute in onset, and, as a rule, constant. Early in the case there is no abdominal tenderness, no distention, and no rigidity. The pulse is rapid, the patient is extremely restless, there may be vomiting, but it is never violent, as in acute obstruction; often there is diarrhea, and sometimes bloody diarrhea. These symptoms become particularly significant if there is cardiac or vascular disease. *Obstruction from Meckel's diverticulum* is usually acute, but is sometimes chronic, and occurs particu-

* Legeve, *Gaz. des Hôp.*, Nov. 23, 1895.

† *Brit. Med. Jour.*, Nov. 16, 1901.

larly in young adults and children. It has been stated that other and visible deformities are usually present, but in a study of 69 cases by A. E. Halstead* this was true of but one case, in which harelip existed. In obstruction from Meckel's diverticulum there is often a history of former mild attacks (Halstead). Halstead sums up the symptoms as follows: As the obstruction is high up, the abdomen is the shape of an inverted cone; early in the attack there is often local meteorism, especially under the costal arch of the right side, but there is no distention in the flanks. Early, active peristalsis may be visible. The tenderness is just to the right of the umbilicus, on a level with it or below it. In most cases there is early fecal vomiting.†

Differentiation of Intestinal Obstruction from Other Diseases.—Always examine for a strangulated hernia at every hernial outlet. If obstruction is complicated with an irreducible hernia above the seat of lesion, the hernia will always enlarge and become tender because of accumulation of feces. Functional obstruction may attend peritonitis or may follow the reduction of a hernia. Appendicitis with peritonitis may cause symptoms similar to those of obstruction; but there are fever, a history of pain in the right iliac fossa, and the vomiting is not stercoraceous. Acute pancreatitis produces symptoms so similar to those of intestinal obstruction that a diagnosis cannot always be made. Poisoning by arsenic or by corrosive sublimate should not be confounded with intestinal obstruction.

Prognosis.—Without surgical interference most cases of acute intestinal obstruction die within ten days—usually within seven days. Death may be due to shock, to exhaustion, to perforation, to peritonitis, or to obstruction of respiration and circulation by tympanites. Recovery occasionally happens by the formation of a fistula externally or into another portion of the bowel. In acute obstruction from foreign bodies the obstructing body occasionally passes. Volvulus and strangulation by bands are almost invariably fatal unless an operation is performed. In intussusception recovery occasionally follows the sloughing away of the prolapsed gut, but stricture almost inevitably results from this rare event. Functional obstruction gives a good prognosis. The prognosis of chronic obstruction depends upon the causative lesion. It does not threaten life immediately to anything like the degree that acute obstruction does.

Treatment.—In any abdominal case in which the diagnosis is uncertain and the patient is shocked give an enema of brandy and hot water, wrap the patient in blankets, surround him with hot-water bottles, and study the development of symptoms and signs. In half an hour, as a rule, reaction will be brought about, and a probable diagnosis may be made (Greig Smith). In acute obstruction it is usually customary to empty the stomach by lavage and to evacuate the rectum by means of copious injections given while the patient is in the knee-chest position. The emptying of the stomach is imperative if stercoraceous vomiting has been going on, for vomiting of a quantity of such material while a patient is under ether may cause death by drowning, the fluid flowing in enormous quantity into the bronchi. In very severe cases a general anesthetic cannot be given and the belly must be opened under cocaine. Hutchinson's method of taxis and massage is uncertain, and is as

* *Annals of Surgery*, April, 1902.

† *Ibid.*, April, 1902.

liable to inflict harm as to confer benefit. Some surgeons apply constant compression to the abdomen by means of straps of adhesive plaster. Puncture of the intestine with an aseptic hypodermic needle introduced obliquely to relieve gaseous distention is a decidedly dangerous proceeding. The passage of a small tube from the anus to the sigmoid flexure will empty the colon of gas if no obstruction intervenes. In intussusception it is the custom of some surgeons to give no food by the stomach; administer opium and belladonna to arrest peristalsis, wash out the rectum with copious injections, give an anesthetic, and insufflate hydrogen gas or carbonic-acid gas in order to distend the bowel. Other surgeons treat intussusception by forcing air into the rectum by means of an ordinary bellows, and others inject water by a fountain syringe, the reservoir being at a height of three feet. D'Arcy Power believes in the value of hydrostatic pressure in intussusception in children. He states that the child should be anesthetized and the large intestine filled gradually with hot saline fluid, the reservoir not being raised more than three feet above the patient. The fluid should be retained for ten minutes. My own feeling is that whereas it may be justifiable to try to reduce by gaseous or hydrostatic pressure during the first twenty-four hours of the attack, early operation except in newborn infants gives a better prognosis and is safer and more certain. Without opening the abdomen it is impossible to know the condition of the intestine. Gangrene may occur early (it has been found in less than four hours after the onset of symptoms), and if gangrene exists air distention or hydrostatic pressure will cause death. Rushmore's reported case shows that there may be "no systemic symptoms to indicate the presence of gangrene" ("Annals of Surgery," August, 1907). Another point against conservative treatment is the common uncertainty as to whether complete reduction has been accomplished. Vomiting may continue for hours after genuine reduction and the bowels may not move for some time. Waiting to be sure reduction was accomplished will probably be responsible for death if reduction was not obtained. After the first twenty-four hours it is never justifiable to use gaseous or hydrostatic pressure because of the great risk that ulcer or gangrene may exist. Pressure cannot be accurately regulated, and if the bowel is much damaged, may lead to rupture. If the case is not seen until after the first day, or if injections have been used and have failed, all surgeons believe that laparotomy should be performed.

Frederick Holme Wiggin has made a study of the reported cases of laparotomy for infantile intussusception, and considers that operation done within the first forty-eight hours will give a mortality of 22.2 per cent.* (see Operation for Intussusception). In very young infants the mortality of laparotomy is very high and it is a fair question if on them immediate laparotomy should be advised without a trial of conservative methods if the case is seen during the first twelve or twenty-four hours. The mortality of operation is very large on those under eighteen months of age. But even in those under six months of age Wiggin thinks the mortality after operation is not above 22.2 per cent. if operation is done within forty-eight hours, and my personal feeling is that operation should be the method of treatment even in the case of a young baby.

I agree with Rushmore that operation done during the first twelve hours

* Med. Record, Jan. 18, 1896.

would greatly reduce the mortality, perhaps to the figures he expects would come from such a practice, viz., 12.5 per cent.

In obstruction of the main mesenteric vessels operation is of no avail. In obstruction of branches it may be possible to resect the involved region of bowel, a region which is found to be gangrenous or at least is becoming so.

In obstruction from fecal impaction use large rectal injections and give small repeated doses of salines or of castor oil. If there are signs of inflammation, do not give cathartics, even in small doses, but give opium and belladonna to arrest vomiting and to relax spasm. Impactions in the rectum can be removed by the use of a spoon. In acute intestinal obstruction, if the symptoms grow worse, do not wait, but open the abdomen before collapse comes on and find the cause of the obstruction. If it is a gall-stone or enterolith, try to crush it without opening the intestine; if this fails, push it up a little distance, incise the bowel, remove the stone, and close the incision with Halsted sutures. Pilcher* reports 40 cases operated upon for gall-stone obstruction with 21 deaths. If there is fecal obstruction, break up the masses by pressure and push the fecal plug down without opening the bowel. If there is intussusception, reduce the prolapse and shorten the mesentery; but if reduction is impossible, perform an anastomosis or a resection and enterorrhaphy, or make an artificial anus. In volvulus untwist and shorten the mesentery; but if this is impossible, treat as an irreducible invagination. In obstruction from adhesions try to separate them and straighten out the bowel, stitching healthy peritoneum over each raw spot to prevent recurrence. Anastomosis may be necessary. In flexion separate the intestines, remove the flexion by a V-shaped incision, and suture the wound in the bowel (Senn). In chronic obstruction it is often advisable to perform an exploratory laparotomy, discover the condition, and determine what is to be done to correct it. Some tumors external to the bowel may be removed. Growths in the bowel-wall may be removed by resection of the involved portion of intestine, or an anastomosis may be performed, or it may be necessary to make an artificial anus. In obstruction from Meckel's diverticulum that structure may be found twisted, the gut near it may be kinked or twisted, or the diverticulum may act as a band, the bowel being caught under it or kinked over it. Intussusception of the gut below it sometimes occurs; so does invagination of the mucous membrane of the diverticulum; so does chronic inflammation and cicatricial narrowing of the diverticulum or gut (Halstead). The diverticulum may be gangrenous, perforated, or cystic.

After opening the abdomen the surgeon must be guided by conditions. The diverticulum should be removed, just as the appendix is removed in appendicitis, and complications relating to the gut must be dealt with.

The mortality after operations for acute intestinal obstruction is very high (from 60 to 75 per cent.). If the diagnosis were made earlier, operations would be done earlier and the mortality would be much less. Nine out of 10 of these cases that I see in hospital work are gravely shocked and practically dying on admission. If a patient with obstruction is very gravely shocked, I usually follow Moynihan's plan, of simply opening the bowel and draining it in its most distended coil without any search being made for the lesion. The object is to drain the poisons from the intestine, poisons which are the active

*Med. News, Feb. 8, 1902.

agents in killing the patient. The abdomen is opened under cocaine, the incision being small. A distended coil of intestine is sutured to the peritoneum about the abdominal incision, every care being taken that the stitches do not penetrate the mucous membrane of the gut (Moynihan). A purse-string suture is now inserted so as to enclose an area of the exposed gut; an incision is made into the gut in this enclosed area, and gas and feces flow out. Paul's glass tube is passed into the gut and the purse string suture is tied. Instead of Paul's tube we may use a rubber tube sutured as is the tube in Kader's gastrostomy (Elsberg, in "Annals of Surgery," May, 1908). The obstruction is thus temporarily relieved, and if the patient recovers, the causative lesion may be subsequently sought for and attacked. If a fecal fistula follows the enterostomy and refuses to close, it may be closed by operation. If Elsberg's plan is followed a persisting fecal fistula will be rare. Francis T. Stewart has devised a method by which the bowel can be drained without any risk of infection of the peritoneal cavity, a risk which always exists in using Paul's tube. Stewart places a clamp at either extremity of the loop of bowel and surrounds it with gauze. One half of a Murphy button is inserted into the empty loop through a small incision. The other half of the button is squeezed into a rubber tube the diameter of which is somewhat smaller than the flange of the button. The two parts of the button are then clamped, and the clamps

Fig. 520.—Fecal fistula. *a*, Direction of fecal flow; *b*, *c*, belly wall.

Fig. 521.—Artificial anus, showing spur: *a*, Spur; *b*, *c*, belly wall; *e*, direction of fecal flow.

are removed from the loop of bowel. The intestine is sutured to the wound margins and the feces drain into a receptacle on the floor. Fig. 522 shows Stewart's operation. In any cases of intestinal obstruction if gangrene exists the temptation to do immediate resection is strong. I have done it a number of times with a very large mortality. Of late I have been following the plan of Mikulicz and results have been far better. The gangrenous loop is brought outside of the abdomen, it is fixed parallel to the wound and enterostomy is performed above it. If a fecal fistula forms it is subsequently closed by appropriate methods. Postoperative obstruction coming on soon after a surgical operation is often not recognized for a time, and the surgeon will be in doubt as to whether he is dealing with peritonitis or intestinal paresis. When in doubt, wash out the stomach with warm salt solution, administer salines in small doses frequently repeated, employ enemata, and give two or three doses of atropin at intervals of two hours. Each dose should be gr. $\frac{1}{4}$. Atropin is given with the idea that it increases peristalsis and contracts blood vessels. It is probably merely sedative, relaxes spasm, and is useless if strangulation exists. If these measures are not quickly followed by the passage of flatus or feces, open the abdomen; never wait for the advent of stercoraceous vomiting (see Legeve).

Fecal Fistula and Artificial Anus.—A fistula is an abnormal opening in the intestine through which gas or a portion of the feces escape (Fig 520). If all the intestinal contents escape through the opening, it is called an *artificial anus* (Fig. 521, Senn). A surgeon may make a fistula deliberately (*intentional fistula*). A fistula may be the product of disease or injury (*accidental fistula*). Senn enumerates the following causes of accidental fistula: wounds, injury of the intestine, intestinal ulceration, intestinal strangulation, foreign bodies in the intestinal canal, malignant tumors, actinomycosis, pelvic and abdominal abscess, appendicitis, injury of the bowel during an abdominal operation, the application of ligatures, catching by sutures, and the employment of drainage-tubes.

Treatment.—Many fistulae close spontaneously. This can be hoped for only if the opening is quite small, if the general health of the patient is good,

Fig. 522.—Stewart's method of enterostomy.

if the cause has passed away, if the fistula is not lined with mucous membrane, and if there is no spur (spur is shown at *a*, Fig 521). In most cases of fistula not high up it is well to give nature a chance to effect a cure, and not to be in a hurry to operate. The part is cleansed frequently with peroxid of hydrogen, the patient is kept recumbent, food is given which does not leave much residue, pads of gauze with pressure are applied, and the bowels are kept regular.

If the track is lined with granulations, it may be touched with lunar caustic, if it is lined with mucous membrane, the actual cautery should be applied; any collection of pus which exists should be drained. If these methods fail, an operation must be performed. The fistula may be sutured by extraperitoneal manipulation (Greig Smith); it may be covered with skin (Dieffenbach); the spur may be removed by means of a clamp; or resection may be performed. In most cases it is best to incise a button of skin around the opening, temporarily suture the fistula, open the peritoneal cavity, deliver the bowel, and suture carefully (Senn's method). In some cases partial exclusion of the fistulous part is necessary, the bowel being divided above the fistula, the end near the fistula sutured, and the other end anastomosed to the bowel below the fistula. In other cases complete exclusion may be performed (page 1107).

Ulcer of the Bowel.—In typhoid fever and in dysentery ulceration occurs. An ulcer may be due to tuberculosis or cancer. An ulcer of the duodenum (see below) is due to the same causes as an ulcer of the stomach. An ulcer of the jejunum sometimes develops after the performance of gastro-jejunostomy for gastric ulcer (page 1075). *Curling's ulcer* is a chronic ulcer of the duodenum following a burn of the cutaneous surface and due to embolism. An ulcer may heal, and, by causing thickening and constriction, produce chronic intestinal obstruction. It may perforate, causing collapse and subsequent peritonitis.

Peptic Ulcer of the Duodenum.—Occurs usually in that portion of the duodenum which is above the opening of the bile-duct; in other words, only in the region acted on by the acid fluid from the stomach. In Perry and Shaw's list of 149 cases, the first portion was involved in 123, the second portion in 16, and the third and fourth portions in 2. Reversing the rule in gastric ulceration, duodenal ulceration is more common in males than in females in the proportion of 3 or 4 to 1. It may occur at any period of life, from early youth to extreme old age, but is most common between the tenth and fortieth years. Duodenal ulcers are usually single, but may be multiple, and they are one-twelfth as common as gastric ulcers. A gastric ulcer may exist with a duodenal ulcer. Murphy sums up the supposed causes into hyperchlorhydria, local infection, embolism, and thrombosis, and disturbances of the organs of elimination (for instance, a burn of the skin which may cause *Curling's ulcer*). An indurated chronic ulcer may exist, and this may heal and produce cicatricial stenosis. An acute ulcer is apt to perforate. Just as chronic gastric ulcer may be latent, no symptoms ever being observed, so may chronic duodenal ulcer be latent. Usually there is pain coming on about three or four hours after taking food, and located in the epigastric or right hypochondriac region. This pain lasts until the next meal and is relieved when the meal is taken, hence we say that food relieves it. If the digestion of the evening meal is delayed the pain rouses the patient from sleep, but a glass of milk will quiet it. Patients usually discover these facts. The pain is less severe than is usual in gastric ulcer and in many cases does not radiate to the back, although in others it does radiate to the right scapular region. Symptoms of indigestion are not nearly so marked as in ulcer of the stomach. Vomiting is far less common than in gastric ulcer and it does not relieve pain. In one-third of the cases there is hematemesis, and sometimes there is blood in the stools. The stools may be,

at times, dark and tarry from blood. The hemorrhage from the bowels may be so profuse as to kill or almost kill the patient. It may be so frequently repeated as to make him profoundly anemic. In many cases there is no visible blood in the feces, but the guaiac or alon tests show occult blood. Vomiting of quantities of blood is much rarer than in gastric ulcer. Moynihan* mentions the following complications: severe hemorrhage; perforation; periduodenitis; cancer, and cicatricial contraction involving the bile-duct.

Perforating ulcer is more common than we once thought. Perforation is usually on the anterior wall. It is much less common on the posterior wall. It is extremely rare on the superior wall and practically never occurs on the inferior wall. Moynihan gathered 49 cases from literature and added 2 of his own. In the great majority of cases perforation of the duodenum cannot be differentiated from perforation of the stomach by a study of the symptoms. In some cases the symptoms resemble appendicitis. In most cases there is a sudden onset of violent abdominal pain, followed by vomiting, shock, rapid pulse, and tenderness of the epigastric or right hypochondriac region. As a rule, after a few hours the patient reacts from shock. Shedd's case got better in four hours and walked some distance to the hospital.† Lucy's case got better a short time after the onset, walked home, and attended to a horse, but then became rapidly worse. The improvement is apparent, not real, and is only temporary. The symptoms quickly become worse, and when they become worse, besides the pain and tenderness and rapid pulse, there will be occasional vomiting, rigidity of the abdomen, usually an elevated or normal temperature, and possibly diminution of the area of liver dullness.

Treatment.—In duodenal ulcer the risks of serious hemorrhage and of perforation are much greater than in gastric ulcer, and operation should always be recommended if the diagnosis is made. We used to say operate only if the symptoms are not amended by rigid diet and medication; if severe hemorrhage occurs or if cicatricial contraction interferes with the passage of food through the bowel or bile into the duodenum. Moynihan refers to four cases of chronic ulcer operated upon and all recovered. In some cases excision is practised, in others excision with gastro-enterostomy or gastro-enterostomy alone.

If grave hemorrhage occurs and is repeated the surgeon should open the abdomen, ligate the bleeding vessels, bring the outer coats of the bowel together over the indurated area, and perform posterior gastrojejunostomy (Wm. J. Mayo, in "Surg., Gynec., and Obstet.," May, 1908). In such a bleeding ulcer the vessels entering it are usually varicose.

In perforation operation is performed, as in gastric ulcer, as soon as possible. In these cases, as in perforated gastric ulcer, I believe operation should be immediate and that we should not wait for a possible reaction from shock. The ulcer is inverted by two rows of silk sutures. Some surgeons do not drain, but I would feel it safer to drain. B. G. A. Moynihan‡ gathered 49 operations for perforated ulcer with 8 recoveries. Mr. T. Crisp English reports 8 operations for perforation of duodenal ulcers, with 2 recoveries ("Lancet," Nov. 28, 1903). In perforated duodenal ulcer the extravasated

* Lancet, Dec. 11, 1901.

† Ibid., March 26, 1902.

‡ Ibid., Dec. 14, 1901.

fluid is apt to flow into the right iliac region. If an erroneous diagnosis of appendicitis was made, on opening in the right iliac region, by giving vent to this fluid, might for a time confirm the surgeon in error, but the character of the fluid should make evident the condition of affairs.

Ulcer of the Jejunum after Gastro-enterostomy.—(See page 1075.)

Perforated Typhoid Ulcer.—Perforation occurs in 2 or possibly 3 cases out of 100. About 70 per cent. of perforations occur in the second, third, or fourth week. Perforation in a typhoid ulcer is usually effected rapidly, a large opening is formed, and a considerable quantity of fecal matter is passed into the peritoneal cavity. In some perforations very little fluid escapes. Severe pain and a nervous chill indicate that perforation is occurring or has occurred. Some maintain that the two above-named symptoms associated with marked leukocytosis indicate that perforation is about to occur, and they call this stage the *preperforative* stage. That distinct symptoms may in some cases point to impending perforation is, I believe, true, and in one case I operated on the conviction and found two areas almost perforated. In most cases, however, I do not believe that there is a distinct preperforative stage, but the perforation exists when the symptoms are first noted. The conviction that perforation was occurring would be strengthened by a progressive increase in the leukocyte count. It is to be remembered, however, that the leukocyte count is increased by sweating, cold bathing, vomiting, hemorrhage, severe diarrhea, or some positive complication. When perforation occurs, violent pain develops. As a rule, there are tenderness, rapid pulse, costal respiration, abdominal rigidity, vomiting, and shock. Usually there is temporary reaction from shock, the subnormal temperature giving way to a normal or to an elevated temperature. The vomiting in some cases becomes stercoraceous. There is constipation and sometimes dulness on percussing the flanks. The face is Hippocratic. The patient may die of the preliminary shock or may react and die subsequently of blood-poisoning. In a few hours after perforation distinct leukocytosis may be observed, but it may never take place at all. Even when leukocytosis arises, it may disappear as peritoneal infection spreads and systemic poisoning deepens. Le Conte points out that rupture of the mesenteric glands simulates intestinal perforation.

Treatment.—Leyden suggested operation in 1884 and in the same year Mikulicz did the first successful operation. Before Mikulicz's paper was published my colleague, Dr. James C. Wilson, published a paper in which he advocated operation. Death is practically certain without operation. Operation should save at least one-fifth of the cases. Operation should be done at once, proper means being adopted to combat shock. In many cases a general anesthetic should not be given, but a local anesthetic should be employed. The incision should be made in the right iliac region and the colon should be first located and then the end of the ileum. By locating the colon we obtain a fixed point from which to begin our search for perforations, and by opening the abdomen in the right iliac region we come down at once onto the perforated gut in the vast majority of cases. When a perforation is found, it should be inverted with two layers of Halsted sutures. It is not wise to excise the ulcer. If the bowel is very badly damaged, resection can be considered, but it is usually wiser to make a temporary artificial anus. After finding a perforation and closing it, examine to see if there are others.

Close every perforation, and if a point is found where the bowel-wall indicates that perforation is liable to occur, invert the area of ulceration by sutures. Clean the wound with hot salt solution. Leave the wound open, insert gauze, and establish tubular suprapubic drainage. Elevate the patient in bed and employ continuous proctoclysis of salt solution ten times for typhoid perforation with three recurrences of shock. In one case the perforation was not found at postmortem in the hepatic flexure of the colon, the gall bladder was visible for the ulcer of the bowel. One case improved for several days, developed another perforation, and died of it. Autopsy showed that the sutured perforation was soundly closed. A man, brought to me by Dr. Godfrey, was operated on after perforation. There was one perforation near the cecum and fecal extravasation. The opening was large and situated in the ileum. The several inches of bowel between the ulcer and the cecum presented several ulcers almost perforated. The patient recovered after resection. After cleansing the abdomen an artificial anus was made to the perforation. The patient recovered and subsequently the artificial anus was successfully abolished by a resection. In another case, on opening the abdomen a violent appendicitis was found, the appendix was swathed in lymph and gangrenous. The appendix was removed, showed a perforation in a loop of gut two feet from the cecum, and considerable extravasation. The perforation was closed, the cecum was cleansed, drainage was inserted, and the patient recovered. Cultures from the appendix and from the peritoneal cavity were negative. In a third case, that of a young woman, im-

diagnosed by Dr. Kaltefleiter because of pain, tenderness, and definite and increasing leukocytosis. Two ulcers of the ileum were perforated. They were covered over by sutures, the wound was closed without drainage, and the patient recovered. Culture from the peritoneal cavity was negative. In all these cases were operated upon in the Jefferson College Hospital.

Primary Intestinal Tuberculosis.—According to Kocher, 80 cases on record. He reported 29 cases to the Society in 1892. Primary tuberculosis is very rare, whereas secondary is common. The exact propriety of rigidly regarding primary as doubtful. Kocher's cases came from tuberculous infection in infancy from enlarged glands, pleurisy, or bronchitis; that, in all probability, there had for some time been a latent tuberculous focus, and from this focus came the attack of the intestine. Intestinal tuberculosis, in its early stages, begins with the formation of multiple ulcers, due to the action of the tubercle bacillus. Primary intestinal tuberculosis usually begins with several, or even many ulcers in the ileum or perhaps in the cecum. The ulcers tend to heal and form strictures. Occasionally, there is enormous tumor-like thickening of the cecum, called *cecal tuberculosis*, the *conglomerate tuberculosis* of Mayo. The symptoms are slight, attacks of pain occurring now and then, gradually developing. The urine shows the diazo reaction.

Treatment.—In the first stage the proper treatment is excision of ulcerated areas, possibly excision of the cecum. Later, if stricture is causing chronic obstruction, an operation may be performed to give relief. Laparotomy, careful separation of adhesions which are not fused with the gut, and the introduction of iodoform may prove of value.

Malignant Tumor of the Intestine.—*Sarcoma* is very rare, but does sometimes arise, particularly in young persons, and it enlarges very rapidly. It is most prone to attack the large intestine. Jopson and White* report 1 case and also collect 22 others. The mesenteric glands frequently enlarge. *Cancer* is not uncommon, attacking especially the middle aged. According to Rolleston, the average age in duodenal cancer is fifty-two years, in jejunal and iliac cancer forty-seven, in cancer of the cecum nearly forty-eight, and in cancer of the rest of the large intestines about forty-nine years. It is most common in the neighborhood of the ileocecal valve and in the sigmoid flexure. Ewald collected 1148 cases of cancer of the intestine. In 64 cases the cecum was involved; in 24 cases the ileum was involved. It produces pain at the seat of growth, and after a time constipation, or constipation alternating with diarrhea, and finally intestinal obstruction. In some cases the symptoms appear suddenly, acute obstruction taking place or intussusception occurring. It is usually possible to palpate the tumor, which is hard and immovable. The patient wastes rapidly and is apt occasionally to pass blood at stool. The growth does not enlarge very rapidly and glands are not involved early. In some cases the supraclavicular glands enlarge. In more than one-half of the cases which die of intestinal cancer there is no lymphatic infection.†

Treatment.—Early in the case exploratory laparotomy should be performed, followed, if possible, by excision with end-to-end or side-to-side approximation. This is done for either cancer or sarcoma. It may be possible to remove enlarged glands. In cancer of the cecum extirpate the cecum and implant the end of the ileum into the side of the colon (Wm. J. Mayo). If excision is impossible, the growth should be side-tracked by performing lateral anastomosis. In advanced cancer of the large bowel, if resection is impossible, make an artificial anus above the tumor (cancer of rectum, page 1182).

Appendicitis.—Appendicitis, which is an inflammation of the vermiform appendix of the cecum, is almost invariably the primary lesion of all of those various conditions known as typhlitis, perityphlitis, paratyphlitis, etc.—terms which seldom imply pathological entities, and are in most instances well relegated to obscurity. I say in most instances, not in all, because I believe there is such a condition as primary inflammation of the cecum, although it is extremely rare. This rare condition may cause perforation, perityphlitic abscess, or peritonitis when the appendix is sound. It is not to be distinguished clinically from appendicitis (McWilliams, in "Annals of Surgery," June, 1907). Involvement of the cecum as a result of appendicitis is common. It was recognized by some observers many years ago that such a disease as inflammation of the appendix existed, but the majority of the profession did not grasp the fact. In 1750 Mestevier, of France, reported a case of perforative appendicitis with peritonitis.‡ In 1812 a perforated appendix was shown

*Am Jour Med Sciences, Dec., 1901.

†Wm J Mayo, Jour Am Med Assoc., Oct. 19, 1901.

‡Jour. Méd. et Chir., 1760.

to the Medico-Chirurgical Society of London, and in 1835 Southam reported an appendiceal abscess (Manley). In 1848 Hancock reported an appendicular abscess ("Lancet," 1848, p. 380). It is interesting to note that this was a case of appendicitis in pregnancy. Ten days after a premature delivery an abscess was opened. About two weeks after operation two fecal concretions came out of the wound. In 1827 Dr. L. Méllier described appendicitis, and named among its symptoms fixed pain in the right iliac fossa and colic. This brilliant and original man was years ahead of his contemporaries. He reported cases of undoubted appendicitis verified by autopsy, described gangrene, perforation, associated peritonitis, and appendiceal concretions. His original article, Manley tells us, is in the "Journal of Medicine, Surgery, and Pharmacy" for 1827, second series, 110.* Méllier said: "If it were possible to establish with certainty the diagnosis of this affection, we could see the possibility of curing the patient by operation. We shall perhaps some day arrive at this result."† In spite of Méllier's writings, the profession adhered for half a century to the view of Dupuytren, put forth in 1833, that abscesses in the iliac region take origin from the cecum and not from the appendix. Dr. Reginald Fitz, of Boston, in 1886 persuaded the world that the appendix is the real seat of most inflammations in the right iliac fossa. This structure is particularly liable to infection because of the large amount of lymphoid tissue in its make-up, because it is in a dependent position, is always full of bacteria, has a poor blood supply, and is readily blocked by kinking or by swelling of its mucous membrane. Further, as a vestigial structure, it has a low resisting power. The appendix is a long and narrow diverticulum (musculomembranous in structure), which comes from the posterior and internal part of the head of the colon, and which probably has no physiological function (in herbivora and rodents it is a functionally active organ). The structure of the appendix is similar to the structure of the colon, except that the muscular structure is ill developed and trivial in amount. Lockwood points out that there is an extensive lymph system in the appendix, and that the submucous and subperitoneal tissues communicate by numerous gaps in the muscles.‡ This structure has a poor blood-supply, and in consequence gangrene occurs from rather trivial causes. It is supplied by a branch from the superior mesenteric artery. In women there is sometimes an additional supply by a vessel running in the appendiculo-ovarian ligament. The nerves are derived from the superior mesenteric plexus. The appendix averages about four and a half inches in length, but varies in size between the limits of one-third of an inch and a little over 9 inches. In 641 autopsies the longest appendix was 9½ inches and the shortest was one-third of an inch (Monks and Blake). Its diameter is, as a rule, about equal to that of a No. 9 English bougie; its canal is narrow and is partly closed by the valve of Gerlach (Talamon). The appendix enters the cecum at its posterior internal part, which is usually the seat of the most intense pain in inflammation, and corresponds to a point on the surface two inches from the anterior superior spine of the ilium, on a line drawn from the umbilicus to the iliac spine, which is known as "*McBurney's point*." The free part of the appendix

* Thomas H. Manley, Med. Record, July 19, 1902.

† See R. J. Lee Merrill's article in the Amer. Med.-Surg. Bull., Dec. 19, 1860.

‡ Brit. Med. Jour., Jan. 27, 1920.

in one-third of all persons is in relation with the posterior surface of the cecum; in almost one-third of all persons it is fixed in the iliac fossa, so that if perforation occurs, the contents will be voided in the retroperitoneal tissue (iliac abscess). In some cases it is external to the cecum; in some it passes downward, and in some inward. It is important to remember that the appendix may be met with in the most unexpected situations. When the ascending colon is displaced, the diverticulum may be upon the left side. It is not unusual to find its tip in the middle line, up toward or adherent to the gall-bladder, or in the pelvis. In about two-thirds of all cases the appendix is completely covered with peritoneum; in one-third of all cases it is in contact, in some part of its length, with cellular tissue (Talamon). Byron Robinson has called attention to the fact that the appendix is frequently in contact with the psoas muscle in men, and may be bruised by this muscle. In 10,000 autopsies the appendix is said to have been absent five times. In most cases where surgeons have been unable to find the appendix it was not absent, but was covered with peritoneum. Occasionally the appendix is found in a hernial sac.

Etiology and Pathology.—Appendicitis is very rare in infants. I operated unsuccessfully on a male two years of age for gangrenous appendicitis. Savage operated unsuccessfully on a baby sixty-one days, and Weiss operated unsuccessfully on a child twenty months old.* J. P. Crozer Griffith† has collected 15 cases in children under two years of age. One of these patients was three months of age. Nine of the 15 were operated upon, with 7 recoveries. In 4 of the cases the appendix was in the scrotum. In 2 cases a diagnosis of intussusception was made. In children of nine or ten years of age the disease is by no means infrequent. Appendicitis is common at any period beyond childhood, being more frequent in young and middle-aged people than in the aged. It is about four times as common in males as in females. It is more common in summer than in other seasons, and in warm countries than in cold or temperate climes. Appendicitis is a bacterial disease. It is produced occasionally by pus cocci, but most commonly by the action of the bacterium coli commune of Escherich. The colon bacilli, which normally inhabit the appendix, are harmless when the appendix is healthy, but become active for harm when the diverticulum is bruised, obstructed, irritated by the presence of uric acid, congested because of chilling of the cutaneous surface of the body, or distended by the ingress of colonic fluid (C. Van Zwulenburg in "Annals of Surgery," March, 1905). It seems probable that flatulent distention of the colon may be responsible for forcing fecal matter in quantity into the appendix and may lead to plugging of the opening (Rubin, in "Jour. Am. Med. Assoc.," vol. xliii, No. 18). When non-traumatic inflammation occurs, swelling of the mucous membrane occludes the opening into the colon, and the lumen of the appendix dilates and fills up and becomes distended with a thick mucopurulent fluid. Ulcers sometimes form, which may only involve the mucous membrane, may pass deeply into the coats, or may even perforate. Dieulafoy‡ maintains forcefully that appendicitis is due *always* to the conversion of the appendix into a *closed* cavity, but cases are met with which disprove this assertion. Various conditions may bring about this transformation.

* Manley, in Med. Record, July 9, 1902.

‡ Progrès médical, No. 11, 1896.

Partial obstruction may be caused by calculi, which are composed of material and hordes of bacteria mixed with salts of lime. Calculi are not formed in the colon but are formed in the appendix. The theory that concretions form in the colon and are forced out by peristalsis has been very largely abandoned. Dieulafoy describes it as *appendicular lithiasis*, and says it has a tetanic character, and has a kinship with gout and rheumatism; it is caused by local infection of a catarrhal area, by the formation of a stricture, or by several causes acting in unison. The condition is always dangerous. It is frequently associated with perforation as cause or effect. It is a mass of virulent bacteria. It leads to necrosis or gangrene. Talamon taught that the appendix contracts on the concretion, reflex contraction of the muscular coat of the appendix is accompanied by violent pain (*appendicular colic*). The stricture is so rudimentary that it does not seem probable that it would produce traction, even should they arise, would produce violent symptoms. Pozzi believes that appendicular colic may be caused by bending of the appendix or malposition of the appendix. He says that pain may arise when there is no lesion in the appendix, inflammation of the peritoneum or pericecal structures.* Appendicular colic is really inflammation of the appendix and the peritoneum. The term appendicular colic has been used with conservatism, and, as Lockwood shows, if an appendix is found in an individual who suffers from attacks of appendicular colic, he found that the diverticulum is inflamed or the lumen is obstructed. Foreign bodies, such as pins, fish-bones, nails, buttons, stones, and grape-seeds may enter the appendix, but it is generally supposed, most alleged grape-seeds found in the appendix are fecal concretions. Fitz found concretions in 15 cases. He collected the records of 459 postmortems, and found 15 concretions and 16 foreign bodies. Appendicitis due to a foreign body or a pin, is known as *traumatic*; appendicitis due to a grape-seed or a pin, is known as *stercoral*. A foreign body may cause instant perforation. If impaction of a foreign body in the orifice of the appendix is closed, the circulation is stopped, the contents are retained, the coats become congested, the diverticulum becomes inflamed, microbes multiply with great rapidity, and the appendix inflames and may become gangrenous or ulcerated. Interference with the blood-supply of the appendix leads to appendicitis. This may be brought about by two conditions, concretions, pressure, or bands; and the production of these conditions. In women appendicitis is due to tubo-ovarian disease. Appendicitis is rarer in women than in males, probably because in many females the appendix has a direct communication with the ovarian ligament. In women disease of the uterus or ovaries or actually causes appendicitis. Catarrhal colitis, habitual constipation, and indigestion with flatulence

* *Progrès médical*, No. 19, 1896.

ditis. In fact, in a great many cases there has been a more or less prolonged history of diarrhea or constipation and flatulent indigestion before the development of acute appendicitis. An acute attack of appendicitis may arise after the eating of a large and indigestible meal, especially if such a meal was taken late at night. Bolting the food and eating large meals at irregular hours predispose to an attack. It seems probable that catarrhal appendicitis may result from extension of a catarrh of the colon, and may also in rare cases arise from external traumatism. In most cases, however, in which appendicitis seems to be produced by a blow, the injury simply "awakened a sleeping dog" and stirred into acute inflammation an appendix already diseased. If before perforation the appendix adheres to the cellular tissue behind the cecum, cellulitis or abscess without peritonitis may result. When appendicitis goes on to perforation, there is always some peritonitis; but if the steps to perforation are gradual, and if the causative organism is the colon bacillus, the peritonitis may be local, and will sometimes, by formation of adhesions, make a barrier between the appendix and the peritoneal cavity before operation occurs. When perforation takes place suddenly, diffused septic peritonitis is inevitable. When the causative organism is the streptococcus, general peritonitis is very apt to arise. Peritonitis may arise without perforation by contiguity of structure or by migration of bacteria through the congested walls of an obstructed appendix. In some cases perforation takes place into the peritoneal cavity, but pus is circumscribed by matting together of the intestines with plastic exudate. The appendix may become gangrenous very rapidly or after some time. A case of appendicitis in which gangrene and perforation come on very quickly is spoken of as *fulminating appendicitis*. In some cases, if the perforation is very small and the appendix is swathed in lymph, or if perforation does not occur, the inflammation may subside. Perforation rarely occurs from liquid pressure or from the pressure of a concretion; it is generally due to ulceration produced by the action of micro-organisms. Appendicitis which subsides may at any time recur, and the life of such a patient is under constant menace. An enormous number of people have had appendicitis. Toft recorded 500 autopsies, and in 36 per cent. of them there were positive signs of past attacks. The disease is occasionally unsuspected during life. These facts prove that the disease may subside without the aid of surgery.

Forms of Appendicitis.—In what is known as *appendicular colic* the appendix is temporarily obstructed because of transitory inflammatory swelling of the mucous membrane of the outlet, and the stercoral contents are retained in the diverticulum. The peritoneal covering is not involved in the inflammation. This condition is called by Fergusson "*constipation of the appendix*." If not relieved, it will eventuate in appendicitis with involvement of the peritoneum. It is an unfortunate term, sometimes used as an excuse for avoiding operation. In such cases a concretion is frequently or usually present.

Simple parietal or catarrhal appendicitis is not limited to the mucous membrane; hence the term *catarrhal* is not strictly correct. The vessels of the appendix are distended with blood, the lumen at the intestinal end becomes partially or completely obstructed, the epithelium desquamates from numerous glands, the mucosa ulcerates, and the lumen of the appendix becomes filled with a mixture of mucus, bacteria, and portions of organic matter. Bacteria enter the lymph-spaces of the wall of the appendix, and pass rapidly from the

the colon the case may be chronic from the beginning. If the appendix is gradually and completely obliterated, the condition is *obliterative appendicitis* (Senn). This progressive obliteration from repeated attacks of inflammation, or may be simply a degeneration. *Recurrent appendicitis*, it was once said, may be due to inverting the mouth of the appendix, making of this diverticulum a drag-net for bodies; but we now know that it is more probably due to the appendix opening, so that it quickly closes from slight swelling and converts the appendix into a closed vase filled with septic material. *Suppurative appendicitis* is due to purulent infiltration of the walls. Pus in the lumen is also characteristic of *appendicitis*. Pus may form about the appendix, a condition known as *pericardial or appendicular abscess*. *Gangrenous appendicitis* is a form of gangrene, due to interference with the circulation and to tissue death from the action of micro-organisms. Perforations occur, and they are usually fatal. The entire appendix may slough off. Interference with circulation may be caused by an obstruction, by a bend or twist or bruise of the appendix, or by the action of virulent organisms on an appendix whose tissue-resistance is lowered by injury or disease. In gangrenous cases the vessels of the appendix are usually obstructed by thrombi or the changes of arteritis. In rare instances appendicitis is due to tuberculous ulceration, in typhoid ulceration, and genuine appendicitis may arise during typhoid.

Fowler suggests the following classification of cases of appendicitis: (1) endo-appendicitis; (2) parietal appendicitis; (3) peri-appendicitis.

As a matter of fact, appendicitis is always one disease, which varies in severity, and it is useless to divide it into a great number of symptoms.

Symptoms and Signs.—In what is known as *appendicular colic*, the patient suffers from disorder of digestion and occasionally has a localized abdominal pain associated with trivial and temporary tenderness in the right iliac fossa. The colicky pain is about the umbilicus and right iliac fossa. There is often nausea and usually constipation. This condition, if not treated, is followed by the evidences of *peritoneal inflammation*. The

Various forms of appendicitis (from drawings by Dr. M. H. Richardson). 1. Obstruction from narrowing of appendix. 2. Inflammation of distal end of appendix, perforation by a fecal concretion. 3. Inflammation of nearly the whole of the appendix, fecal concretion in lumen.

monitory symptoms have lasted a variable time, and the acute symptoms very frequently appear in the early hours of the morning. The first definite symptom is severe colicky pain. The tongue is coated and usually dry. Great thirst is often complained of. The face is expressive of pain, or later, in a severe case, becomes Hippocratic. The posture assumed for greater ease is one of recumbency with the right thigh and knee or both thighs and knees partly flexed. Respirations in acute appendicitis are shallow and thoracic. The development of acute pain is usually the most prominent symptom. The pain is at first colicky and located about the umbilicus or through the abdomen in general, this distant, primary, or generalized pain, according to Treves, corresponding to the distribution of the superior mesenteric plexus. This primary pain may subside if the appendix succeeds in emptying its contents into the colon, but it may also subside if the appendix becomes gangrenous or ruptures (Murphy). Usually, in from twelve to thirty-six hours the pain becomes localized in the right iliac fossa, and associated with tenderness and hyperesthesia of the skin—in other words, true inflammatory pain develops. It is due to peritoneal inflammation. The usual location of the pain in the right iliac fossa depends on the fact that the appendix is usually placed in that region. Occasionally, when the appendix crosses the belly, the pain is located on the left side, and occasionally, for like reasons, in the gall-bladder region, the right loin, or the pelvis. If the pain of appendicitis is violent, the patient presents some evidences of shock. Nausea is the rule in appendicitis; vomiting usually occurs early—about three or four hours after the beginning of pain. In children vomiting is often violent and persistent, but in adults, after the early hours of the attack, vomiting occurs, as a rule, occasionally or not at all, although nausea is complained of. Early vomiting is a reflex symptom due to distention of the appendix (Murphy). If vomiting persists, it points to peritonitis, to pus-formation, or to intestinal obstruction unless it results from the administration of morphin. There is usually constipation in acute appendicitis, although diarrhea occasionally occurs. In appendicitis there is always some elevation of temperature, although it may be very slight and of brief duration. The fever is not ushered in by a chill, but the temperature mounts in the course of a few hours to 102° or 103° F. or even higher. The fever does not begin until several hours or a number of hours after the onset of pain. In a very mild case the temperature remains elevated for a day or two and then falls to normal. In severe cases it is apt to remain elevated for a longer period, but it is always to be borne in mind that in very grave appendicitis the surgeon may find very little elevation of temperature, no elevation, or actually a subnormal temperature. In gangrenous cases, and in cases in which a large perforation suddenly forms, and when general peritonitis develops, there is usually, for a time at least, a subnormal temperature. A sudden drop of temperature indicates, as a rule, a calamity, particularly gangrene of the mucosa of the appendix, which prevents absorption (Murphy) or perforation of the appendix. Leukocytosis is usually present (see Diagnosis). The pulse in appendicitis is in most cases rapid. A very rapid pulse (over 110) is significant, usually, of a severe case, and the auguries are especially ominous if the pulse is rapid but the temperature is normal or subnormal. Occasionally, however, a slow pulse exists, even in the worst cases.

Examination of the abdomen discovers, early in the case, general abdominal rigidity; but usually in the course of twenty-four hours or more the general rigidity passes away, the abdomen distends more or less, and rigidity of the lower half of the right belly becomes evident and persists. If general peritonitis begins early, general abdominal rigidity does not abate or pass away. If general peritonitis begins later, general abdominal rigidity, which was present at first but which passed away, returns. Rigidity may not exist in the very beginning of appendicitis, in a case in which the appendix is retrocecal or pelvic, in some abscess cases, or in a case with relaxed belly walls.

A symptom almost invariably present in appendicitis is tenderness. In some cases the tenderness is diffuse; in most it is localized, or at least most acute, in the right iliac fossa. The point where tenderness is usually most acute is a spot about 2 inches internal to the anterior superior spine of the ilium, on a line drawn from that bony point to the umbilicus. This is known as "*McBurney's point*," and overlies the usual point of origin of the appendix. In some cases, however, the greatest point of tenderness is nearer the gall-bladder; in others in the loin; in others toward the umbilicus, in the mid-line, or on the opposite side; in others in the rectum. The seat of greatest tenderness depends on the situation of the appendix, and it is usually at *McBurney's point*, because this usually overlies the origin of the appendix. The lesson is that in appendicitis there is a point of tenderness or of greatest tenderness in a region which the appendix could occupy. If tenderness exists on the right side and then develops in the left side, severe spreading peritonitis usually exists (W. Meyer). When the appendix becomes gangrenous, local tenderness may for a time disappear, because the peritoneum of the involved region has become anesthetic; later, however, it returns, spreads, and may become general. In view of the fact that tenderness in the right iliac fossa is often demonstrable in tubal and ovarian disease, the sign in males "is of greater significance than in females" (A. H. Tubby, on "Appendicitis," Medical Monograph Series). Pressure upon the left side will, in some cases, cause pain in the right iliac region. When rigidity abates or disappears, the case may go on to cure, but sometimes a mass becomes evident in the right iliac fossa. The mass, of variable shape, is at first hard, and if of any considerable size, is dull on percussion. In some cases, when no mass is palpable through the abdominal wall, rectal examination detects one. This mass may be agglutinated bowel and omentum or a collection of coagulated inflammatory exudate. It may gradually disappear or an abscess may form. The evidences of general peritonitis are: great distention because of intestinal paresis, general abdominal tenderness, rectal tenderness, very rapid pulse, hiccough, persistent vomiting which may become regurgitation, and, as Meyer points out, percussion dulness over the right iliac region or entire lower abdomen.

In some cases the symptoms, at first trivial, become grave. In some all the symptoms are violent from the beginning, the attack tends to linger, and is followed by persistent soreness of the appendix and harassing digestive disturbances. Any case of appendicitis may become suddenly desperately grave because of perforation or gangrene, and in any case general peritonitis may develop. After sudden perforation or rapid gangrene the temperature falls, hiccough begins, abdominal distention, pain, and tenderness become marked and general, and the pulse becomes very rapid. In some cases

these grave symptoms are present almost from the start (fulminating cases). A sudden perforation produces collapse, and, if reaction takes place, general peritonitis arises. Peritonitis, be it remembered, may arise without either perforation or gangrene. If pus forms, it may be unlimited by adhesion. In such cases there is the rapid onset of fatal peritonitis and septicemia. Pus may be limited by adhesions and be practically extraperitoneal. In such a case a lump is felt in the right iliac region, but dusky discoloration and edema of skin very seldom exist. The surgeon does not wait for fluctuation before he makes a diagnosis. In an abscess case there are usually irregular fever and sweating, but rigors do not occur. Hawkins says we should always suspect pus if the symptoms continue after the sixth day, and particularly when the symptoms abate and suddenly increase between the seventh and tenth days. A limited collection of pus may be liberated into the peritoneal cavity by rupture of the abscess-wall. Such a rupture may be caused by pressure or muscular effort; rupture is followed at once by shock and later by diffused peritonitis. An abscess may rupture externally or into the vagina, intestinal tract, or bladder. It is desirable, if possible, to locate the situation of the appendix, and this is usually determined by locating the seat of swelling and of greatest tenderness. The surgeon should not lose sight of the fact that the appendix may be found in the most unexpected situations. In every case a rectal or vaginal examination should be made, in order to detect swelling and tenderness, and thus determine if the inflammation took origin in or has come to involve the pelvic region. Pain at the end of micturition points to involvement of the vesical peritoneum.* In cases where there is not *localized* swelling and is not local tenderness,—for instance, in gangrenous or perforative appendicitis with general peritonitis,—“diagnostic localization” is impossible (Van Hook).

Terminations and Prognosis.—Acute appendicitis may terminate in death, in complete recovery, or in a condition of lowered vitality during the existence of which acute attacks are almost certain to occur. Sometimes after and sometimes without an antecedent acute attack the patient develops persistent soreness and tenderness in the right iliac region. Between the attacks of recurrent appendicitis there may be soreness, tenderness, and gastro-intestinal disturbance, or there may be no evident trouble whatever; yet, even in the latter case, there may be an ulcer or ulcers of the mucous lining. If a patient has once had appendicitis, he will always be liable to suffer from another attack if the appendix has not been removed. The inability becomes almost a certainty if the intestinal end of the appendix is narrowed or if the lumen is obstructed at any point, if a concretion exists, or if there is an area of ulceration or of desquamating epithelium. After an attack the appendix may remain enlarged and tender; exercise or indiscretion in diet may cause it to become tender or the patient may have occasional attacks of colicky pain. If any of the above conditions exist, another attack may be confidently anticipated if operation is not performed. In such cases the appendix can usually be palpated. The method of palpation proposed by Robert T. Morris is very useful.† It is applied as follows:

* Van Hook, in Jour. Am. Med. Assoc., Feb. 20, 1897.

† See Medical Record, Sept. 17, 1898.

The surgeon stands to the right of the patient and uses three fingers of the right hand to feel with and three fingers of the left hand to press with. Morris insists that no muscular effort should be used by the hand which feels. The feeling fingers are pressed by the other fingers beneath the margin of the right rectus muscle on a level with the umbilicus, and are drawn toward the patient's right side, and the colon will be felt to roll under the fingers. The process is repeated several times until the end of the cecum is reached. The appendix is sought for by rolling the cecum from side to side with the finger-tips, and working toward the proximal end of the appendix.*

Adhesions may form as a result of appendicitis, general peritonitis may arise, the appendix may slough or become perforated, or abscess may ensue upon local peritonitis. Lymphangitis of the appendix may accompany, and septic lymphangitis or phlebitis and secondary hepatic and lymphatic infections may follow, appendicitis. They are thought to be most common after mild attacks of appendicitis. The secondary *lymphatic and hepatic infections* are of the greatest importance. There may be abscess of the liver, subphrenic abscess, or retroperitoneal lymphangitis.

A subphrenic abscess may result from infection carried from the appendix by the lymphatics, from pus ascending along the posterior cellular spaces, or by direct invasion from the peritoneal cavity (John C. Munro, in "Annals of Surg.," Nov., 1905); such an abscess is usually on the right side but may be upon the left.

Lymphangitis is the rule in appendicitis, and when we open the abdomen, there is usually evidence of it in the lymph-glands of the mesentery, and in children particularly these glands are apt to be enlarged. One lymph path from the appendix is through the ileocecal glands, another is posterior to the cecum and retroperitoneal, and the latter reaches the liver and diaphragm (Munro). In lymphatic infection an abscess may form anywhere in the course of the lymphatics. Abscess of the liver usually results from portal invasion but may result from lymphatic infection.

Among other possible consequences of appendicitis may be mentioned pyemia, empyema, inflammation of the parotid gland, and thrombosis of the right iliac vein. A positive prognosis of any case of appendicitis is an absolute impossibility. The future of every case is cloudy with uncertainty, and the most that can be attained in the field of prediction is a scientific guess of more or less probability. All surgeons have seen apparently hopeless cases recover, and have observed cases with the most trivial symptoms grow progressively worse or suddenly develop a fatal complication. Further, after one attack other attacks are very apt to arise. The medical man who estimates that 80 or 90 per cent. of cases get well without operation has probably dealt with many catarrhal cases, and he certainly is optimistic as to freedom from future attacks, because, as stated before, recovery from an attack does not of necessity mean freedom from the disease. In appendicitis there may be delusive evidences of improvement: for instance, the abatement of pain and the lessening of fever, being regarded by the patient himself as indubitable signs of improvement, may in reality be indicative of gangrene. In spite of the previously mentioned difficulties and obscurities we can in the majority of cases decide with a reasonable probability of accuracy

* Robert T. Morris, in Medical Record, Sept. 17, 1898.

whether or not the patient is becoming worse. In a delusive improvement some signs and symptoms improve, but all do not; and in endeavoring to form a prognosis, *all* the signs and symptoms must be noted and weighed: pain, tenderness, rigidity, distention, nausea and vomiting, delirium, intestinal obstruction, shock, the temperature, the rapidity of the pulse, the blood examination, etc. If *all* these elements, not only some of them, point to improvement, we may be reasonably confident that improvement is really taking place. If only some of them point to improvement, we will in many cases be altogether uncertain as to the significance of the change.

Diagnosis.—The diagnosis is not invariably certain, as many light-hearted operators seem to believe. It is frequently far from easy and is sometimes altogether impossible without exploratory operation. Sonnenburg maintains that we can diagnosticate the pathological condition of the inflamed appendix. Personally, I am unable to do this with any certainty, although I always try, and am often right and just as often wrong.

In attempting to make a diagnosis, besides the ordinary examination of the abdomen a rectal or vaginal examination should be made, associated in many cases with bimanual palpation. If an appendix is enlarged and an individual has a thin abdomen which is not rigid, it is often possible to palpate the appendix. Sometimes it can be felt after the administration of ether when it could not be detected before. In an acute case forcible or prolonged palpation is always unjustifiable, as it may force an ulcer to perforate, or may rupture an abscess, and the information gained is not of sufficient importance to justify the risk. In a chronic case information of great value may be obtained and there is no real risk in the maneuver. I am persuaded John B. Murphy is correct in attaching the greatest possible importance to the order in which symptoms appear. Pain *precedes* nausea and vomiting, elevated temperature, and abdominal tenderness. If fever precedes pain, the condition is not appendicitis. If vomiting precedes pain, the condition is probably not appendicitis.

The disease may be confused with a number of different conditions. It sometimes is confused with typhoid fever; in fact, an early typhoid fever associated with marked abdominal pain gives a picture very similar to that furnished by appendicitis.

In typhoid fever the temperature is usually distinctly higher than that commonly encountered in appendicitis. Maurice H. Richardson* tells us that in every case in which typhoid is suspected, operation is not justifiable on the hypothesis of existing appendicitis, unless there are local pain and localized tenderness in the appendix region, associated with definite muscular resistance or distinct rigidity; and that operation should be postponed in a case in which the constitutional signs are severe and the local signs are difficult to detect; but when there are pain, tenderness, and rigidity with or without distention, operation must be performed, even when one recognizes the possibility of the existence of typhoid fever. Richardson lays down the following rule: Soft abdomen plus high temperature suggests typhoid, even if there are pain and tenderness. In appendicitis there is usually leukocytosis; in typhoid leukocytosis is absent, except when perforation is imminent or has occurred, or when some other complication exists. I have

* Boston Med. and Surg. Jour. Jan. 9, 1902.

seen the operation performed twice for supposed appendicitis in each case was found to be early typhoid fever.

Acute intestinal obstruction is sometimes confused with appendicitis, and the mistake is particularly likely to occur in cases of intussusception. In acute obstruction, as in appendicitis, the pain is first appreciated about the umbilicus; but in obstruction the pain is localized in that region, does not pass to and localize itself elsewhere, and is not associated with tenderness of the right iliac fossa; the vomiting is persistent; in appendicitis, except in the early stage, the vomiting is usually trivial and often absent, although in children it may be persistent. In acute obstruction shock is much more common than in appendicitis, and early and great distention of the abdomen. The temperature in obstruction is usually subnormal; in appendicitis it is at least in the majority of cases, the temperature is elevated. In intussusception, however, in acute intestinal obstruction the constipation is usually complete, whereas in cases of intussusception it is usually incomplete. In children, intussusception is particularly confusing the diagnosis, because, after the fit of pain, there is usually no fever in this condition, and a palpable mass is found in the right iliac fossa; but in intussusception the mass does not remain fixed, but alters its position; it is movable, and usually suffers from tenesmus and the passage of blood and mucus. One should bear in mind that in acute appendicitis associated with obstruction may exist; and that the diagnosis may be made without recognizing the appendicitis.

Lesions of the kidney are sometimes mistaken for appendicitis.

In renal colic the pain runs into the groin and testicle or ovary. If the pain usually passes down the front of the thigh or into the leg, and if tenderness exists, it is found in the loin or in the groin, or in the right iliac fossa. Besides this, there are other symptoms. The urine may contain blood or pus, and there may be frequency of urination, though one should bear in mind that in cases of inflammation of the vesical peritoneum there may be urinary difficulties. An x-ray picture may exhibit a shadow of the kidney, and a movable kidney is distinctly palpable. In renal colic there is vomiting in the beginning, just as in appendicitis. In movable kidney the vomiting is often longer than is common in appendicitis. Movable kidney may exist coincidentally. Very confusing cases are those in which a movable kidney accompanies appendicitis. I have seen it twice and in neither case was there any apparent connection between the appendix and the kidney or bladder. They must have been due to acute nephritis. It may occur in some cases of appendicitis, the nephritis being secondary to a bacterial disease. This form of nephritis is described by Debove as "Néphrite toxique Appendiculaire." As pointed out by M. G. Gery, "Sept., 1908," hematuria may also be due to disease of the kidney, ureter, or bladder.

Gall-bladder difficulties, too, may be confounded with appendicitis. I have operated upon a case of cholecystitis under the impression that it was one of appendicitis, and upon a case of appen-

adherent to the gall-bladder, in the belief that the condition was cholecystitis. In an inflammation of the gall-bladder, with a distended gall-bladder hanging low down, and with muscular rigidity, the distinction is always difficult and sometimes impossible. In ordinary gall-stone colic the condition is usually sudden in onset; it is characterized by pain in the epigastric region, passing toward the shoulder-blade and the shoulder, the pain being most acute and becoming more or less localized in the region of the gall-bladder; and there is always tenderness over the gall-bladder region. In gall-bladder colic the vomiting is violent and continuous.

The perforation of a gastric ulcer or of a duodenal ulcer may be diagnosed as appendicitis. In perforation of a gastric ulcer there is usually a history of previous difficulty with the stomach, though this is not always the case. The onset of perforation is sudden, with much greater shock than is characteristic of the onset of appendicitis. The pain is violent and the pain and rigidity and tenderness are in the epigastric region.

Among other conditions that may be confused with appendicitis may be mentioned malignant disease of the cecum, tuberculosis of the cecum, acute tuberculous peritonitis, twisting of the pedicle of an ovarian tumor, tubal disease, extra-uterine pregnancy, membranous colitis, perinephric abscess, tuberculous abscess of the loin or of the groin, and abscess from hip-joint disease.

Pneumonia of the right base and pleurisy may cause abdominal pain and be mistaken for appendicitis. There may even be superficial tenderness in the abdomen, but deep pressure is well tolerated (Donald W. Hood, "Brit. Med. Jour.," Dec. 30, 1905). There may be abdominal rigidity. The abdominal pain seldom persists for more than a few hours. It is intensified by deep respiration and is accompanied by high fever. As Hood says, whenever a patient suffers from vomiting, abdominal pain, and high fever examine the chest. In young children pneumonia is particularly apt to cause abdominal pain and rigidity. Beyond a doubt more than one abdomen has been opened for supposed appendicitis when the real condition was pneumonia.

In reaching a diagnosis in doubtful cases of appendicitis I believe that the blood-count is often of service. It is, of course, not to be maintained that the diagnosis of appendicitis may be made by counting the blood; but the blood-count may furnish evidence that, when added to the other signs and symptoms, may be of great importance. In nearly every case of appendicitis the hemoglobin is diminished by at least 30 per cent. In a catarrhal appendicitis or in an interstitial appendicitis the leukocytosis is trivial; but in cases of abscess or of gangrene of the appendix the leukocytes, as a rule, rise from 15,000 to 20,000. It is to be remembered, however, that when the patient is profoundly septic, the systemic condition is so depressed that leukocytosis is impossible; hence leukocytosis may be absent in trivial catarrhal cases or in grave cases with overwhelming general sepsis. This latter condition, however, is extremely rare. The blood-count will not help one in making the differentiation between appendicitis and an inflammatory disorder of the pelvis or abdomen, but will aid one in making a diagnosis from typhoid fever, intra-abdominal or pelvic neuralgia, and movable kidney (see J. C. DaCosta, Jr., study of 118 cases: "Am. Jour. Med. Sciences," Nov., 1901).

Appendicitis in Children.—The disease is much more often thought of (page 985). There is usually a history of gastro-intestinal disorder. The onset is apt to be sudden, the symptoms as a general thing are violent, and the case is rapid. Vomiting is usually more violent and prominent. There is a great likelihood of pus formation, and general peritonitis is more common than in adults. Occasionally in young children with so much pain and rigidity in the lower abdomen that the child is unable to point to appendicitis, and an attack of appendicitis may occur with or soon after a pulmonary inflammation. I have seen children in which pneumonia was ushered in by abdominal pain. In children the appendix occupies a lower position than in adults, and abdominal tenderness is usually lower than in adults, though it reaches the right side of the pelvis, a painful point can be made by a finger in the rectum, hence a digital rectal examination is made. This usual involvement of the pelvis is responsible for the urinary and painful micturition which is very common (Karewski). When the bladder symptoms are very prominent they dominate the picture, and the bladder is thought to be the real seat of disease. In a child is more apt to result in general peritonitis than in an adult (Selter). I agree with Springer ("Prag. med. Wochenschr.," xxxiv, Nos. 7 and 8) that operation in children should be given, and that purgatives should not be given.

Appendicitis in Pregnant Women. Appendicitis is unfortunately, a very rare complication of pregnancy. In 7 years for appendicitis in the Mount Sinai Hospital of New York only 7 were pregnant. Cooke, in "N. Y. Med. Jour.," May 1900, states that in 30,000 cases under the care of the New York Hospital there were but 5 cases of acute appendicitis (Cooke, *Ibid.*), which occur in pregnancy have had previous attacks.

The condition may arise at any stage of pregnancy, and is rapid in progress, and accompanied by vomiting. Early pain and tenderness are significant and are located regionally. If pregnancy is absent. Cooke points out that later in pregnancy the pain may be so spasmodic as to cause them to be attributed to biliary colic. The pain is often located in the region of the liver or even on the right side of the abdomen (*Ibid.*). Two hundred and fifty cases have been reported and operated on (Renvall).

Appendicitis in the pregnant is far more dangerous than in the non-pregnant. In about 40 per cent. of cases abortion occurs, and in some cases of successful operation the child is born from infection. In some cases of successful operation the child is born from infection. The diagnosis is often very difficult because of the pregnancy.

Tuberculous Appendicitis (Fig. 523).—Acute symptoms resembling acute appendicitis. There is usually a history of chronic disease of the ileocecal valve. There is a stenosis existing at the ileocecal valve. There is a large abscess, and an abscess of large size is apt to form. The appendix is not always involved in the tuberculous process. Capable enlargement, are sometimes mistaken for cancer.

* Andrews, *Annals of Surgery*, Dec., 1900.

Malignant Disease of the Appendix.—This is a very rare condition (less than $\frac{1}{2}$ of 1 per cent. of appendices removed for supposed inflammation). It is impossible of recognition clinically, but is sometimes discovered postmortem or during operation for supposed acute or chronic appendicitis or pelvic disease. Inflammation does not cause the malignant disease, but the malignant disease is apt to block the appendix and so cause inflammation. The condition may be carcinoma, sarcoma, or endothelioma, and usually there are distinct inflammatory changes. It is more common in women than in men. Rolleston and Jones collected 42 cases. McWilliams reported 3 cases and collected 25 not in Rolleston's table. This makes 90 reported cases ("Am. Jour. Med. Sciences," June, 1908). Since writing his article McWilliams has found 15 more cases reported. No case is counted in which the colon is diseased. The combined statistics show the average age of the patients to be only twenty-

Fig. 523.—Tuberculous appendix with perforation and abscess.

nine years. Two patients were only eight. In most cases the appendix alone is diseased; in some the colon or glands of the mesentery are involved. In three-fourths of the cases the growth is distal to the middle. Glands are involved late. Out of 90 cases in McWilliams' table only 8 had enlarged glands, and in 4 of these it was proved that the glands were not cancerous. In about 5 per cent. of cases concretions were found. The chance for permanent cure after removal of an appendix the seat of malignant disease is very good if the disease is limited to the appendix, and is particularly good if the growth is spheroidal-celled carcinoma (Rolleston and Jones). Metastasis is rarely noted. The growth is seldom larger than an almond.

Treatment.—If the diagnosis were always certain from the beginning, and if the case were seen at the very start by a surgeon, immediate operation in every case would be eminently proper. If this plan could be followed,

low the plan of treatment suggested by Ochsner to control peristalsis and favor limitation of infection. The patient is kept perfectly quiet, no cathartics are given, no food or drink is administered by the mouth, and thirst is allayed by enemata of salt solution. Nutritive enemata may be given. It is also my custom to place a hot-water bag instead of an ice-bag over the appendix region.

To permit peristalsis favors diffusion of the infection; to prevent peristalsis is to favor the formation of encompassing and defensive adhesions.

Many surgeons use the ice-bag, but I do not believe in it in these cases. We have already shown (page 99) that cold as a remedy for inflammation is useful only in the brief stage of hyperemia, and when a surgeon sees a case of appendicitis, there is certainly more or less stasis. Cold adds to stasis and does harm, and I am persuaded that the routine use of the ice-bag is responsible for some cases of gangrene. Again cold actually antagonizes the migration of leukocytes and the formation of adhesions.

Heat is a remedy which favors limitation of the process. It relieves stasis, stimulates the activity of the leukocytes, favors the formation of an encompassing barrier of phagocytic cells, and aids the cellular proliferation which leads to the formation of adhesions. Hence I prefer the hot-water bag.

The ice-bag, when applied before the diagnosis has been made, that is, in the earliest hours of the attack, when it might be thought to be most serviceable, allays pain and lessens rigidity in some cases, almost like a full dose of opium, and hence masks the symptoms as does that drug.

Opium should never be given until the diagnosis is made. In the first place, it is not needed, for if the pain is so violent as absolutely to demand opium, operation should be performed. In the second place, opium masks the symptoms, makes the patient feel comfortable, and gives the physician an unfortunate and ill founded sense of security. The pain about the umbilicus, if severe, can be distinctly and safely relieved by the administration of thirty minims of spirits of chloroform every half-hour until three doses are taken. Opium should not be given if the surgeon, having decided not to operate at once, is awaiting an interval, because it may prevent or delay the recognition of some disastrous change. If a patient refuses operation, it can be given.

When we decide to wait for an interval, the case should be seen again within six hours. We are accustomed to follow McBurney's rule, which is as follows: If on seeing the patient again, six hours after the first visit, the patient is worse, operate at once. If he is no worse, there is no pressing danger.

If in twelve hours after the beginning of the attack the symptoms are not intensified, they will soon begin to abate; if the symptoms have become worse during this time, operate. If in twenty-four hours after the beginning of the attack the severity of the symptoms lessens, it is usually possible to wait for an interval; but if during the second twenty-four hours the abatement in the severity of symptoms has not gone on and there is doubt as to the condition, operate at once.* When the attack has subsided, and about three weeks or more have passed, the appendix can be removed with remarkable safety. After a patient has had two or more attacks of appendicitis all surgeons agree that the appendix should be removed.

If pus is present some surgeons delay operation in the hope that firm

* For McBurney's views, see N. Y. Polyclinic, Jan. 15, 1897

adhesions will form around the pus, and that the pus will simply be the opening of an abscess. I do not believe in operation in a pus case. The pus may become limited, pass up toward the liver or down into the pelvis, and be a peril.

If only one attack has occurred, there may never be a question arises, Should the appendix be removed? I do not know that a man has really recovered after pus operation. Many cases reported as cured by medical means have been cured by operation. As Lockwood puts it,* "To say that a man has been cured by medical means is in many cases of a man with a stone in his bladder has recovered from a cystitis by rest in bed."

Even after a first attack, if the appendix remains tender after exercise, or if attacks of colicky pain occur, operation is necessary.

In some cases a single attack of appendicitis is followed by dyspepsia and ill health, and in such cases operation is necessary. In the majority of cases, after even one well marked attack, operation is necessary. It is always necessary after two attacks (of appendicitis).

Appendicitis cases which are far advanced in general peritonitis, by the surgeon some operators decline to touch. If we operate on such cases we will lose very many but these few would have died if we had not operated. Operation is not a cure, but occasionally saves lives. The operation should be an incision to relieve tension and afford exit to infected contents of the appendix if it is easily accessible, otherwise drainage of the pelvis. After such an operation the patient should be in Fowler's position and a continuous stream of salt solution should be caused to trickle into the rectum (see Murphy's Text-book, page 1006).

Appendicitis in a child is treated exactly as in an adult. In a pregnant woman is treated as in the non-pregnant woman, particularly indicated, and it is not proper to induce abortion. If there is general peritonitis in a patient far advanced in pregnancy, it is proper to empty the uterus, primarily to obtain drainage and secondarily to obtain a chance for life and secondarily to obtain a living child.

When operating upon a woman, bear in mind that a uterine disease may have preceded, actually caused, the appendicitis; examine the adnexa and remove them if necessary.

An operation for tuberculous appendicitis is rarely successful, but the rule of operating should be, when possible, to remove the diseased bowel and resect the diseased bowel. Andrewst mentions a special case of tuberculous disease, total extramural anastomosis, and the formation of an artificial anastomosis.

Congenital Idiopathic Dilatation of the Cecum (Disease).—This condition is of prenatal origin. It is

* Brit Med Jour., Jan. 27, 1900.

† Annals of

life or it may not become so until adult years, being aggravated and developed but not caused by habitual atony of the bowel. The supposed cause is an anatomical anomaly (perhaps elongation) leading to looping of the colon, a muscular aplasia leading to dilatation and valve formation. Various causes have been suggested.

The victim of this condition is obstinately constipated and has a distended abdomen, usually from early infancy, although, as previously stated, the condition may not manifest itself until childhood, youth, or even adult life. It is most difficult to get the bowels to move at all. Gay reported a case in which there was no bowel movement for three months and periods of several weeks are by no means uncommon. Now and then an attack of diarrhea may cause the emptying out of great quantities of feces. The abdomen is enormously distended and the patient is emaciated.

The abdominal veins are distended and the rectus muscles may be separated. In Finney's cases (as in some other reported cases) the cords of distended gut could be seen or felt to be more prominent on one side than on the other. There is no abdominal tenderness and pain is absent unless there is diarrhea.

Borborygmus is often very loud. Vomiting is rare.

The urine shows marked increase of indican.

The disease does not directly cause death, but the ill-nourished condition lessens the chance for recovery from any attack of illness.

Treatment. Medical treatment consists of the ordinary plans for combating constipation. Some surgeons have removed almost the entire large intestine, others have performed entero-anastomosis, others colopexy, others have established a permanent artificial anus, others have made an artificial anus preliminary to entero-anastomosis. Finney believes that the operation of choice is resection of the affected gut followed by entero-anastomosis.

Splanchnoptosis.—This condition is due to relaxation of the abdominal walls and decrease of intra abdominal tension, which leads to gradual stretching of suspensory ligaments and finally to movement of the viscera downward. The prolapse may involve all the abdominal viscera, one viscus, or several viscera. Prolapse of the stomach is known as gastroptosis (page 908), prolapse of the liver, as hepatoptosis (page 1021), prolapse of the spleen, as splenoptosis (page 1048); prolapse of the kidney, as nephroptosis (page 1273), and prolapse of the intestines, as enteroptosis or *Glénard's disease* (page 1001).

The causative relaxation of the abdominal walls is most common in women, but is by no means confined to that sex. It may be produced by ascites, pregnancy, muscular effort, febrile maladies, or wasting diseases. In some cases no cause can be assigned. Such a relaxed abdomen may be thin, but is not unusually thick, the fascial strands and muscular fibers are stretched, attenuated, and separated, the belly bulges downward and forward, and a viscus or the viscera follow because of lack of support.

Enteroptosis, or Glénard's Disease.—This disease is a prolapse of the intestine. It may be but a part of ptosis or prolapse of all the abdominal viscera; it may exist alone, it may be associated with movable kidney, prolapse of the stomach (gastroptosis), of the liver (hepatoptosis), or of the spleen (splenoptosis).

In Glénard's disease the intestines occupy the lower portion of the abdomen, and the belly below the costal margins is flat, is dull on percussion,

and the pulsations of the aorta are very evident. The transverse colon begins to descend first, and other parts follow. The splenic and hepatic flexures are affected; there is venous engorgement of dependent parts of the abdomen (Lambotte, in "Presse Med. Belge," 1901, Nov. 24). The patient is dyspeptic, anemic, and neurasthenic. The condition, of apparent cause, may be caused by wearing corsets, lifting heavy weights, and by prolonged vomiting, leading to dragging on the duodenum, the tube becoming flattened. The flattening of the duodenum may be followed by ulceration, and in such a case the stomach dilates, otherwise it does not. The tenth rib is firmly attached by fibrous tissue to the ninth costal cartilage. In enteroptosis the tip of the tenth rib is freely movable from the ninth costal cartilage (*Stiller's sign*).

Treatment.—In many cases medical treatment alone is the usual plan: Employ lavage, massage, proper abdominal support; insist on regular exercise and dyspepsia. There are two possible surgical procedures: (1) The suture of the prolapsed viscus to shorten the shortening by sutures of its supporting ligament, to lessen the area of the abdominal wall and thus increase tension. Depage makes the abdominal wall less in cases with separation of the recti, resects and sutures the wall. I believe that Depage's method of shortening the diaphragm cannot permanently succeed, because the viscera, when damaged, will eventually stretch the wall, it will be damaged done to its nerve supply by operation, and hence and if it should, the patient will be worse off than in the course, whatever operation is done, diastased rectus abdominis is imated and sutured. For ptosis of the small intestine shortened, as suggested and performed by Davis of Chicago.

In prolapse of the transverse colon good results are obtained by attaching the splenic and hepatic flexure (*Lambotte's operation*). The surgical treatment of the stomach is considered on page 968; of the liver, on page 1022; of the kidney, on page 1276.

THE PERITONEUM

Acute Peritonitis.—Peritonitis, or inflammation of the peritoneum, is a common and usually a very dangerous disease.

Aseptic irritation by a traumatism or a chemical irritant causes *peritonitis*, a condition which is strictly limited, and which is characterized by pain and tenderness; which may cause aseptic fever, fibrin-ferment and the products of tissue change, which may lead to temporary or permanent adhesions, and which may be repaired.

Peritonitis, as the term is used by the surgeon, is caused by bacteria. Bacteria may reach the peritoneal cavity by means of the entrance of foreign bodies; by extravasations

vermiform appendix, gall-bladder, urinary bladder, kidney, Fallopian tube, or uterus, or by the passage of micro-organisms through the damaged walls of any of these viscera or structures; by way of an open Fallopian tube; from the breaking of an abscess into the peritoneal cavity; from areas of necrosis due to volvulus, strangulation, or intussusception of the intestine; twisting of the pedicle of an ovarian tumor, a floating kidney, or a floating spleen; blocking of a mesenteric vessel by a thrombus or an embolism; gangrene of the pancreas or spleen, and fat-necrosis.* In some cases the peritoneum may contain a point of least resistance, and bacteria contained in the blood reach this point and produce infection. It was once taught that cold could produce peritonitis, but it seems probable that it can only act by producing an area of least resistance. The capacity of the rheumatic poison to produce peritonitis is doubtful.

The peritoneum, as Byron Robinson pointed out and Fowler confirmed, is in reality a great lymph-sac, and peritonitis is lymphangitis. "When the peritoneum is infected the lymphatics furnish an exudate which clots in the lymph-channels, blocks them, and limits or prevents absorption. This blocking of the lymph-channels serves to preserve the life of the subject, on the one hand, while a failure in this respect, either because of the enormous and overwhelmingly rapid increase of septic material and the large size and number of channels necessary to destroy and obstruct, on the other hand, permits the destruction of the organism."† Absorption takes place most actively from the region of the diaphragm, hence peritonitis in this region is peculiarly fatal. Absorption takes place very rapidly from the intestinal region, although not quite so quickly as from the diaphragmatic area. Absorption takes place slowly from the pelvic region, hence peritonitis of this region is much less dangerous than is the disease in the intestinal region, and vastly less dangerous than is the disease in the diaphragmatic region (Fowler).

When severe bacterial infection of the peritoneum occurs, exudation of blood-liquor takes place, leukocytes migrate from the blood-vessels beneath the endothelial layer, particularly into the peritoneal cavity, and the causative bacteria rapidly spread about the cavity. The fibrinous exudate, in many infections, coagulates in masses on the free surface of the peritoneum and thus serves a useful purpose by blocking the lymph-channels and hindering absorption of toxins and bacteria. This fibrinous exudate may break down in a wide-spread suppuration or may be organized into an adhesion. In very virulent streptococcic infections a patient may die and there may be scarcely any coagulated exudation or may be none at all. Exudation and migration take place also into the subserous tissues and into the muscular coat of the bowel, and the segment of bowel which is attacked becomes paralyzed and distended with gas, the gas within causes it to rise up, and, as peristalsis is absent, obstruction occurs (James P. Warbasse, in "Am. Jour. Med. Sciences," July, 1905). Absorption of poison in peritonitis takes place in part from the peritoneal cavity and in part from the subserous tissues. Warbasse believes that the inflamed peritoneum is scarcely an absorbing surface, but in cases in which coagulated exudate has not formed

* See Park's "Surgery by American Authors."

† George R. Fowler, "Diffuse Septic Peritonitis," in Medical Record, April 14, 1900.

or has been destroyed, it seems probable that it is an accident, and absorption may occur from some regions, but not from others.

Various bacteria may be responsible for peritonitis, *Staphylococci*, *Streptococci*, *Pneumococci*, and *Colon bacilli*. The spread most rapidly and widely are due to *Streptococci*. In this infection the protective exudate does not coagulate, barriers are not heaped up, encompassing adhesions do not form, absorption of toxins, and overwhelming systemic poisoning may cause a very grave form of peritonitis, but less rapid and less common than that caused by *Streptococci*. In fact, the process is often encountered by coagulated lymph, leukocytes, and adhesions. The omentum is thickened, and is apt to apply itself about the area of infection. *Staphylococci* and *Pneumococci* produce peritonitis which is more localized than that produced by *Colon bacilli*. In most cases of peritonitis infection exists: for instance, *Colon bacilli* and *Staphylococci* and *Streptococci*. In some apparently severe cases of peritonitis cultures have remained sterile.

Forms of Peritonitis.—An accurate bacteriological classification is as yet possible.

Peritonitis can be named, according to regions, *pelvic*, *suprapubic*, etc.; it can be divided pathologically into *diffuse septic*, *perforative*, *serous*, and *fibrinoplastic* (Senn); it can be named, clinically, into *traumatic*, *puerperal*, *perforative*, *metastatic*, *serous*, etc.; it can be divided, clinically, into *circumscribed suppurative*, *diffuse septic*.

Circumscribed Suppurative Peritonitis.—In this condition frequently met with in appendicitis, the area of infection is limited by coagulated exudate, leukocytes, and adhesions, and after a time distinct localization becomes evident.

The symptoms of circumscribed peritonitis are pain, at first local, tenderness in a particular region, muscular rigidity, vomiting, rapid and often wiry pulse, constipation, fever, and dorsal decubitus with the thighs flexed. After a time an abscess can usually be detected by palpation, and there may be dullness, local rigidity, irregular temperature, sweats, and possibly a fluctuating wall. An abscess, though limited for a time, is always liable to rupture, its walls and produce general peritonitis. Such an abscess is produced by muscular effort on the part of the patient or by manipulation on the part of the surgeon; its occurrence is accidental, and the symptoms of general peritonitis quickly arise.

Diffuse or general septic peritonitis is apt to destroy the peritoneum presents any marked change. Death ensues from the action of toxic alkaloids. Septic peritonitis may arise during purulent lymphatic infection; it may be due to infection from without or an accident; to perforation of an ulcer; to gangrene of the intestine; to rupture of an abscess into the peritoneal cavity; or to perforation is called *perforative peritonitis*. Perforation may be caused by a chad, shock, or rapid collapse. Gas may pass into the

and if it does so, the area of liver dulness may be lessened or abolished. Symptoms and signs of hemorrhage may arise. Diffuse septic peritonitis is announced by a very rapid pulse, which is at first wiry and later gaseous; a temperature which may be at times febrile, but which is apt to be subnormal or which soon becomes so; diffused abdominal pain, general tenderness, dry tongue, delirium, persistent vomiting, constipation, and collapse. Rigidity may exist, and also intestinal obstruction; often, but not invariably, there is distention. In puerperal peritonitis or septic peritonitis from operation there is often no severe pain; in perforative peritonitis there is acute pain. Patients usually die within five or six days.

Diffuse or general suppurative peritonitis differs clinically from diffuse septic peritonitis in the fact that it is less apt to be fatal and wide-spread. In fact, adhesions may form about an area representing a considerable portion of the peritoneal cavity. The causes of both are identical. In septic peritonitis death occurs from absorption of toxins before obvious pathological changes occur in the peritoneum, in suppurative peritonitis the microbes are fewer, are less virulent, or vital resistance is more decided, and suppuration follows marked changes in the peritoneum. In suppurative peritonitis the pyogenic bacteria are always present, and there exists in the peritoneum a wound or damaged area to constitute a point of least resistance.

Symptoms. Chilliness or a rigor is common, followed by fever, the temperature rising to 102° or 104° F.; pain is intense, and is accentuated by motion and pressure; the attitude of the patient is assumed to relieve pain (he lies upon his back, with the shoulders raised and the thighs drawn up); there are vomiting, obstinate constipation, and rigidity of the abdominal walls, followed by distention when the intestine becomes parietic from septic poisoning. The pulse is rapid; is at first wiry, but may become gaseous. The constipation may be due either to tympanitic distention or to the shock and toxemia inhibiting intestinal peristalsis. Vomiting is frequent. In perforation gas often passes into the peritoneal cavity, and it may obscure the liver-dulness; in tympanites without perforation the liver is apt to be pushed up and its dulness often remains, but on a higher level. Pus unconfined by adhesions will gravitate to the most dependent part of the peritoneal cavity. In some cases of suppurative peritonitis there is no tympanitic distention or rigidity; in some cases there is no fever, and a subnormal temperature may even exist.

Treatment of Peritonitis.—After an abdominal operation the patient may have pain, slight rigidity, constipation, nausea, etc., and the surgeon is in doubt if peritonitis is beginning. Our custom is in such cases to give a saline cathartic, which will empty the peritoneal cavity of fluid, will favor the elimination of microbes, and will combat inflammation. The old time remedy was opium, but Tait denounced it as inefficient, and showed that it masked the symptoms and often created a false sense of security in the very midst of imminent dangers. The usual method of administering salines is to give \mathfrak{ss} of Rochelle salt and \mathfrak{ss} of Epsom salt every hour until a free movement occurs. Administer an enema of turpentine at the time the first dose of the saline is given. This treatment will often abolish pain and distention and will perhaps prevent peritonitis after an abdominal operation. If, however, genuine peritonitis actually exists, operation is required. When diffuse septic or suppurative

tive peritonitis exists, the abdomen should be opened. If a perforation exists, it should be closed. If there is an inflamed appendix, it should be removed. Until recently it was surgical custom to break up adhesions, eviscerate, wash the belly with gallons of very warm salt solution, wipe out the space between the liver and diaphragm, wipe out the pelvis, wipe off the intestines, and remove masses of adherent coagulated exudate. We thus produced dreadful shock, tried to cleanse the peritoneal cavity when it is impossible thoroughly to cleanse it, carefully removed the exudate which was doing good by plugging the lymph-spaces, and yet did not reach the infection inside of the lymphatics, which is, after all, the greatest source of danger. Then we drained through two or more incisions and put the patient recumbent in bed, and thus permitted infected material to flow up to the diaphragm, where it is quickly absorbed. The mortality from this procedure was dreadful. John B. Murphy has taught us wisdom and has combined some of the conservative views of Ochsner with the use of the semi-erect position of Fowler, and with

Fig. 524 — Murphy treatment for suppurative peritonitis

the continuous rectal irrigations that several advocated. Murphy's plan is founded upon the following principles:

First, that the initial lesion of the peritonitis should be got rid of as quickly as possible and with the slightest possible amount of handling. For instance, we should remove a gangrenous appendix; we should close a perforation in the bowel, etc. Flushing of the peritoneal cavity with gallons of salt solution is inadvisable. It cannot thoroughly cleanse the peritoneum, it may diffuse the infection to regions that it had not previously reached, and it may tear up adhesions. Inflammatory exudate should not be removed from the intraperitoneal structures. It is nature's method of sealing the lymph-spaces; and if we remove it, we open thousands of channels, previously sealed, to the dissemination of the infection. A drainage-tube should be introduced through the operation wound, and a suprapubic incision should also be made, and a drainage-tube be carried through this into the pelvis. When the operation is completed, the patient should be placed in the semi-erect position, which is commonly called *Fowler's position*. This is done in order that the intraperitoneal fluids may gravitate away from the dia-

phragm, where absorption is extremely rapid, and into the pelvis, where absorption is much slower.

When the patient is placed in the bed, quantities of warm salt solution are passed slowly into the rectum. The mucous membrane of the large intestine absorbs fluid with great rapidity when that portion of the gut is in its normal condition of moderate distention. Overdistention leads to spasm, which expels the fluid. Hence the fluid must be given at low pressure and administration should be continuous. The simplest sort of apparatus is shown in Fig. 526. It consists of a fountain syringe, a large rubber tube, and a rectal tip of hard rubber. The nozzle that is used is angled, has one opening on the end and several on the side, and this nozzle is passed so that the angle fits to the sphincter. The tube is strapped to the thighs by adhesive plaster. The

Fig. 526.—Alcohol or gas heater in operation, showing it properly connected. A short glass tube connects catheter to rubber tubing (Murphy)

hose that comes from the nozzle is attached to a reservoir, the base of which is hung from 4 to 6 inches above the level of the patient's buttocks, and the fluid, therefore, enters the rectum only about as fast as the rectum will absorb it. The reservoir is kept hot by bags of hot water. The fluid is allowed to enter continuously, unless it should run out from the side of the tube; if this happens, the flow may be cut off for a short time and then allowed to begin again. Gas from the bowel passes into the openings of the tube, and every now and then bubbles up through the reservoir. By this continuous, low-pressure instillation (*proctodysis*) an enormous quantity of fluid is absorbed by the rectum. In some cases a number of quarts are taken up in twenty-four hours. The absorption of this fluid greatly increases the amount of urine eliminated and stimulates the heart. The reservoir must not be high. Increase of pressure will cause expulsion of fluid and defeat the possibility of continuous administration. The plan so often followed of keeping the reservoir high and limit-

ing the flow by a clip on the tube is a mistake. Murphy says: "It should never have a headway of more than 15 inches hydrostatic pressure, and it gives the best and most uniform results at 4 to 7 inches" ("Jour. Am. Med. Assoc.," April 17, 1909). A straight tube is sometimes responsible for expulsion of the fluid, because it touches the posterior rectal wall of a patient in Fowler's position. Fig. 525 shows a more elaborate apparatus.

After the water has been entering the rectum for some time, a profuse discharge of sour-smelling material comes from the drainage tube. This discharge may be profuse for one day, two days, or longer, when its sour

Fig. 525. Proctolysis apparatus consisting of fountain syringe, large rubber tube, and vaginal hard-rubber or glass tip (Murphy).

smell disappears and it greatly lessens in quantity. The outflow of this fluid from the wound means that saline fluid from the rectum has entered the lymph spaces and flowed into the peritoneal cavity. Murphy thinks the lymph current has been reversed. Whether this is true or not the peritoneum certainly seems to become a secreting instead of an absorbing surface, and the lymphatics are washed out. During the time that this treatment is pursued the patient has no food or water given him by the mouth. Stomach feeding is rigidly forbidden, in order to prevent peristaltic movements. Small amounts of opium may be given to prevent peristalsis. If the patient is in a weak condition, stimulants or food can be given by the rectum, the solution in the reservoir being allowed to reach a low level, and then the material that it is desired to give is poured in. Besides the above method of treatment anti-streptococcal serum is given.

I am convinced that this method of treatment is of the greatest value, and that the principles upon which it rests are entirely sound, and I have had a number of striking successes from its employment.

A *circumscribed suppuration* is treated as follows: Open the abscess. It will be possible, if the abscess is adherent to the abdominal wall, to open the abscess directly without opening the peritoneal cavity. If this is not possible, after opening the abdominal cavity pack gauze pads in such a manner about the abscess as to prevent the diffusion of pus when the abscess is evacuated. After opening the abscess the primary lesion is sought for and, if possible, removed. The surgeon should not, in most cases, tear away the abscess walls in an attempt to find the primary lesion, but should rather let it go undiscovered. Pack iodoform gauze against the intestines to reinforce the barrier of lymph and insert a tube. It is frequently advisable to leave the wound open and drain with iodoform gauze.

Every patient with peritonitis requires stimulants and frequent feeding with liquid food.

Tuberculous Peritonitis.—Tuberculosis of the peritoneum is not very

common. In 1170 autopsies in the Boston City Hospital tubercle existed in some region in 197, and in 14 of these the peritoneum was involved.* Primary local peritoneal tuberculosis is occasionally, though very rarely, seen by the surgeon. In a great majority of cases of peritoneal tuberculosis other distant structures are involved. In about half of the cases the lungs are involved. In 28 cases reported by Bottomly † not one was primary. In every one of these cases the diagnosis was confirmed by the microscope, by the tuberculin test, or by autopsy. In most supposed cases of primary peritoneal tuberculosis another focus of disease exists, but is not demonstrable by clinical methods or has been overlooked. The disease sometimes exists as a part of a general tuberculosis. Tuberculous peritonitis may be only a part of acute miliary tuberculosis. Bacteria may be swallowed with tuberculous food or a tuberculous patient may swallow tuberculous sputum and intestinal tuberculosis may result, the peritoneum being involved later. Peritoneal infection may follow a tuberculous lesion of the intestine, the bacteria may enter by way of the Fallopian tube, the initial lesion may be tuberculous appendicitis or tuberculosis of the mesenteric glands. The germ may lodge from the blood

Fig. 127.—Tube with orifices filled with chalk in order to show openings better.

or lymph. The lymphatic form most commonly attacks the cecum. Tuberculous peritonitis is four times as common among women as among men, and most frequently attacks those between twenty and forty years of age, but I have seen it in a child of five and in a colored man of sixty. There are two groups of cases—the common chronic form and the rarer acute condition. The acute form begins suddenly, and such cases, as pointed out by Lejars, resemble acute appendicitis. In either the acute or chronic condition it is frequently the case that pulmonary phthisis exists. Cirrhosis of the liver is sometimes found with tuberculous peritonitis. There are three forms of chronic tuberculous peritonitis: the *ascitic*, the *fibrinoplastic*, and the *caseous*, ‡ although, as a matter of fact, these so-called forms are only stages of the same disease. Tuberculous infection may exist for some time without causing symptoms, acute symptoms may suddenly arise, or intestinal obstruction may take place. Symptoms sometimes develop quickly after pregnancy. In other cases the symptoms appear gradually and progressively grow more positive.

Symptoms of the Chronic Form. Usually the disease begins insidiously. The digestion is found to be disturbed, there is nausea, the bowels are out of

order, the abdomen is distended and tender, the patient is weak, loses flesh rapidly, and frequently pain is the symptom which leads to the diagnosis. Pain may be present from the very beginning, and a gastro-intestinal disorder have existed for some time before the ascites will develop.

In many cases there is ascites, but the amount is small. In some cases the fluid is serous, in some serous and bloody. Chylous fluid occasionally exists in the presence of tuberculous masses. Ascites may be either free or associated with adhesions. In some cases, and especially in the chronic form, the ascites, and the condition is characterized by the presence of adhesions which bind coils of intestine to each other, to the stomach, liver, and other viscera. In this condition the fluid is slowly absorbed, and small cavities are formed between adhesions. This is the most chronic form of tuberculous peritonitis, the mesenteric glands are enlarged, and there is moderate fever, but there may be episodes of high fever, or of subnormal temperature, or the temperature may be normal in the evening and subnormal in the morning. When the fever is markedly elevated, pain, tenderness, and distension are present. In some cases there is a continued fever resembling typhoid. Tubercles may be detected. These formations may be free, or encysted exudate, or enlarged mesenteric glands. In the chronic period, there is probably tuberculous ulceration of the peritoneum.

In every suspected case a bimanual examination should be made, either, in order to discover if there are any masses (see also the section on the subject).

In many cases a careful examination will detect tubercles in the regions of the body, particularly of the lungs. If tuberculous glands of the lungs or pleura is detected, if tuberculous glands of the lymphatic system, if a nodule not due to gonorrheal inflammation is detected, or if there are indurations in the prostate, the diagnosis of tuberculous peritonitis is much enhanced. In some cases the diagnosis is confirmed by the presence of the superficial abdominal veins. In some cases the disease undergoes spontaneous cure. In the majority of cases the tuberculous peritonitis directly or from association with other organs.

If an intraperitoneal tuberculous area case is detected, and such an abscess may break into the surface, and may be responsible for the formation of a fistula.

In a case of tuberculous peritonitis intestinal obstruction may result from the gut getting caught by bands or adhesions, or by the formation of tubercles.

Symptoms of the Acute Form.—This is acute peritonitis. It comes on rather suddenly, but usually shows the previous existence of malaise, loss of flesh, and anemia. The symptoms are those of acute peritonitis, right iliac fossa as in appendicitis. There is

tain amount of rigidity, nausea and vomiting, colicky pain which may be very severe, general abdominal tenderness, fever, and exhaustion. It may be possible to palpate masses like tumors, or to feel nodules in the prostate or epididymis, or to detect tuberculosis in some other part.

Treatment.—In some cases there is a tendency to spontaneous cure, and in them medical treatment is of great service. The patient should be placed under antituberculous conditions (page 245), nutritious food and tonics should be administered, the abdomen should be counterirritated and massaged, and purgatives should be given frequently. Guaiacol applied daily to the abdomen is thought by some to be of service, but I doubt it. A mixture is made of 1 part of guaiacol and 5 parts of olive oil; one dram of this mixture is rubbed into the abdomen, and the part is covered with a piece of flannel held in place by means of a binder. If medical treatment is not soon productive of benefit, the advisability of operating must be considered. It is a curious fact, but one confirmed by ample evidence, that after simple abdominal section, without the introduction of germicides and without drainage, at least 30 per cent. of the cases recover from the disease in from six months to one year. Some surgeons doubt the curative effect of operation. For instance, the late Professor Fenger was strongly of the opinion that many patients recover after operation, but not as a result of operation. In his opinion they recover because they were strong, free from fever, and well nourished, and because the disease tended to spontaneous cure. He further believed that some died from operation because the traumatism lessens the already lowered tissue resistance. The majority of surgeons, however, believe that operation in many cases tends to cure. Ochsner, in a paper before the American Surgical Association in 1902, proved that simple incision and evacuation of fluid tends to cure. It is uncertain how an operation tends to cure. It has been thought that the ascitic fluid is a culture-medium for bacilli, and when it is withdrawn the bacilli die, but opposed to this view is the fact that aspiration is rarely curative. It has been suggested that the operation brings numerous phagocytes to the peritoneum; that it stimulates vital resistance; that it leads to the exudation of antitoxic serum. The entrance of air seems to play a definite and important part in effecting a cure.

The ascitic cases are most frequently benefited by operation. In encysted fluid operation often cures.

In cases in which there are numerous adhesions operation is not so likely to produce a cure. Great care should be exercised in separating adhesions, because the bowel is apt to be torn and a fecal fistula may result. It may be necessary to separate adhesions or short-circuit a portion of gut to relieve obstruction. Drainage should not be used unless a cold abscess exists. Not only is drainage of no service, but it is dangerous; death is more apt to ensue in a drained case and a fecal fistula will arise in nearly one-fourth of the cases. If operation is performed for cold abscess, tube-drainage must be used for some days. In a woman with tuberculous peritonitis the abdomen should be opened in the mid-line, and if the Fallopian tubes are tuberculous, they should be removed. In a man the incision should be made over the appendix, and if this is tuberculous, it should be removed. In either sex it may be necessary to resect tuberculous intestine or perform anastomosis because of stricture. (In confirmation of these views see W. J. Mayo, in "Jour. Am. Med.

Assoc.," April 15, 1905.) The Mayos have performed 26 radical tubal operations on cases of tuberculous peritonitis and 25 recovered. Of these, 7 had previously been operated on from one to four times by simple laparotomy ("Jour. Am. Med. Assoc.," April 15, 1905). In a very advanced case, in a case with notably high temperature, or in a case with marked and advancing tuberculosis in another region, an operation should not be performed except to relieve obstruction or drain an abscess. If a patient does not die within a few months after the operation, he will probably recover, and in most cases operation secures at least temporary improvement (Bottomly). The mortality from operation is 1 or 2 per cent. (Fenger).

Pneumococcus Peritonitis.—This condition is an unusual one. It is most apt to arise during the progress or after the termination of pneumonia, but is sometimes primary—is far commoner in females than in males and in children than in adults. Out of 74 reported cases, 57 were children under five years of age (Dr. Max von Brunn, in "Beiträge zur klinischen Chirurgie," Bd. xxxix, Heft i). The condition may appear in a sufferer from otitis media. The symptoms in children are sudden in onset. The first symptoms are general abdominal pain, usually a continuous pain with colicky exacerbations, tenderness, rigidity, vomiting, elevated temperature, distention, and diarrhea. In a few days the symptoms abate and some of them disappear, although pain, tenderness, and rigidity are apt to localize at some point, particularly about the umbilicus, and perhaps remain for a number of weeks. In such a chronic case physical signs of a fluid collection are usually demonstrable. In the chronic stage, as Brunn points out, there is seldom severe tenderness and there may be no fever at all, and a septic temperature is very rarely observed. Pus may form, and if it does, it contains pneumococci. Adhesions practically always form. These adhesions glue the intestines together and often encompass pus. Rapid emaciation and progressive weakness are always noted. In adults the symptoms are irregular and less characteristic than in children (Brunn). The prognosis is excellent.

Treatment. Is incision and drainage.

Subphrenic Abscess.—A subphrenic abscess is a collection of pus beneath the diaphragm. The pus, as a rule, occupies a part of the lesser peritoneal cavity; in rare instances it is extraperitoneal (when it is of renal origin); in some cases it is contained in the area between the diaphragm, cardiac end of the stomach, and liver or spleen. It is an unusual thing for such an abscess to break into the general cavity of the peritoneum, but it may break into the pleural sac (Maydl).

Causes. Perforation of a gastric ulcer, perforation of the gall bladder or gall-ducts, ulceration of the duodenum, disease of the liver, spleen, pancreas, intestine, appendix, or kidney, hydatid disease, internal injury, metastasis, external injury, caries of rib, or disease of the pleura may be responsible for a subphrenic abscess (Maydl). Charles A. Elsberg* has collected 73 cases of subphrenic abscess after appendicitis. He points out that the condition may arise from direct extension or by way of the lymph channels, and may be either intraperitoneal or extraperitoneal, although in the majority of cases it is intraperitoneal. In all but seven of these cases there was suppuration about the appendix. The pus was thick and foul in all the cases. In 15 per cent. of

* Annals of Surgery, Dec., 1901

them gas was also present, and in 25 per cent. of these cases the diaphragm was perforated. In one case on which I operated the abscess developed after cholecystitis.

Symptoms.—A patient with subphrenic abscess usually complains of pain in the lower part of the chest on the right side. The area of liver-dulness is distinctly enlarged, and there is tenderness in the lower part of the right chest when pressure is made through one or through several intercostal spaces. Frequently friction sounds may be heard about the region of the dome of the liver. Sometimes the symptoms are obscure or indefinite, and not accompanied with particular pain. If the abscess happens to contain a considerable amount of gas, and about one-half of such abscesses do contain gas,—not only will there be no increase in the area of liver-dulness, but the normal area of dulness may be diminished or obliterated. The presence of gas is due to some connection with an organ which contains gas. It is very common for a pleural effusion to be associated with a subphrenic abscess. A pleural effusion will be preceded by or accompanied with symptoms pointing to the lung or pleura; and it is to be remembered that the area of percussion-dulness found in the pleural effusion shifts its position whenever the position of the patient is changed, which is not true of the area of dulness found in subphrenic abscess. When the abscess breaks through the diaphragm, the patient develops collapse, cough, and other thoracic symptoms; and if the abscess breaks into a bronchus, the patient will expectorate pus. In subphrenic abscess the diaphragm of the diseased side is paralyzed—a condition rarely met with in liver-abscess. There are general symptoms of suppuration and a swelling in the subdiaphragmatic region following some recognized causative condition. The history of chills with recurrent fever and sweats is rather indicative of abscess of the liver; but in abscess of the liver there is usually pain in the shoulder-blade of the right side, and this is rarely encountered in subphrenic abscess. The proof of the diagnosis is not, however, obtained until an exploratory incision has been made and the purulent matter has been examined. In many cases the abscess-cavity will be found to contain gas as well as fluid. Empyema and subphrenic abscess resemble each other. In empyema the upper limit of the fluid is concave; in subphrenic abscess it is convex. In empyema the flow of pus through an aspirating-needle will be most marked during expiration; in abscess, during inspiration. The same is true of the rush of gas. In empyema the needle does not oscillate; in abscess it does.* If an abscess contains gas, percussion elicits a tympanitic note over a part of the cavity and there is an alteration in the area of tympany with an alteration in the position of the patient. An abscess of the liver almost never contains gas and decidedly changes the outlines of the organ.†

Treatment. Incision and drainage. The incision in some cases may be made in the lumbar region, in some cases through the abdominal wall (epigastric region, iliac region, hypochondrium). In other cases the chest wall is incised, the ninth or tenth rib is resected, and the abscess is opened below the pleura or the pleura is opened and the diaphragm is incised. If appendicitis is the cause, be sure the appendicitis is well; and if not, open and drain freely

*Wharton and Curtis, "Practice of Surgery."

†In a case of abscess of the liver secondary to appendicitis operated upon in the Jefferson Hospital the abscess did contain gas produced by gas-forming bacteria.

(Elsberg). If it is necessary to open the pleural sac, first try to stitch the parietal to the diaphragmatic layer of the pleura, or, if this is impossible, protect the cavity with iodoform gauze to prevent infection.

THE LIVER, GALL-BLADDER, AND BILE-DUCTS.

Rupture and Wounds of the Liver.—Rupture of the liver is due to very great force, and is usually accompanied by injury of other viscera. It may be produced by a blow, by a fall, or by the end of a broken rib. The superior surface or margin most often suffers. It is a very fatal accident. Out of 543 reported cases, over one-half died of hemorrhage within twenty-four hours of the accident.* At least 80 per cent. will die if not operated upon. Wilms† collected 19 cases, and only 3 recovered after operation. Eusebrath‡ has collected 37 cases of suture of the liver for rupture and 22 of them recovered (59.5 per cent.). The first operation was performed by Willeit in 1888. An attempt should be made to save the patient by opening the abdomen and arresting hemorrhage, and in a suspected case an exploratory operation should be performed. A wound of the liver causes violent hemorrhage which is usually rapidly fatal. Such a wound is apt to divide bile-ducts and allow bile to escape into the peritoneal cavity. Bile, if sterile, will do little harm, but if it contains bacteria, it will produce diffuse peritonitis. Even sterile bile is corrosive and may cause fibrous peritonitis. The symptoms of a rupture or wound of the liver are those of severe intra-abdominal hemorrhage, with collapse, hepatic tenderness, and respiratory embarrassment. Soon after the injury the abdomen is soft and flat, but it quickly becomes rigid and ultimately distended. The diagnosis becomes more probable when it is known that violence was applied in the hepatic region. Usually there is abdominal pain and often pain in the back. Sugar may appear in the urine. In a few cases after several days jaundice and skin itching have been noted. The area of liver-dulness is usually increased. Patients do not always die from a serious traumatism of the liver. Some recover because operation has been performed. Some few recover without operation. This last fact is proved by reports of autopsies in which scars were found in the liver parenchyma (Nussbaum). The fatality which usually ensues on a liver injury may be due to hemorrhage or peritonitis. If a surgeon is called to a patient suffering from wound of the liver, he must open the abdomen to arrest hemorrhage. If a penetrating wound is suspected, it may be desirable to enlarge the wound in the abdominal wall layer by layer, in order to determine that the liver is wounded. If the left lobe of the liver is wounded, or if it is uncertain which lobe is wounded, the incision should be median. If the right lobe is wounded, a curved incision is made along the line of the costal cartilages. In some cases these two incisions are joined.§ The convex surface of the liver can be reached by Lannelongue's plan. Lannelongue resects the eighth, ninth, tenth, and eleventh costal cartilages and draws the ends of the ribs well out. It can also be reached by Langenbuch's plan, that is, by cutting the coronary ligament and the right lateral ligament. This allows the liver to be pulled well up into the wound in the belly.

wall. The site of the wound can be discovered if the hepatic vessels are grasped between the thumb and a finger (the finger in the foramen of Winslow and the thumb in front on the gastrohepatic omentum). This completely arrests hemorrhage, and the blood that has gathered may be sponged out and the wound sought for in a clear field (see Pringle, of Glasgow, in "Annals of Surgery," Oct., 1908). When the wound in the liver is discovered and well exposed, deep sutures of catgut should be inserted in the liver and the capsule should be stitched with fine silk (Schlatter). If sutures fail to arrest hemorrhage, the liver should be sutured to the belly-wall and the wound in the liver packed with iodoform gauze. It is useless to try packing without first attaching the liver to the abdominal wall, because pressure will simply push the liver away and will not arrest the bleeding. The cautery is a very useful means of arresting bleeding. It should be avoided if possible in a large wound, because, even if it arrests primary hemorrhage, secondary hemorrhage may occur. After arresting hemorrhage, wash out the abdomen with hot saline fluid, insert drainage, and close the abdominal wound. In a case of the author's in the Philadelphia Hospital the liver was wounded by the sharp ends of fractured ribs. The abdomen was opened, a wound was found, and bleeding was arrested by suturing the liver to the belly-wall and packing the wound. The patient died, and necropsy showed another wound on the posterior portion of the organ. The possibility of such an occurrence should not be lost sight of.

Tumors and Cysts of the Liver.—The liver may be the seat of primary carcinoma, sarcoma, or endothelioma, of angioma, lymphangioma, adenoma, fibroma, myxoma, or lipoma. Many tumors called adenomata are really adenocarcinomata. Secondary malignant growths are far more common than primary neoplasms—in fact, 96 per cent. of liver tumors are secondary. Primary cancer of the liver is found once in every 2000 autopsies (Eggel). The commonest variety is the nodular, but the diffuse form, known as *cancerous cirrhosis*, may occur. The nodular form is most often encountered in the right lobe, and it has been found in persons under the age of twenty. Metastases occur early. "There is always more or less coexisting cirrhosis of the liver" (Leonard Freeman, in "Trans. of Am. Surg. Assoc.," 1904). It takes origin from the hepatic cells. The frequency of cancer of the liver secondary to cancer of the stomach has already been alluded to. The commonest primary tumor of the liver is cavernous hemangioma. It is especially apt to take origin in the atrophying liver of an elderly individual. Primary sarcoma may arise at any age and may even be congenital. The growth is rapid and emaciation is soon noted. The liver enlarges, often greatly. Jaundice and ascites are rather rare. The patient soon becomes very weak. There is always pain. As Knott points out ("Surgery, Gynecology, and Obstetrics," Sept., 1908) the condition may simulate abscess, and if it arises in a middle aged or elderly person can scarcely be differentiated from carcinoma.

Knott (*Ibid.*) has collected 59 cases of primary sarcoma from literature, and adds 14 reported by personal communications, and 1 of his own, 74 in all.

He shows that 28 cases have been operated upon. In 9 the operation was exploratory and no attempt was made to remove the growth. In 19 the growth was extirpated, with 10 recoveries and 9 deaths. One of these patients was well after nineteen months, 1 after two years, 1 after seven months. Operation is indicated for a circumscribed growth.

Among the cysts occurring in the liver are blood cysts, bile cysts, and hydatid cysts. Terrier and Auvray in 1901 reported their experience with operations for hepatic tumors.

Angiomata have been removed successfully by hepatic resection. A hot knife at a red heat being used to cut through the normal liver tissue at the base of the tumor, the large vessels being tied with catgut. If this is not feasible because of excessive hemorrhage. If a tumor is small, the base may be encircled by an elastic ligature held in place for five or six days later the tumor may be cut across with a hot knife. assisted Prof. Keen in such an operation.

Carcinoma of the liver has been extirpated, but it is not recommended unless it is recognized early enough and is found to be sufficiently small. Operation is proper only when there is no evidence of primary cancer. In 1901 Terrier and Auvray collected 10 cases of primary cancer. In most cases there has been rapid recurrence. Schrader's case was well at the end of seven months. Freeman's at the end of sixteen months. (For operative treatment of liver cancer, see Freeman, in "Trans. Am. Surg. Assoc.," 1904.) Hughes in 1906 reported 96 cases of resection of the liver with a mortality rate of 26%. The best method of arresting hemorrhage is the use of sutured catgut passed by blunt needles, as advised by Mikulicz.

Hydatid cysts of the liver may be of small size and produce no signs or symptoms; or may be of large size and produce a large tumor. In the epigastrium the mass may be prominent. In a cyst of the right lobe the dulness is found in the axillary region and encroaches on the pleura. In a large cyst fluctuation may exist. Hydatid fremitus is a vibration imparted to the chest wall of one hand when the fingers of the other hand knock up the fluid. There may be no discomfort produced by even a large cyst, but the patient suffers from a dragging sensation in the epigastrium and from anorexia. Suppuration in the cyst produces the symptoms of abscess and septicemia. Rupture of the cyst produces shock and even death. It may take place into the pleural sac, the lung, or the peritoneum. If shock is recovered from, inflammation arises, the area of the rupture becomes the seat of the structures damaged. The escape of even a small quantity of fluid into the peritoneal cavity produces urticaria (*hydatid fever*). For diagnostic purposes is not advisable.

Treatment. Exploratory incision may be necessary to determine the nature of the lesion, and the operation is completed at this time. After the diagnosis is made it is packed around with gauze and a trocar is introduced into the cyst through a considerable thickness of liver tissue over the cyst, incise the capsule with a hot knife. When the fluid is evacuated, the sac is incised through the wound in the abdominal wall, and is attached to the abdominal wall by ligatures (*marsupialization*). The endocyst can then be removed by irrigation. A large drainage-tube is introduced.

Syphilis of the Liver. This is a tertiary lesion. It is characterized by irregular patches of inflammation in Glisson's capsule (eventuate in hepatic sclerosis)—as a large solitary gum.

* Russell S. Fowler on "Tumors of the Liver," Brooklyn Med.

of cases of gumma present a solitary lesion)—or as multiple, and usually small gummata. Gummata are most usual upon the anterior surface of the right lobe. The large gumma is often mistaken for cancer of the liver and it is a curious fact that in hepatic gummata we are often unable to obtain any history of syphilis. Syphilis may be mistaken for ordinary cirrhosis, but in the latter disease the general nutrition is more impaired than in the former, and vomiting of blood, dilated cutaneous veins, ascites and indigestion are far more apt to be present (Archibald MacLaren, in "Annals of Surgery," August, 1908). These patients are apt sooner or later to develop jaundice, colicky pain, moderate fever, and palpable enlargement of the liver.

Treatment. Mercury and iodid will cure most cases. If these drugs fail, it is proper to remove the tumor, if solitary, by resecting the involved area of the liver. MacLaren (*Ibid.*) collected 9 cases of resection for solitary gumma and added 1 of his own. There were 2 deaths in this series.

If an area is opened for exploration and a solitary gumma is discovered, the abdomen should be closed and specific treatment be tried before resorting to resection, that is, if specific treatment has not been tried before.

Abscess of the Liver. An abscess of the liver may be produced by bacteria, especially staphylococci and streptococci. These organisms reach the liver by the general circulation, or, what is more frequent, are taken up from the intestinal tract and reach the liver by the portal circulation, or pass to the liver by the lymphatics. Appendicitis with lymphatic infection may result in hepatic abscess. A subphrenic abscess may break into the liver and thus induce a liver abscess. Liver abscess may directly result from peritoneal infection. The fact that abscess of the liver is in hot countries frequently preceded by amebic dysentery led to the presumption that amœba coli produces the abscess, and in a large majority of cases of tropical abscess amœba exist in the pus or at least on the abscess walls. Habitual intemperance and constant overeating predispose to abscess of the liver. The disease may follow traumatism, dysentery, diarrhea, cholangitis, suppuration of a hydatid cyst, gall-stones, typhoid fever, appendicitis, and a chill to the surface of the body.* Abscess of the liver may be metastatic, and such abscesses are multiple. It may be caused by foreign bodies and parasites. A tropical abscess is an abscess of the liver in an inhabitant of a hot country.

There are three forms of abscess of the liver: traumatic, pyemic, and tropical.

Traumatic abscess may result from a wound of the liver or may follow a contusion without a break of the skin. In the latter case bacteria from the blood are arrested in the injured liver tissue. Such an abscess is usually solitary. Streptococci, staphylococci, or colon bacilli may be found.

Pyemic Abscess.—Multiple abscesses exist, but they may fuse into one. It is frequently due to suppurative inflammation of radicles of the portal vein, infected emboli forming and reaching the liver; it may follow ulceration of the intestine, hemorrhoids, or appendicitis.

Occasionally abscess may arise from the extension of an infective process, such as pyelephlebitis, or in cholelithiasis with obstruction. In these latter cases both the bacillus typhosis and the pneumobacillus of Friedländer have been found as the direct bacterial agent. Colon bacilli are a common

*G. B. Johnston, *Annals of Surgery*, October, 1897

cause. Abscess of the liver following appendicitis or infection (*portal pyemia*) or to lymphatic infection, but in a case of mine in the Jefferson Hospital it was having probably joined to form one. *Echinococcus* suppurate and form abscess. I operated unsuccessfully which was brought to me by Dr. Hultsizer. The round and the balantidium coli sometimes cause abscess, and served in measles, epidemic influenza, and perforating

Tropical Abscess of the Liver.—Tropical abscess in temperate climates, but is extremely common in antecedent in either climate is dysentery. The reason of the disease in tropical regions is that the chief cause, *coli*, is found widely distributed in hot countries; and of the liver is a common condition among the white regions. It has been pointed out that tropical abscess among white persons that abuse alcohol, the condition of the liver making that organ a nutritious soil for it; disposing factors are protracted malaria and chilling body.

Major Charles F. Kieffer, U. S. A.,† in a lecture of the liver, states that in his own experience he found abscess cases in soldiers, that dysentery was present in a second series of 25 cases in natives and civilians of dysentery in 22 cases. Some observers—notably dysentery is the antecedent factor in 97.5 per cent. It is out that in all the figures allowance must be made for dysenteries, as well as for cases in which no effort was of dysentery one or two years previously. It is also a case of amebic infection of the colon may have been as to have caused but a transient diarrhea, which then gotten. Again, as Kieffer observes, amebae occasion without producing any dysenteric evidences. His of 20 to 25 per cent. of severe amebic dysenteries lead to of the liver, and that at least 85 per cent. of all tropical infection with the *amoeba coli*. Occasionally, an abscess after the dysentery; but, as a rule, it does not follow ward—weeks, months, a year, or even two years.

When an abscess of this sort forms in the liver, it is enlarged and congested, and an area or areas of necrotic abscess may be present; there may be an abscess with it; several abscesses may coalesce, making a very large multiple abscesses may exist. In about 70 per cent. of tropical abscess is solitary (Kieffer).

The right lobe of the liver is the region most frequently affected; an abscess is found in the right lobe in from 70 to 80 per cent. of cases; it is more often toward the convexity of the liver than toward the base.

An abscess of the liver contains characteristic

* Major Chas. F. Kieffer, U. S. A., in Phila. Med. Jour.
† Phila. Med. Jour., Feb. 21, 1903.

it is different from the pus found in other abscesses, and, in fact, is not pus, but is necrotic liver-substance. Liver abscesses due to pyogenic organisms contain true pus; a tropical abscess, free from pyogenic infection, does not. Ordinary pus contains hordes of leukocytes; but the pus of a tropical abscess contains very few. Riesman is of the opinion that the reason there are so few leukocytes is that the abscess contains a substance that, by chemotaxis, repels leukocytes. The pus is of a reddish-brown color, is thick, and frequently contains some blood. Occasionally it is offensive in odor. Microscopic examination shows it to contain portions of necrotic liver tissue, some liver-cells that are not destroyed, elastic tissue, blood, pus-cells, and amebæ (Kieffer). On bacterial examination it may be found that the pus is infected, containing staphylococci, streptococci, or pyogenic bacteria. In about 20 per cent. of the cases the pus contains neither bacteria nor the amœba coli. In over 60 per cent. of the cases the pus of a recently opened abscess is free from bacteria. In cases in which the fluid is sterile it is possible that bacteria were originally present, but have died. The reason for the death of micro-organisms in this pus is in great doubt; because, as Riesman points out, bile cannot kill them, and organisms may be grown in the pus. Kieffer says that in the large majority of cases amebæ are readily demonstrable in the pus; but that in some few cases it is necessary to rub a piece of gauze on an abscess-wall in order to obtain amebæ, and that in others they can be demonstrated only after the abscess has been discharging for some days. The causative rôle of the amœba has been doubted by some observers, but most surgeons who have had experience in the tropics believe it to be a fact.

Symptoms.—The symptoms may be very definite and positive; they are frequently misleading and obscure; and in some cases nothing whatever directs the surgeon's attention to the liver until the patient passes a huge quantity of pus at stool or coughs up an enormous amount of the characteristic material. If rupture takes place, death usually ensues. As a rule, the symptoms of a tropical abscess are positive and marked.

Kieffer sums up the chief symptoms under four heads: *fever, sepsis, enlargement of the liver, and pain*. In about three-fourths of the patients fever and sweats are definitely present; in about one-fourth they are absent or are very trivial. The type of fever met with is what has been previously spoken of as hectic. Usually there is an evening rise, preceded by a chilly sensation or by a chill; and as the temperature begins to fall, toward morning, there is a profuse sweat. It is seldom that there is any violent chill, though there is frequently a slight one. The sweats are extremely exhausting. They may occur either during the night or in the daytime, according to the time in which the patient sleeps. Kieffer says that they should not be called night-sweats, but rather *sleeping-sweats*. In very chronic cases there may be no pyrexia. As a rule, the temperature resembles that of malaria, but it is not controlled by quinin and the blood is free from malarial parasites. Sometimes the temperature suggests typhoid, with the exception that from time to time there are episodes of subnormal temperature. The patient loses flesh and strength, the appetite fails completely, and the skin becomes pasty or dirty yellow.

The entire liver is usually enlarged, and the enlargement may be detected

by percussion, and in some cases a hard, smooth area can be felt. Sometimes the liver reaches as high as the third rib anteriorly and the scapula behind, and it may extend downward to the spine of the ilium. It is rarely, however, that the liver extends in a downward direction; it is usually upward. On the right side of the chest appears to be rather full, and there is actual obliteration of several intercostal spaces. If an abscess is adherent to the surface, there may be skin edema and tenderness. In very rare instances, if a very large abscess comes near the surface, fluctuation may be obtained. By auscultation it is frequently found that friction-sounds in the region of the diaphragm and the liver.

The liver becomes tender. This tenderness may be elicited particularly by pressure upon the lower edge of the organ, or by pressure through the intercostal spaces. There is not always pain as a rule, there is. The pain may be dull and heavy; when it nears the surface of the organ, the pain becomes sharp. The pain is persistent and is not strictly localized, but is referred to the right shoulder-blade, and the point of the shoulder. It is aggravated by pressure, coughing, sudden or violent movement, and by the esophagus when food is swallowed. When the upper lobe is involved, the patient breathes as if he had pleurisy; and emphysema may develop, with marked effusion.

Paralysis of the diaphragm rarely occurs in abscess of the liver. Respiration is not much affected, unless the diaphragm or the pleura become involved, though the patient frequently coughs. A severe cough suggests that the abscess is on the costal surface of the organ. Such a cough is aggravated by recumbency. When the patient lies on his right side, and almost on the right side, the right shoulder being drawn down and the right knee drawn up, there is tension of the abdominal muscles. In about one-fourth of the cases of abscess of the liver jaundice occurs; usually, however, if the abscess is on the inferior surface. Jaundice does not occur unless the common or hepatic ducts are compressed or cholangitis exists. The count is of no particular help in the diagnosis, as there is usually leukocytosis. The urine is usually scanty. Diarrhea is not common, but constipation may exist, and nausea and vomiting are means unusual.

Diagnosis.—With an antecedent history of dysentery, the diagnosis is easy. Without such a history, it is always difficult and uncertain. In the tropics exploratory aspiration is freely used, but even this is not so certain with subsequent exploratory aspiration, if necessary, would be more certain.

Symptoms of Traumatic Abscess.—Are similar to those of a liver abscess.

Symptoms of Pyemic Abscess.—The liver is enlarged, and there is slight jaundice, and the general symptoms of pyemia are present.

Treatment of Tropical Abscess.—Make an exploratory incision. If the abscess is adherent to the parietal peritoneum and is of a soft substance, at once proceed to operation. If it is not ad-

by a considerable layer of liver substance, stitch the visceral peritoneum to the parietal peritoneum and postpone further interference for forty-eight hours. The operation consists in evacuating the pus with a trocar and cannula, incising the abscess, stitching its edges to the edges of the abdominal wound, irrigating, and inserting a drainage-tube. If the abscess is covered by a layer of liver tissue, after locating it with an aspirating cannula open into it with a cautery knife and arrest hemorrhage by packing. When the parietal and visceral layers of peritoneum are adherent, packing will arrest bleeding; if they are not adherent, packing will only push away the movable liver (John O'Connor). If pyothorax exists, resect a rib, open the pleural sac, and reach the abscess in the liver by an incision through the diaphragmatic pleura and the diaphragm (*trans thoracic hepatotomy*).

Rogers and Wilson ("Brit. Med. Jour.," June 16, 1906) advocate aspiration and examination of the pus. If amebæ only are present, they inject a solution of quinin, a material quickly fatal to amebæ. The dose is 30 grains of dihydrochlorate of quinin in a sterile solution. If the abscess holds less than 10 ounces of pus, the quinin is given in 2 ounces of fluid; if it holds more, in 4 ounces of fluid. The authors report 2 cases cured by this method.

Treatment of Traumatic Abscess.—Is the same as for tropical abscess.

Treatment of Pyemic Abscess.—Surgery is usually futile, because multiple abscesses exist, but an operation should be performed in the hope that it may do good. In a case in the Jefferson Hospital in which abscess of the liver followed appendicitis the patient recovered after operation.

Hepatoptosis (Floating or Movable Liver).—Hepatoptosis may be congenital, but is usually acquired. In a congenital case certain ligamentous supports of the liver are absent. In the following discussion the acquired form is the variety referred to. This condition is rare. Ninety-eight cases have been reported.* It is a form of splanchnoptosis and is due to relaxation of the abdominal wall and stretching of the supports of the liver. It may occur alone, but it is more often a part of a general abdominal relaxation or of Glénard's disease, and often a kidney is movable, or uterine displacement or hernia may exist. The liver may descend into the lower abdomen, may be upside down (Demarquay), may rotate on its transverse axis (Griffiths), the anterior surface may become posterior, or the organ may lie with the superior surface in the right flank and the inferior surface looking to the left,† may be movable, or may be anchored by adhesions. It is most common in women. The liver is supported by ligaments and also by the inferior vena cava, which vessel is firmly adherent to the central tendon of the diaphragm (Faure), by the abdominal wall, and by the intestines (Glénard). The cause of the condition is in dispute. It can result from relaxation of the belly-wall, relaxation of the ligaments, enteroptosis, great enlargement of the gall-bladder, increase in weight of the liver, atrophy of the connective tissue between the liver and diaphragm, pregnancy, the growth of a liver tumor, and tight lacing. Either a strain, cough, or the dragging of an adherent tumor may be the exciting cause.

Signs and Symptoms.—An abdominal mass may appear suddenly after a blow or a strain, and if it does appear suddenly there is always pain in

* J. H. Carstens, Jour. Am Med Assoc., May 17, 1902.

† Terrier and Auvray, Rev. de Chir., Aug. and Sept., 1897.

the hepatic region, nausea, and weakness. When the condition comes on gradually, there may be no symptoms for a long time, but, as a rule, there is some pain in the loin which becomes worse after exercise or effort. In rare cases jaundice appears, and occasionally there is ascites. The abdominal walls are relaxed and the signs of splanchnoptosis are manifest. When the patient stands, a transverse furrow of skin covers the lower part of the umbilicus (*Glénard's sign*). In most cases the shape, the mobility, and the absence of the liver from its proper position are diagnostic. Even when the organ is dislocated and attached in its new situation, it is missed from its proper abode, and palpation outlines the characteristic shape. When the patient lies down, the liver usually returns to place, and in most cases it can be restored by manipulation. In some cases, however, it will not return to place and cannot be restored by manipulation. A floating liver causes a recognizable enlargement in the right loin, and the mass usually moves on respiration.

Treatment.—In many cases the patient can be kept comfortable by wearing an abdominal support, and can be distinctly improved by the use of massage and electricity to the abdominal wall, the administration of tonics, and a course of forced feeding. If these means fail and the patient suffers, an operation should be performed. The operation of *hepatopexy* was devised by Marchant. He opens the abdomen and tries to restore the liver to its proper position. This can usually be accomplished. In some cases it can be done after adhesions have been separated. In other cases it can be only partially accomplished. After the liver has been restored, he sutures it by means of catgut or silk to the abdominal wall or costal cartilages, the stitches passing through the hepatic parenchyma and being carried through the liver by means of a round and blunt needle. The sutures attaching the liver to the belly-wall are tied beneath the skin. Marchant scarifies the dome of the liver in order to favor adhesions. Ramsay rubs the upper surface of the liver with gauze to promote adhesion and transfixes the round ligament with a suture which is carried around the cartilage of the seventh rib. In a severe case Depage advises us to associate hepatopexy with an excision of a portion of the abdominal wall to amend relaxation (*laparotomy*). If, in operating on a floating liver, it is found impossible to get the liver back into its normal position, fix it with sutures as near its proper abode as is possible. Terrier and Auvray report 11 cases of hepatopexy. One case died and eight completely recovered.

Floating Hepatic Lobe (Partial Hepatoptosis).—This condition is not uncommon in cases of chronic disease of the gall-bladder and is most often met in cholelithiasis. It is believed that it can be caused by tight lacing. A tongue-like projection forms upon the right lobe of the liver (*linguiform lobe*). It can be palpated below the costal margin and the dullness of the mass on percussion is continuous with liver-dullness. A linguiform lobe can usually be moved laterally and forward and backward; it is always tender and is sometimes the seat of pain.

Treatment.—When this condition is associated with gall-bladder trouble, it may disappear, or at least cease to cause pain, when the gall-bladder is drained by cholecystostomy. Langenbuch has successfully removed a linguiform lobe.

Cholecystitis (Inflammation of the Gall-bladder).—Inflammation

of the gall bladder is produced by infection. Healthy bile is sterile; and when bacteria are found in the bile, the condition is one of disease. Micro-organisms may find entrance into the gall-bladder by way of the blood, the bile becoming infected secondarily to the infection of the gall bladder; or they may enter by way of the ducts, from the intestine. The conditions that follow infection depend upon the characteristic tendency and the virulence of the infecting germs. A trivial infection produces mucous catarrh; a more active infection causes suppuration, and possibly ulceration; a very violent infection leads to gangrene.

In most cases of cholecystitis an inflammatory swelling blocks the cystic duct, and obstructs it so that the bile stagnates in the gall bladder. In many cases this condition lasts but a short time; and when the obstruction is relieved, bile flows down the duct. Occasionally, as a secondary consequence, cholangitis, or infection of the hepatic ducts, follows.* Occasionally, also, the obstruction of the duct is not relieved, and a quantity of clear, thin mucus gathers in the gall-bladder and overdistends it—the condition known as *hydrops*. The gall-bladder may likewise become distended with pus, constituting an *empyema* of the gall-bladder; and any overdistended gall-bladder may rupture. A gall bladder may distend to a most enormous size. Terrier reported a case of distended gall-bladder in which the viscus contained 42 pints of fluid. F. W. Collinson ("Brit. Med. Jour.," May 29, 1909) reports the case of a woman of thirty-one years of age who was tapped twice before operation and at each tapping 25 pints of fluid were withdrawn. At the operation 22 pints were obtained. Collinson's case arose from blocking of the common duct as a result of traumatism, followed by kinking of the cystic duct and subsequent opening of the common duct. In cases of very chronic inflammation of the gall bladder this structure becomes fibrous and contracts, until it may become no larger than the thumb, in which condition it may contain a very small amount of thickened bile. In some inflammatory conditions due to infection the bile mixes with thickened mucus, and micro-organisms form the nucleus upon which bile salts are deposited to form gall-stones. As the same author points out, cholelithiasis may result from cholecystitis, and may cause chronic cholecystitis, because the stones existing in a gall bladder are sources of irritation.

Bacteriology of Cholecystitis.—It has been proved by abundant observation that the fact that bile contains micro-organisms is no evidence that the gall-bladder is inflamed; but that when the gall-bladder is inflamed, micro-organisms are demonstrable in the bile. We know that the bile is infected during the course of typhoid fever, and that it is frequently so in pneumonia. The colon bacillus is not unusually demonstrable in cholecystitis; and pus-cocci, either in pure culture or mixed with other germs, constitute the most common cause of the inflammation. It is probable that bacteria entering the gall-bladder and not being particularly virulent produce no immediate harm when the flow of bile is unobstructed, though even then they may become the nuclei of gall-stones; but if the bacteria are very virulent, they may actually lead to obstruction. Stagnation of the bile favors infection, and infection may be the cause of stagnation. Each influence reacts upon the other and aggravates the other, and it seems more than

* Joseph McFarland, Proceedings of the Phila. Co. Med. Soc., Sept., 1902

possible that infection of the gall-bladder is to be regarded as serious only when there is obstruction to the outflow of bile. The same variety of germ may, under some circumstances, cause catarrhal, and under others suppurative, inflammation; that is, when bacteria are virulent and tissue resistance is slight, suppurative cholecystitis results; but when the bacteria are not virulent and the tissue resistance is powerful, the gall-bladder is not infected at all, or only catarrhal inflammation is produced. I operated upon a case of acute suppurative inflammation of the gall-bladder three weeks after the termination of an attack of typhoid fever. The culture taken from the gall bladder showed an unidentified bacillus, which was not the colon bacillus or the paracolon bacillus, and which was not identical with the typhoid bacillus or the paratyphoid bacillus. It strongly resembled the typhoid bacillus, but possessed no agglutinative power (the author, in "New York Med. Jour.," April 8, 1905).

A patient in the medical ward of the Jefferson Hospital was supposed to be developing a typhoid relapse, but no fresh spots appeared, and there were pain, tenderness, and rigidity in the region of the gall-bladder. I operated and found the gall-bladder full, dark-colored, and surrounded by numerous recent adhesions. It could be emptied slowly by pressure. There was no pus. It was drained and the symptoms promptly passed away and the man recovered. The culture was reported sterile. I cannot understand this finding, as inflammation undoubtedly existed. It may have been peritonitis rather than cholecystitis, but from what cause is unknown. No culture was taken from the peritoneal cavity. The finding of sterile bile at the end of an attack of undoubted typhoid is of interest.

Catarrhal Inflammation of the Gall-bladder and Bile-ducts.

—This condition is known as catarrhal jaundice, acute or chronic, and is usually treated by the physician; but, as A. W. Mayo Robson points out, chronic catarrhal jaundice sometimes resembles the jaundice of organic disease, and is occasionally associated with gall-stones, malignant disease, or hydatid cyst. The same authority asserts his belief that chronic catarrhal jaundice usually results from interstitial pancreatitis and duct obstruction. This condition usually comes on without pain. If there is pain it means some complication. Robson ("Surg., Gynecol., and Obstet.," Jan., 1908) names among such complications catarrhal cholecystitis, cholangitis, gall-stone, and duodenal ulcer. The jaundice is striking. There is loss of flesh and anemia, and the liver is enlarged and smooth. Robson tells us that if the gall bladder is not shrunk from stone, and if there is great duct obstruction, the bladder will be distended. Chills and fever mean infective cholangitis. In a case of chronic catarrhal jaundice in which medical treatment fails, surgical treatment must be considered (cholecystostomy or cholecystenterostomy).

Catarrhal Cholecystitis.—This is a catarrhal inflammation of the gall bladder usually without jaundice. The gall-bladder becomes thick and its mucous membrane is frequently plicated. Very thick mucus is secreted, which gathers in masses, and the descent of these plugs causes pain that is sometimes indistinguishable from that produced by the passage of a gall-stone. Such a plug may temporarily block the cystic duct. In catarrhal cholecystitis the gall-bladder is frequently distended, but rarely admits of palpation; and there are no adhesions to surrounding structures, unless

gall-stones have been present (Robson). Catarrhal cholecystitis may lead to the formation of gall-stones; may result from the presence of gall-stones; or may be found in cases in which gall-stones have been present, but have passed. In one case upon which I operated the gall-bladder was enlarged, thick, and without adhesions; the mucous membrane was convoluted; and the viscus was filled with thick, tenacious mucus, and the mucous membrane of the gall-bladder contained many minute concretions. In this case stone-formation was probably beginning to follow upon catarrhal cholecystitis. In another case a woman had presented violent symptoms of gall-stone colic, and stones had been recovered from the feces; but on opening the gall-bladder no stones were found—only a condition of catarrhal cholecystitis. Jaundice is rare in catarrhal cholecystitis unless gall stones are present; it is, however, occasionally noted. Even if jaundice does occur, it is slight and lasts but a short time. The painful attacks that occur during catarrhal cholecystitis are similar to gall-stone attacks; but the pain is less violent and of briefer duration, and jaundice is not apt to follow the passage of a plug of mucus and is apt to follow the passage of a gall-stone. Further, as Robson has shown, in cholecystitis with gall-stones there is usually tenderness on pressure over the gall-bladder; and there is rarely tenderness in uncomplicated catarrhal cholecystitis.

Treatment.—The majority of the cases recover under medical treatment. If a case fails to recover under medical treatment, one cannot be sure whether there are gall-stones or not; but an operation is indicated in either case. Cholecystostomy should be performed, and the gall bladder should be drained for a week or two. This treatment will almost always produce cure.

Croupous Inflammation of the Gall-bladder and the Bile-ducts.—This is an extremely rare condition, due to the formation of a thick membrane in the bile-passages, which causes obstruction to the flow of bile and spasmodic contraction of the gall bladder. The symptoms are identical with those of gall-stones. Robson points out that a study of the evacuations may discover membranous intestinal casts; and that, as membranous enteritis is usually associated with croupous inflammation of the gall bladder and bile-ducts, a diagnosis may thus be reached. The same author says that one may, in some cases, even find a cast of the gall-bladder in the evacuations.

Treatment.—If medical treatment fails, cholecystostomy should be performed and drainage should be employed for a considerable time.

Suppurative Inflammation of the Gall-bladder and Bile-ducts.—

Adopting the classification of Mr. Robson, we divide these suppurative inflammations into simple suppurative cholecystitis, suppurative and infective cholangitis, phlegmonous cholecystitis and gangrene of the gall-bladder, ulceration of the gall-bladder and bile-ducts, pericystic abscess with adhesions, and certain consequences of these conditions, such as stricture of the gall bladder and bile ducts, perforation of the gall-bladder and bile-ducts, and fistula of the gall-bladder and bile-ducts. Suppurative inflammations of the gall bladder and the bile-passages are due to infection with virulent organisms or to infection when the tissue resistance is at a low ebb.

One fact must strike the physician in regard to these cases, that is, that

there is a strong similarity between the possible changes of acute cholecystitis and the possible changes of acute appendicitis. In the gall-bladder, as in the appendix, there may be a catarrhal inflammation, which may not advance beyond this stage, or which may advance into a more dangerous form, in each structure, blocking and stagnation favor infection and aggravate existing infection; in each there may be suppuration, ulceration, gangrene, and perforation; in each there may be grave complications and disastrous and fatal consequences; and in each prompt surgical operation is usually life-saving.*

Simple Suppurative Cholecystitis.—This condition is also spoken of as *suppurative catarrh* of the gall-bladder or *simple empyema* of the gall-bladder. It is a rare condition, unless gall-stones exist, or unless some infectious disease—especially typhoid fever—has antedated the condition. I operated for this condition upon a boy of eleven years of age three weeks after the termination of an attack of typhoid fever. It is not only typhoid fever that may be causative, but also other continued fevers. No matter, however, what organism is primarily responsible,—be it colon bacillus, typhoid bacillus, or what not, a mixed infection with pyogenic cocci usually takes place. Pyogenic cocci may alone be causative. In simple suppurative catarrh of the gall-bladder when the duct becomes blocked, the condition known as simple empyema exists; and when hydrops of the gall-bladder undergoes suppuration, simple empyema is produced.

In an ordinary case of suppurative catarrh following gall-stones one usually obtains the history of a number of attacks of biliary colic, the pain finally having become persistent, instead of intermittent; and a definite swelling being palpable in the gall-bladder region. This swelling is tender on pressure. There are usually constitutional symptoms, sometimes trivial, often severe. The trivial symptoms are a somewhat rapid pulse, sweating at night, and some elevation of temperature. The more severe symptoms are chills, a remittent fever, and profuse sweats. The development of severe symptoms indicates that a dangerous change is taking place—usually ulceration of the gall-bladder, occasionally phlegmonous cholecystitis. Distinct jaundice is rare in simple empyema, though the patient usually shows loss of flesh, has a very poor appetite, and suffers considerably from thirst.

To distinguish an enlarged gall bladder from any other intra abdominal mass is sometimes difficult. Very large gall-bladders, such as have been placed on record by Collinson, Terrier, Lawson Tait, Gersuny, and others, may be mistaken for ovarian cysts. Alban Doran discusses such cases in the "Brit. Med. Jour.," June 17, 1905. An enlarged gall-bladder moves on respiration, unless the mass becomes adherent to the abdominal walls, when it will cease to do so. An enlarged gall bladder is sometimes mistaken for a movable kidney, and the diagnosis between these conditions is discussed in the section on Movable Kidney (page 1275).

Treatment. The gall bladder should be opened and drained by the operation of cholecystostomy. After it has been exposed, it is packed about with gauze pads, a considerable amount of the contents is removed through an aspirator, the gall bladder is opened and irrigated with salt solution, and a search is made for any cause of obstruction in the cystic duct. This

* The author, Proceedings of the Phila. Co. Med. Soc., Sept., 1922.

cause should be removed, and any gall-stones that are present should, of course, be taken away. The walls of the gall-bladder will frequently be found diseased and softened, so that it is impossible to apply stitches. In some cases, if the gall bladder is badly diseased, it should be removed; but in others, incision with drainage is sufficient.

Recurrent Simple Empyema of the Gall-bladder.—In this condition a person develops, at intervals, pain, fever, tenderness, and enlargement of the gall-bladder. Then the symptoms clear up and he is well for a time, but they again become manifest; and at last they may become persis-

FIG. 528.—Gall-bladder removed by cholecystectomy for calculus, empyema, and gangrene.

tent or violent, because of the development of some complication. In these cases it is impossible, after a number of attacks, to palpate any enlargement of the gall bladder; and when an operation is performed, the gall bladder is found shrunk, thickened, and deeply placed, containing some purulent matter, and strongly fixed to the surrounding structures by adhesions.

Treatment. Cholecystectomy is usually the proper operation.

Acute Phlegmonous Cholecystitis. Some call this condition *acute empyema*. It is extremely dangerous, and is apt to cause gangrene of the gall-bladder. It is due to infection with extremely virulent organisms. It may produce rapid peritonitis and death without perforation, but oftener perforation takes place. It is generally associated with the presence of calculi, but sometimes none are found; and the condition sometimes develops during typhoid fever or septicemia.

This disease begins with sudden and violent pain in the gall-bladder region. This pain usually radiates toward the right shoulder-blade, and soon becomes general throughout the abdomen. There are tenderness in and great rigidity over the gall bladder region, thoracic respiration, exhausting vomiting, septic fever, and in some cases jaundice. If an operation is not promptly performed, general peritonitis quickly takes the patient's life. In one case upon which I operated there were intense jaundice, tenderness, violent pain, abdominal rigidity and distention, chills, and septic fever; and when the abdomen was opened, it was found that a portion of the gall-bladder was gangrenous and that a calculus projected through the gangrenous opening.

It is this form of cholecystitis that is especially likely for appendicitis. In making a diagnosis the situation of the tender point is of importance, and likewise the situation of the tender point placed gall-bladder or an abnormally situated appendix. Acute phlegmonous cholecystitis is usually accompanied by constipation, and the sudden onset and the abdominal distension of the disease being mistaken for intestinal obstruction. It is often confused with perforating ulcer of the stomach or of the duodenum.

Treatment.—In any case of doubt an exploratory incision should be made. If phlegmonous cholecystitis is found to exist, the gall-bladder, whenever possible, be extirpated; but if the desperate condition forbids this operation, it should be surrounded with iodoform gauze, and a drainage tube should be carried well up toward the cystic duct.

Pericystic Abscess.—Pericystic abscess may follow cholecystitis. It is especially common in the condition known as simple empyema. When a pericystic abscess exists, there is usually abdominal tenderness and rigidity and the temperature is raised. It is a suppurative process. The causative micro-organisms may have entered through a diseased gall-bladder wall, rupture not existing, or the abscess may be due to ulceration or perforation of the gall-bladder wall.

Treatment. Operation should invariably be performed. It is frequently difficult. After a pericystic abscess has been opened, it may be found necessary in some cases to extirpate the gall-bladder. In others, cholecystostomy and drainage will prove sufficient.

Suppurative and Infective Cholangitis.—The infective cholangitis is gall-stones lodged in the common duct. In those cases in which a gall-stone acts as a ball-valve. A. W. Robson, though he believes that infective cholangitis does occur when gall-stones are freely movable in the common duct, sets it forth as distinct from the common duct. It is much more common in such cases to find gall-stones in the common duct.

In such cases the patient gives a history of attacks of jaundice without fever for several years, and then of attacks of jaundice with fever. Finally comes an attack that is fatal. Jaundice, varying in intensity, ensues upon this, and it may fade, it seldom completely disappears between the attacks. Robson points out that the interval between the attacks may be long, and that the rigors may be repeated daily or at uncertain intervals. The gall-bladder is usually, but not always, contracted; and that if the inflammation has persisted for some time, the liver becomes distinctly enlarged. There are tenderness over the gall-bladder or in the epigastric region, and persistent jaundice which may vary in hue.

Infective cholangitis, even after it has lasted for a considerable time, may be recovered from; but it may pass on into an acute form in which poisoning takes place from the biliary elements. Cholangitis may arise, an empyema of the gall-bladder may develop, or there may be an abscess of the liver or some other dangerous or fatal complication. The ague-like attacks of infective cholangitis have been called *intermittent hepatic fever* (page 1034).

Treatment.—After an incision has been made, the duct is opened and the cause removed; but, as Mr. Robson points out, the complication should be anticipated. When one finds that carefully applied medical treatment has led to free the patient from gall-stones, they should be removed surgically.

Suppurative Cholangitis.—Suppurative cholangitis is usually a development of the ordinary infective cholangitis, which has just been discussed. Among the other causes that Robson sums up are acute infectious diseases, particularly typhoid fever and influenza; cancer of the bile-ducts; and catarrhal disease.

In this condition the liver enlarges notably and becomes tender. In some cases there is an empyema of the gall-bladder, but this is rare; in fact, the gall-bladder is usually very much shrunken. When, in a chronic case, there are enlargement of the liver, blocking of the common duct, and enlargement of the gall-bladder, the inference is in favor of cancerous obstruction of the common duct. If the obstruction is due to cancer, there will usually be little pain; but when it is due to gall-stones, there will be violent attacks of pain, accompanied by rigors and fever, with deepening of the jaundice. In this disease there is always jaundice, usually unfading; but in cases of a valve gall-stone in the duct it will be mitigated from time to time (page 34). The patient suffers with septic fever and very rapid loss of flesh.

The condition is generally fatal, unless operation is performed early. There is a strong tendency for abscess of the liver to form, and in one case in which I operated a subphrenic abscess had developed.

Treatment. Cholecystostomy with free and prolonged drainage. If an abscess of the liver exists, it should also be drained. If gall-stones are gathered in the common duct, they should be removed.

Typhoid Cholecystitis.—As previously stated, typhoid bacilli are usually present in the bile during, and perhaps are present months or years after, an attack of typhoid fever. They are not always present, however, in a case of cholecystitis following typhoid on which I operated an unidentified bacillus was found ("New York Med. Jour.," April 8, 1905); in a case on which I had made an artificial anus for typhoid perforation and subsequently performed intestinal resection I drained a greatly distended gall-bladder at the second operation and cultures of the bile remained sterile; and in a case of typhoid with distended and apparently inflamed gall-bladder in which I operated the bile was reported to be sterile. Because typhoid bacilli are usually present in the bile during typhoid does not mean that most cases of typhoid have cholecystitis; cholecystitis is not very common, and arises when bacilli are very numerous or very virulent, when vital resistance is lowered, when there is antecedent inflammation of the gall-bladder, when there are gall-stones, and particularly if there is a block of the duct causing stagnation of bile. Bacilli then may do no harm at all, but they may cause a catarrh, a purulent catarrh, suppuration of the gall-bladder walls, suppuration outside of the gall-bladder, or perforation. When bile or inflammatory exudate contains typhoid bacilli, agglutinins are present and may precipitate masses which become nuclei for gall-stones.

The most usual period for cholecystitis to arise is during the third week of the fever, but it is not uncommonly met with during convalescence and is perhaps mistaken for a relapse.

The condition may arise months or a year after the attack of typhoid, and yet a pure culture of typhoid bacilli may be obtained from the gall-bladder. Strange to say, cases of cholecystitis have been operated on in persons giving no history of having had typhoid, and typhoid bacilli have been obtained from the gall-bladder. Such a person may have had a very mild attack of typhoid, or he may be immune to typhoid fever and yet the bacillus may be capable of causing inflammation. Many cases of typhoid cholecystitis are probably unrecognized because of the trivial symptoms, or because a high position of the liver renders the real seat of pain obscure, because the general symptoms are uncertain, because toxemia blurs perception of pain, or because the condition is confused with appendicitis. It is rare in children, more common in adults. Most infections result from the bacilli ascending the common duct, some are by way of the lymphatics (Charles H. Mayo), some by an adhesion of the gall-bladder to the bowel, some by way of the portal circulation and the bile-ducts. Mixed infection may occur, and a secondary staphylococcus infection may be followed by disappearance of the typhoid bacilli. The symptoms of typhoid cholecystitis are pain and tenderness in the gall-bladder region, rigidity of the upper half of the right rectus muscle, perhaps a palpable mass, an elevated and remittent temperature, sweats, perhaps jaundice, and sometimes leukocytosis. In some cases perforation occurs. Erdmann reported 1 case and collected 34 from literature ("Annals of Surg.," June, 1903).

In an ordinary case without perforation incise and drain the gall-bladder.

If perforation exists, do cholecystectomy if possible; if not, drain. No attempt should be made to suture the perforation. If perforation exists and operation is not done, death is practically certain. Of 27 cases not operated upon, all died; of 7 cases operated upon, 4 recovered (Erdmann).

Gall-stones. Gall stones are formed during life in the gall bladder or bile-ducts by the agglutination of materials which have precipitated from bile. The nucleus of a gall stone may be a mass of bacteria, a blood clot, epithelium, crystals of cholesterol or carbonate of lime, or a cast of a small duct.* A condition of the body thought to lead to the formation of gall stones is designated by the term *cholelithiasis* (Brockbank). But one stone may be present or great numbers may exist. Solitary stones may be round or cylindrical. When several stones or many stones exist, the mechanical pressure often leads to the formation of facets (Naunyn). In color, calculi may be pale yellow, green, black, or brown. Some are heavier than bile and some are lighter. Brockbank gives the following varieties of gall-stones: pure cholesterol stones, stratified cholesterol stones, common or gall bladder calculi, mixed bilirubin-calcium calculi, pure bilirubin-calcium calculi, certain rare forms.† Gall stones usually take origin in the gall-bladder, may arise in the common duct, the cystic duct, the hepatic duct, or the small ducts of the liver. As a rule, however, calculi in the common or cystic duct are not formed there, but were transported from the gall-bladder or hepatic duct.

Causes.—Gall stones are very commonly found postmortem. In Germany it is estimated that they are found in 12 per cent. of all cases. In 1655 autopsies in the Johns Hopkins Hospital gall-stones were present in

* Bevan, in Chicago Med. Recorder, April, 1898.

† Brockbank's treatise on "Gall stones."

6.94 per cent. of all cases.* The usual estimate is 5 per cent. of autopsies. The cause is a catarrhal condition of the bile-ducts, due particularly to the entrance of bacteria from the intestine (colon bacilli, typhoid bacilli, pus-organisms, pneumococci). This catarrhal condition causes stagnation of bile. Healthy bile is sterile, but not germicidal, and bacteria will grow in it. Bacteria have been found in bile years after the termination of an attack of typhoid fever. Experimental infection of the gall-bladder producing mild cholecystitis is almost always followed by gall stone formation.† Welch pointed out that recent gall-stones have bacteria in their center. Cushing tells us that 30 per cent. of gall-stone cases operated upon in the Johns Hopkins Hospital had previously suffered from typhoid fever, but Mayo's experience is not in accord with this view. In view of the fact that bile containing typhoid bacilli must contain agglutinins we can understand how masses could be precipitated to form nuclei. Thirty per cent. of Ochsner's cases had had appendicitis.

The chief predisposing causes are advancing years, insufficient exercise, the daily consumption of unnecessarily large quantities of food, gouty tendencies, conditions which interfere with the emptying of the gall bladder, cardiac disease, and cancer of the liver. Gall stones rarely form before the age of thirty-five. The youngest patient I ever removed stones from was a girl of twenty. The disease is more common in the insane than in the mentally sound, in the white race than in the black, and in women than in men. In 5 per cent. of all females beyond sixty years of age gall stones are present (Naunyn). The special liability of woman may be brought about by tight lacing, pregnancy, inactivity, or movable right kidney. Stout and lazy women are particularly liable to gall stone formation and women who have born children are far more liable than those who have not. Total abstainers seem to possess a greater predisposition than users of alcohol, probably because they are more apt to be large eaters (Herbert F. Waterhouse, in "Lancet," May 8, 1909). There are two forms of the condition to be considered: the acute type, due to efforts made by the gall bladder or duct to expel the concretion, and the chronic condition, in which a calculus is lodged for a long time, or in which, as soon as one calculus is passed into the intestine, "another begins its journey" (Brockbank). The fact that bacteria cause the condition must not lead us to infer that pus is of necessity formed. The bacteria are present in small numbers, or else their virulence is greatly mitigated, they produce only catarrhal inflammation, the bile stagnates, and a stone forms. There may be one stone, two stones, several, or many stones. I have removed 200 from a patient. Multiple stones are faceted. Solitary stones are not faceted.

Many observers believe that inflammation of the mucous membrane causes the secretion of quantities of cholesterol, which material forms a large part of most gall-stones. Others maintain that cholesterol is a normal constituent of bile and is not obtained from the mucous membrane.

Bachmeister ("Munch. Med. Woch.," Feb. 18, 1908) demonstrates that pure sterile bile is permitted to stand for a considerable time cholesterol will be precipitated, and that if epithelial cells are added to this the cholesterol is precipitated much more rapidly. The catarrhal inflammation furnishes

* C. D. Mosher, in Johns Hopkins Hosp. Bull., Aug., 1901.

† Gilbert, in Archives générales de med., Aug. and Sept., 1898.

quantities of epithelial cells and the cells precipitate cholesterol, and in this way inflammation causes gall-stones. It is probable that when gall-stones exist they are all due to a common cause and all began to form at the same time. It is not likely that one begins and then another, and so on. After a stone once begins it may progressively increase in size. In many cases the stone or stones never cause trouble. A gall-stone may begin to descend because of violent muscular exertion, external pressure, or at the onset of a fresh inflammation which leads to loosening of the stone. A very small stone usually passes freely. A larger stone in passing causes colic. A still larger stone remains in the gall-bladder, or becomes fixed in the cystic duct or the intestinal outlet of the common duct. In most cases gall-stones form in the gall-bladder. In some they form in the common duct if stones have previously existed in the gall-bladder. When the common duct retains a stone and is suffering from some degree of obstruction and from infection, stones may form in the hepatic ducts (Wm. J. and Chas. H. Mayo, in "Am. Jour. Med. Sciences," March, 1905). Stones are occasionally found at necropsy in the radicles of the hepatic duct.

Symptoms.—The formation of a stone requires several months, and during the antecedent period of gastro-intestinal catarrh, "the prodromal state" of Kraus, certain symptoms may exist, viz: constipation, flatulence, loss of appetite, migraine, uneasy sensations in the epigastrium or right hypochondrium, sallowness of the skin, slight yellowness of the conjunctivæ, scantiness of urine, which excretion is saturated with uric acid, and may after a time contain a little bile. If this condition is not arrested by treatment, it grows worse. The abdomen becomes decidedly distended, pressure over the stomach or liver may cause distinct uneasiness or even pain, acid indigestion is very troublesome, violent attacks of migraine occur, constipation becomes more decided, the feces become clay colored, gastralgia may occur, the skin is apt to be slightly jaundiced, itching is complained of, the patient is irritable and sleeps poorly. The liver is found to be enlarged, and the urine contains distinct amounts of bile. When the patient reaches this stage, gall-stones are very liable to form. These symptoms may pass away even if a concrete forms. It is quite true that in some cases a stone exists for years without causing trouble. This is particularly true in elderly people. Often it causes unrecognized symptoms and seldom does it fail to cause some symptoms. In many cases the symptoms which stones cause are thought to be due to disease of the stomach (indigestion, flatulence, pain after eating, pyloric spasm, etc.).

As Waterhouse says (*Ibid.*), the symptoms do not bear any relation to the size or the number of the stones. In fact, gall-stones give rise to no symptoms only when infection occurs or when the ducts become occluded and fail to drain, or when a stone starts to pass. If infection occurs, it may pass away spontaneously, but seldom does so. When a stone forms, pain is apt to be a marked feature of the case. John B. Murphy ("Med. News," Nov. 1900) points out that in a person with stones in the gall bladder there may be:

1. The pain of acute inflammation, the result of a severe infection; in this condition there are abdominal rigidity and contracted gall bladder.
2. The pain of tension. In this there is not persistent abdominal rigidity but pressure always causes sudden and transient tension of the belly muscle.

Murphy's method of demonstrating tenderness of the gall-bladder is most valuable, and I always use it. It is as follows: Hook the fingers well up under the liver and tell the patient to take a deep inspiration. On inspiration pain becomes acute and respiration suddenly ceases.

3. Referred pain, which may exist with either of the above conditions. *Colic* is spasmodic pain, and means that a stone has left or is trying to leave the gall-bladder, and is in or is trying to enter a duct. Many persons with a stone or with stones in the gall-bladder never have colic. A sense of pressure or of soreness in the hepatic region, the result of cholecystitis, has added to it sudden and transient paroxysms of pain, due to the passage of thick bile from the gall-bladder and small ducts, or of gravel from the small ducts, urged on by bile pressure. When a stone begins to pass from the gall bladder, violent colic is experienced. Such a colic usually comes on very suddenly, and often about three hours after a meal. It may, however, come on gradually, the patient complaining greatly of flatulence. In some cases it is so sudden and violent as to simulate perforation of the stomach or duodenum. The reason colic is particularly apt to come several hours after a heavy meal is that at that time bile is passing down into the intestine. A bladder containing calculi often tolerates the presence of the foreign bodies for an indefinite length of time, and then suddenly resents their presence and ejects them forcibly or tries to eject them. The pains are violent, spasmodic, and paroxysmal, and over the hepatic and epigastric regions, "radiating upward over the right half of the thorax" (Kraus), and passing particularly from the epigastrium to the right shoulder-blade. The patient is profoundly nauseated and usually vomits, the abdomen is distended, and a condition almost of collapse is soon reached. The temperature is usually normal, or subnormal, but is occasionally somewhat elevated. The patient may shiver and sweating may follow, but rigors are rare. The respirations are shallow, the patient groans, cries out, flings himself about in bed, and often, in seeking for relief, assumes some strange or contorted position. He frequently holds one hand over the liver region. His expression is indicative of intense suffering and apprehension and sometimes of abject terror. The pain is one of the most awful a human being can feel and women who have it assert that the pains of parturition are trivial in comparison. The attack lasts a variable time, and terminates by the stone passing into the intestine or falling back into the bladder. The usual duration of an attack is from four to twenty hours. I have seen attacks that lasted three days, four days, or even five days, almost without intermission. It terminates suddenly if the stone passes or falls back in the gall-bladder. In many cases at the termination of the attack an enormous amount of clear pale urine is passed. During and for a time after the attack the gall bladder may be very tender. After the cessation of colic, if the feces are examined carefully during several days, the stone may be discovered. The fact that no stone is discovered does not prove that no stone has passed, because a cholesterol stone may be destroyed in the intestinal canal. If the stone is passed, jaundice almost invariably follows the colic in from twenty to thirty-six hours and lasts several days. The jaundice results from the stone being in the common duct. If stones do not pass from the cystic duct so as to enter or protrude into the common duct, jaundice does not occur. In 80 per cent. of my cases (excluding common duct cases) there was no history of jaundice. Even when a stone is lodged in the common duct jaundice may

be slight or absent. When jaundice arises after a colic, it comes on gradually, bile appears in the urine, and often, but not always, the stools become colored from absence of bile. Jaundice may be first noticeable in the urine in the conjunctiva. The skin is apt to itch annoyingly, even atrociously. The patient is constipated and very thirsty. The liver is enlarged and tender and the spleen is enlarged. Some writers state that the pulse is slow in jaundice. My experience is in agreement with the much larger experience of Moynihan, who says: "I have not found any reduction in the pulse-rate in jaundice unless a degree of chronic pancreatitis is present" ("Gall-stones and Their Surgical Treatment"). If the stone is impacted, after a time the pains become less violent, and may entirely cease. If it ceases and the stone does not move, pain does not recur; if the stone moves pains recur, and, usually, again and again the patient suffers from aggravation of them. An individual may live about with impacted stone, but again and again fierce attacks of colic occur, and if the stone is wedged immovably in the common duct, producing absolute obstruction, the patient becomes and remains deeply jaundiced. Continuous deep jaundice is seldom seen when stones are lodged in the common duct, because they are seldom absolutely fixed and hence seldom produce complete obstruction. Usually the stone moves from time to time or is at least loose so that bile gets by it at intervals. This condition constitutes the "ball-valve stone," and in it jaundice, though present more or less, is at times much more intense than at other times. It is a jaundice in which the hue is yellow, or deep brown, and it is a jaundice that wanes and deepens. It deepens after each colic and later wanes, but seldom entirely disappears while the stone remains in the duct.

In persistent jaundice due to gall stones the gall bladder is seldom enlarged. Courvoisier showed that when persistent jaundice is associated with enlargement of the gall-bladder the cause is usually pressure on the duct from without (malignant disease of the pancreas).

Slight jaundice is not always easy of recognition. Recognition is particularly difficult in sallow individuals and by artificial light. Moynihan prescribes Hamel's test for slight jaundice. It is made by drawing a little blood from a puncture of the lobe of the ear into a capillary tube and permitting the clot to stand for a few hours. If any jaundice is present the serum, which collects in the upper part of the tube, will be yellow ("Gall-stones and Their Surgical Treatment").

In certain cases when a stone is in the common duct an attack of colic followed by or accompanied by a chill or chills, which may be very violent, moderate, or slight, and by a febrile seizure resembling malaria and *hepatic fever*, or *Charcot's fever*. The temperature rises rapidly and in an hour becomes 104° F. or more, remains high for several hours, and then drops suddenly to normal. It may remain normal for a few hours, a day, two days, several days, or weeks. In this condition there are jaundice and tenderness of the liver. Charcot's fever is brief in duration. It usually means stone in the common duct. If stones are in the bladder, we are more apt to get a persistent slightly elevated temperature. These intermissions distinguish Charcot's fever from the remittent fever of sepsis, and the absence of the plasma in the blood and the history of colic distinguish it from malaria. The fever is due to intoxication with ptomaines from infected bile retained in the

by obstruction. The condition is ominous because it is due to infection, and means inflammation of the duct (*cholangitis*).

The chart of Charcot's fever shows sudden elevations, precipitate descents, and complete intermissions. Moynihan calls it the "steeple chart" ("Gall stones and Their Surgical Treatment"). When infection spreads widely in the smaller intrahepatic ducts, the temperature is high and does not remit. Continuous fever of this type has usually been preceded by Charcot's fever.

If a stone lodges in the cystic duct, it does not cause jaundice unless an end of the stone projects into the common duct. It grows in size from incrustation, prevents the entrance of bile into the gall-bladder, and the bladder may shrivel and thicken or become filled with mucus, the bile being absorbed (*condrops* of the gall-bladder). If a bladder so blocked becomes infected, pus forms, and the condition known as *empyema* of the gall-bladder exists. An *empyema* of the gall bladder may rupture into the bowel, the peritoneal cavity, or even through the skin.

The common duct is involved in 1 out of 5 or 6 cases of gall-stone disease*. Brewer points out that in 67 per cent. of cases the stone is in the duodenal extremity, in 15 per cent. in the hepatic extremity, and in 18 per cent. in the middle. If a stone blocks the common duct, jaundice always exists and persists. Blocking may be complete and the stone may ulcerate into the bowel or the peritoneal cavity. Blocking may be incomplete, the stone acting as a ball valve and producing *intermittent* colic and jaundice, which waves and deepens (page 1034). Fenger points out that if a stone remains fixed in the common duct, the liver becomes tender and enlarged; but if a stone floats about in the common duct, the gall-bladder undergoes atrophy. In complete obstruction the stools become clay colored and bilirubin is found in the urine. Fluctuating jaundice, with attacks of pain and fever, and a shrunken gall-bladder are strongly suggestive of a "ball valve" stone in the common duct. Persistent deepening, painless jaundice, the color of the skin becoming brown or even mahogany, associated with a distended gall-bladder, is strongly suggestive of malignant disease compressing the common duct. The above statements constitute *Courtoisier's law*. It is found true in 90 per cent. of cases. We may add that a persistent jaundice of yellow hue, varying somewhat, and associated with pain or with actual colic, suggests blocking of the duct by an immovable stone.

Gall stones may lead to suppurative inflammation of the gall bladder or bile-passages, ulceration, occlusion of the neck of the gall-bladder, dilatation of the stomach from the formation of adhesions which kink the pylorus, abscess, peritonitis, empyema of the gall-bladder, and cancer of the gall-bladder. In cancer of the ducts gall-stones are seldom found, at least are seldom found in the ducts. Eddes collected 22 cases of cancer of the papilla. In 3 of these cases there were stones in the gall-bladder, in 1 there was a stone in the common duct ("Boston Med. and Surg. Jour.," March 7, 1901). If the patient develops distinct infection of the gall-bladder or bile-ducts, he will suffer from chills, fever, and sweats.

Gall-stones may lead to cirrhosis of the liver. A stone may ulcerate into the bowel and cause intestinal obstruction. It may be difficult to make a diagnosis between gall stones with icterus and cirrhosis of the liver with

* Robson, in *Lancet*, April 12, 1907.

icterus. In the former case the urine contains bilirubin and in the latter case urobilin.

Treatment.—In the prodromal stage and after recovery from an attack insist on the patient taking considerable outdoor exercise. Direct him to take a cold sponge-bath every morning, to move the bowels freely every day, and to employ a simple diet. He should avoid all highly seasoned foods, pastry, rich soups, fatty food, cheese, alcohol, and sweets. Alkalies internally are of value.

During a colic give an enema, apply hot turpentine stupes over the hepatic region, and administer hypodermatic injections of morphin and atropin. If vomiting does not occur, let the patient drink a large amount of warm water to favor it. After the attack administer a purgative.

When the attack has terminated, examine carefully for any evidence of inflammatory trouble in the hepatic region.

In certain cases operation becomes necessary. Mr. A. W. Mayo Robson advises operation in the following cases: * in frequently recurring biliary colic without jaundice, whether the gall-bladder is enlarged or not; in cases of enlargement of the gall-bladder without jaundice, even if there is no pain in persistent jaundice which was ushered in by pain, painful seizures occurring, whether or not febrile attacks occur; in empyema of the gall-bladder in peritonitis beginning in the gall-bladder region; in intrahepatic abscess and in abscess about the liver, gall-bladder, or bile-ducts; in some cases where the stones have been passed, but adhesions remain and produce pain, in fistula cases; in some cases of persistent jaundice due to obstruction of the common duct, although there may be a possibility of cancer existing, in phlegmonous cholecystitis and gangrene of the gall-bladder. Besides these conditions, which may be produced by gall-stones, Robson operates for wounds of the gall-bladder, infective and suppurative cholangitis, and for some conditions of chronic catarrh of the bile-ducts and gall-bladder †. The tendency to operate early for gall-stones is growing. It is true that stones may cause no trouble, but sooner or later they are apt to, there is no tendency whatever to spontaneous cure, and medicine cannot dissolve them in the bladder. Early operations are easy and comparatively safe; late operations are difficult and dangerous, and by early operation dangerous complications (infection, adhesions, obstructive jaundice) are avoided. As Maurice H. Richardson ‡ says: An early operation is less dangerous than the passage of a stone; complications are avoided or lessened; even if the diagnosis is wrong, the condition may be found and removed. If obstructive jaundice exists, operation is dangerous because of the possibility of fatal oozing of blood.

The common operation is cholecystostomy, which consists in opening the gall-bladder, removing the stones, and making a temporary fistula in the bladder. The fistula is permitted to heal, after a time, hence many do it cholecystotomy rather than cholecystostomy. Operation should be done promptly and should not be delayed. To delay permits the gall-bladder to thicken and shrink, and allows the stone to enter the duct. After drainage of stones rarely reform. Wm. J. Mayo collected 2000 operations done by six

* Mayo Robson on the "Gall-bladder and Bile-ducts"

† Robson's treatise, from which the above is taken, is a valuable exposition of surgery of the gall-bladder and bile-ducts.

‡ Boston Med. and Surg. Jour. Sept. 5, 1901.

sons, and in not 1 case did stones reform. Kocher has seen stones recur in 1 case out of 31 cases of cholelithiasis after ideal cholecystotomy (suturing gall-bladder after removing stones), in 1 case out of 19 cholecystostomies, and in 1 case out of 30 cholecystectomies. The operation of incision, removal of the stone, and suture of the gall-bladder is known as *ideal cholecystotomy* or *cholecystendysis*. If calculi exist in the common duct, it may be possible, after cholecystotomy, to manipulate them back into the bladder and extract them from that viscus with a scoop, but this maneuver is impossible unless the cystic duct is dilated. In some cases the gall-bladder is incised, a fistula is made, and the duct and bladder are frequently irrigated. In other cases the stone may be crushed by the fingers manipulating the duct and the concretion within it (*choledocholithotomy*). Robson points out that crushing of the stone is apt to leave fragments which may cause trouble, and it should be done only when the stones are soft. It is wrong to endeavor to force a stone from the common duct into the duodenum. The attempt will fail, and in some cases the patient will be placed in a worse condition by the stone lodging in Vater's diverticulum.* The duct may be opened, and after the removal of the stone closed by sutures (*choledochotomy*) or drained for a time (*choledochostomy*), strands of gauze being carried down to the opening and in some cases a tube being carried up a dilated duct toward the liver. If the stone is impacted near the outlet of the duct, it may be necessary to incise the duodenum in order to remove the stone (*duodenocholedochotomy*). A dilated bile-duct may be anastomosed to the bowel (*choledochenterostomy*) or to the surface (*choledochostomy*). The obstruction may be side-tracked by anastomosing the gall-bladder to the bowel (*cholecystenterostomy*) (p. 1116). Cholecystenterostomy affords drainage, but does not remove the cause of trouble, and infection is apt to be received from the bowel. In some rare cases of common duct obstruction, in which the gall-bladder is distended and the condition of the patient is desperate, anastomose the gall-bladder to the colon (Robson). In some cases of diseased gall-bladder the viscus is removed (*cholecystectomy*). Cysticotomy is incision of the cystic duct. Wm. J. Mayo and others have pointed out that a danger in operations on the common duct is a sudden fall in blood pressure when the duct is being manipulated. All operators have observed it. Ransohoff maintains that it arises only when the portal vein is compressed.

Carcinoma of the Gall-bladder.—In 405 operations on the gall-bladder and biliary passages the Mayo brothers found malignant disease 20 times (5 per cent. of cases). (See Wm. J. Mayo, in "Med. News," Dec. 5, 1902.) Malignant disease may be primary or secondary. In primary carcinoma calculi are always present, and are apparently causative by maintaining chronic irritation. Stones are seldom present in secondary malignant disease.

Carcinoma of the gall-bladder can usually be palpated. It is hard and nodular, and seldom accompanied by much abdominal rigidity. There will be a long history of attacks of gall-stone colic and of recent or comparatively recent grave loss of flesh. Sooner or later jaundice arises, deepens, and persists. Cholecystectomy has been employed for this condition, but offers but little hope. In 2 cases in which I opened the abdomen without suspecting malignant disease of the gall-bladder the liver was hopelessly involved. In 1 case in which I operated for a supposed impacted stone in the common duct an operable cancer of the common duct was found.

* See A. W. Mayo Robson, in *Lancet*, April 12, 1902.

DISEASES AND INJURIES OF THE PANCREAS.

Wounds and Injuries.—The pancreas is very rarely ruptured although this sometimes occurs as the result of blows or crushes. In majority of cases in which the pancreas is damaged other organs are involved; for instance, the stomach, the spleen, and the liver. A gunshot wound of the pancreas is almost certain to injure the left kidney, the stomach or the vertebral column. It will be remembered that in the case of President McKinley the bullet passed through the stomach, damaged the left kidney, and injured the pancreas. Garré ("Beiträge zur Klinische Chirurgie" No. 1) collected 30 cases of subcutaneous rupture of the pancreas and in only 8 of these cases was the pancreas alone damaged.

Symptoms.—When the pancreas is injured alone, hemorrhage is not usually severe; but if adjacent organs are also damaged, it is sure to be profuse. Hence when adjacent organs are damaged there are apt to be immediate symptoms of severe intra-abdominal hemorrhage; but profound collapse is not often present when the pancreas alone is injured. In fact, symptoms may not arise for a considerable length of time after injury of the pancreas. A diagnosis at this stage is impossible without exploratory operation. Severe injury of the pancreas is usually, but not invariably, fatal. After slight damage of the gland the patient may completely recover, but, as a rule, he partly recovers, and, after a number of weeks, a smooth tumor, palpable in the epigastric region, is formed. When operation is performed, the tumor is found to be back of the stomach. It contains a quantity of blood clot, and pancreatic fluid. Such a fluid collection is in the lesser peritoneal cavity and is called a cyst, though it is not a true cyst of the pancreas. Robson and Moynihan, in their valuable treatise on "Diseases of the Pancreas," explain the formation of this collection of fluid as follows:

The injury lacerates the posterior layer of the lesser sac of the peritoneum and the pancreas, to which it is adherent. Blood and pancreatic fluid enter the lesser peritoneal sac. Peritonitis follows. The foramen of Winslow is blocked by adhesions; and the lesser peritoneal cavity, being now a closed sac, is distended with a serous exudate mixed with blood and pancreatic fluid. Collections of this character form very rapidly, and several may gather in a few days. Other results of injury to the pancreas are abscess, pancreatitis, and true cyst formation. A fistula may follow operation or rupture of the pancreas. Such a fistula is very troublesome, often refuses obstinately to heal, and the pancreatic fluid macerates the skin severely. The usual treatment has been to keep the fluid drained off. A treatment suggested by Wohlgemuth has proved successful in 5 cases ("Berliner Klin. Wochenschrift," 1908, No. 8). The fistula heal in from three days to six weeks. The treatment consists of strict antidiabetic diet and large doses of bicarbonate of sodium before and after meals.

By cutting out carbohydrates a powerful stimulus to the flow of pancreatic juice is removed. The bicarbonate of sodium lessens the activity of the stomach contents before they enter the intestine and it is known that hydrochloric acid strongly stimulates the flow of pancreatic juice.

Treatment.—Operation is imperatively demanded, although the p

acts are bad. Garré collected 8 cases, 3 were operated upon, and all died (ibid.). Garré reported a successful case of his own (ibid.). The pancreas was torn in two and the pieces were separated. The splenic vessels were injured. The two portions of gland were sutured together. This stopped the bleeding. Gauze packing was introduced. In a gunshot-wound of the abdomen, when exploration leads the surgeon to surmise that the pancreas has been injured, this organ should be approached by dividing either the gastrocolicomentum or the transverse mesocolon. The pancreas may also be exposed by dividing the gastrohepatic omentum. Accessory injuries must be carefully noted, and if a bullet has penetrated the posterior wall of the stomach, the pancreas is almost certain to be damaged. One should remember that, as Park says, even after opening the abdomen it is difficult to explore the pancreas, especially in a stout person. If there is no evidence of posterior perforation of the stomach by a foreign body, one may assume that the pancreas has escaped. When the pancreas is exposed, if it is found to be bleeding, the bleeding vessels should be ligated and the tear in the gland should be sutured, care being taken not to puncture the main duct of the gland. If this duct has been cut, it must be carefully sutured. In some cases of gunshot-wound it is necessary to resect a portion of the gland. At the termination of an operation upon the pancreas posterior drainage at the costovertebral angle should always be obtained. It is necessary to carefully drain away all escaping pancreatic fluid, as it tends to cause necrosis of tissue with which it comes in contact.

In cases of crush with pancreatic injury the associated injury to other structures usually proves rapidly fatal, but in a less severe case the abdomen may be opened for exploration, and if this is done, the surgeon should proceed as previously directed.

The question of excising a lacerated portion of the pancreas is one of great interest. It is known that dogs have lived for some time after complete excision of the pancreas. Four-fifths of the pancreas can be removed from a dog without producing permanent glycosuria, but if more than this is removed the dog develops saccharine diabetes and eventually dies of it. In man, quite large-sized pieces of the gland have been removed and recovery has followed. Hence it is justifiable to excise a hopelessly damaged portion, bearing in mind Park's caution that the chief danger in excising a portion of the pancreas is injury to the splenic artery.

Movable Pancreas.—In cases of splanchnoptosis the pancreas may become considerably displaced, though this condition cannot be recognized without opening the abdomen. So far, I know of no case in which fixation has been attempted, though, of course, theoretically it could be done.

Pancreatitis.—Pancreatitis often leads to the production of jaundice; it may lead to very rapid loss of weight; occasionally to the presence of fat and sugar in the urine; sometimes to the presence of fat in the stools; and frequently to the condition known as fat-necrosis. Robson and Moynihan point out that when there is no diarrhea and the stools contain undigested muscle-fiber, one may assume that there is a deficiency in pancreatic juice. When there is a blockage to the secretion from the pancreas, if salol is given by mouth, salicyluric acid does not appear in the urine. The test is made by putting gr. xv of salol into gelatin capsules hardened with formalin (Sahli) and giving them with a roll and a cup of water. If pancreatic ferment is in

the intestine, salicyluric acid appears in the urine in one hour or one hour and a half; if the ferment is absent from the intestine, salicyluric acid is not found in the urine because the salol is not split up and absorbed. The test for the acid is ferric chlorid, which, in the presence of the acid, turns the urine violet. The general cause of pancreatitis is infection. Obstruction of the common bile-duct is followed by infection and suppuration of the pancreatic ducts and pancreatitis. Besides the general cause, which is infection, various exciting causes may be named, among which are gall-stones in the common duct and calculi in the pancreatic ducts, traumatism, cancer of the stomach or duodenum, catarrh of the stomach or duodenum, and many infectious diseases. It thus becomes evident that the infection may be by way of the blood; but, undoubtedly, in the vast majority of cases, the infection comes by way of the duct. One manner in which the disease may be produced was suggested by Halsted and Opie, of Baltimore: A stone becomes impacted in the outlet of the common duct; the pancreatic duct, where it emerges above the common duct, not being blocked. The bile and pancreatic juice are thus prevented from entering the duodenum, and the bile flows back into the pancreatic ducts.

That strange condition known as *fat-necrosis* is often present in pancreatitis. In fat-necrosis the fat is decomposed into fatty acids and glycerin. The glycerin is absorbed, but the fatty acids unite with calcium salts and remain in the tissues, forming patches of yellowish-white color and varying size. These patches are found in the fat beneath the peritoneum, in the omentum, and in the mesentery, and even in distant parts (for instance, the pericardium).* It is an undoubted fact that fat-necrosis is not uncommonly found after diseases and injuries of the pancreas, and many assume that it is produced by the entering of the ferment of the pancreas into the fatty tissue. How the ferment gets there is a matter of some doubt. In the case of a wound of the pancreas one can understand the flow of the secretion and its imbibition by adjacent parts; but in other cases one must assume that it has been absorbed by the lymphatics and distributed to more distant parts. When one reflects that in some conditions of the pancreas there is no fat necrosis, while in others this condition arises, it is probable that the pancreatic conditions associated with it are such as to permit the fat splitting ferment to diffuse into neighboring tissues.

In pancreatic disease *hemorrhage* into that organ is common. The hemorrhage is not, of necessity, fatal, but frequently is so. Occasionally death takes place as the result of sudden pancreatic hemorrhage in a person apparently in excellent health. It is thought by Robson and Moynihan that during the existence of cancer of the pancreas there is a strong tendency to excessive hemorrhage after operation. In one case of my own the patient bled to death after the performance of cholecystostomy for obstructive jaundice. The oozing of blood in this case was from the margins of the gall bladder and the adjacent peritoneal surfaces. We therefore conclude that in certain conditions of the pancreas there is a tendency to local hemorrhage in that organ; and that there may also be a tendency to the development of a general hemorrhagic diathesis, the general hemorrhagic tendency being much increased if jaundice exists. During acute inflammation of the pancreas

* Robson and Moynihan, on "Diseases of the Pancreas."

Hemorrhage is almost certain to occur into that gland; in other varieties of inflammation hemorrhage may occur or may be absent. In degenerative lesions of the pancreas a material like unfermented pentose is frequently present in the urine. When the reaction for this material is obtained we speak of it as the Cammidge reaction, after its discoverer. (For Cammidge's improved method, see "Brit. Med. Jour.," May 19, 1906).

Forms of Pancreatitis.—This disease is divided by Robson and Moynihan into the acute, the subacute, and the chronic form; and they say that recorded cases demonstrate the fact that three distinct classes of inflammation may arise: (1) Cases that die within forty-eight hours of the beginning of the trouble. In this group hemorrhage is usually found; and if fat-necrosis is present, it is limited in area. (2) Those that live for some weeks after the beginning of the trouble. In these cases the pancreas may become necrotic or suppuration may occur. Fat-necrosis is usually wide-spread. (3) In the third class of cases long-continued inflammation or repeated attacks produce sclerosis of the pancreas.

Acute Pancreatitis.—The symptoms of this condition come on suddenly and consist of violent pain in the epigastric region, vomiting, constipation, rapidity and weakness of the circulation, cold extremities, and collapse, with a great fall in blood pressure. Some maintain that collapse is due to trypsin, others that it results from the absorption of toxic products from the gland. The pain is extremely violent and is intensified in paroxysms, and there are distinct tenderness and rigidity of the epigastrium. The patient vomits the contents of the stomach and then bilious matter. Distention soon becomes distinct in the upper portion of the abdomen. The patient presents the appearance of one suffering from peritonitis. This condition is not unusually mistaken for intestinal obstruction, but in acute pancreatitis the constipation is not absolute, the patient passes gas, and may even have a bowel movement as the result of the administration of an enema. The condition is usually fatal within a few days, but in very rare instances recovery takes place. In acute pancreatitis from stone in the common duct there is no leukocytosis (Murphy).

The diagnosis cannot be made with certainty and is merely an inference. Reginald Fitz tells us that the existence of this disease should be suspected when a person previously in good health, or who has complained only of occasional attacks of digestive disorder, is suddenly seized with severe pain in the epigastric region, followed by vomiting and collapse; and when, within twenty-four hours or more, there appears a circumscribed swelling in the epigastrium which is resistant or tympanitic. When an exploratory incision is made in the abdomen, if fat necrosis is detected, the diagnosis becomes certain.

In acute pancreatitis the pancreas undergoes rapid necrosis, due, according to some experimenters, to the entrance into the pancreatic duct of bacteria from intestine, and according to others to digestion of the pancreas by its own fluids. The fluids when normal certainly will not digest the pancreas. It seems probable that trypsin is "activated" by the entrance into the duct of material from the duodenum and bacteria may be responsible for activating trypsin (Polya, in "Pflüger's Archiv.," cxxi, Heft 9 and 10).

Treatment. Operation was suggested by Nahn, in 1903. The exploratory operation is carried out in front, and the earlier it is made the better. Robson

operates at once, even in shock. It is quite true that the patient might, if let alone, pass through the acute stage, and that a local abscess might then form, the treatment of which would be obvious. But the danger of waiting is too great to justify delay, and if suppuration should occur it might not remain local, but might spread widely in the retroperitoneal tissues. When observation after exploratory incision into the greater cavity of the peritoneum suggests the existence of acute pancreatitis, the infected area should be exposed either above the stomach through the gastrohepatic ligament, or below the stomach through the gastrocolic omentum. The pancreas should be incised, hemorrhage should be arrested by ligation or packing, an incision should be made at the costovertebral angle, and posterior drainage should be made from the lesser peritoneal cavity. One should follow the rule laid down by Roswell Park, and explore in every case in which the disease is suspected to exist.

Subacute Pancreatitis.—Subacute pancreatitis comes on suddenly, with violent pain, vomiting, and constipation, but there is far less exhaustion and weakness than in the acute form. The vomiting is less marked and the swelling in the epigastric region is not so rapid. The symptoms are similar to those of the acute form, but not so violent nor so rapidly progressive. The temperature frequently rises higher than in the acute form, and it may become irregular or chills may occur. In many cases the patient seems to grow better after a time, the violent pain abating, though some pain and tenderness remain; but he does not gather strength and continues to lose flesh, and there is usually albumin and there may be sugar in the urine. In rare instances fat is found in the urine. In subacute pancreatitis abscess is prone to form. This abscess may make a distinct swelling in front, and may lead to the development of a subphrenic or of a perirenal abscess. In rare cases an abscess of the pancreas tracks its way for a long distance in the subperitoneal tissue, occasionally it opens into the stomach or bowel. Cases of subacute pancreatitis occasionally recover after a long illness, but usually they die.

Treatment. Exploratory incision. Expose the pancreas, either above or below the stomach, determine the condition, remove purulent matter and necrotic areas, arrest hemorrhage with packing; and insert posterior drainage at the costovertebral angle. In some cases close the anterior wound, and in others leave it open.*

Wm. J. Mayo† reports a successful operation for subacute pancreatitis. The patient was a man of fifty-two years, who, seven days before Mayo saw him, had developed violent pain in the epigastrium, collapse, distention, and other signs of intestinal obstruction; but some slight movements had taken place from the bowels, as the result of medication. On admission, the abdomen was tympanitic. An ill-defined mass the size of a fist could be palpated to the right of and above the umbilicus. The pulse was 120 and very weak; the temperature, between 101° and 102°, and there were slight jaundice, restlessness, and hiccough. A diagnosis of gangrenous cholecystitis was made. The abdomen was opened, and the omentum was found to be studded with thick, adherent, infiltrated round spots, the size of a pea or larger. There were some similar spots in the mesentery, and the peritoneal cavity con-

* Roswell Park, *Annals of Surgery*, December 15, 1901.

† *Jour. Am. Med. Assoc.*, Jan. 11, 1902.

tained bloody fluid. On palpation, the pancreas felt like a pudding in a tight sac; and on aspiration a little blood was obtained. The gall bladder was opened, a stone was removed, and some pus was evacuated. Drainage was inserted into the gall bladder, and eighteen days later there was an enormous flow of bloody fluid, containing bile and pancreatic juice, from the drainage-tube. The patient recovered. This plan of treatment free drainage of the pancreas by the performing of cholecystostomy is to be taken into consideration.

Chronic Pancreatitis.—There are many causes of chronic pancreatitis, viz., syphilis, alcohol, bacteremia, block of the common duct (stenosis, stone, etc.), extension of inflammation from the bile-ducts, and ascending infection from the duodenum. It usually results from disease of the bile passages and is often associated with gall-stones. In 2200 operations performed by the Mayo brothers on the gall bladder and bile-ducts, the pancreas was found diseased 141 times (6.4 per cent.).

In 168 cases of pancreatic disease on which they operated, 81 per cent. were caused by or, at least, associated with gall-stones. In operations upon the common or hepatic ducts the pancreas was diseased in 18.6 per cent. of cases. It was diseased in 4.45 per cent. of cases of operation upon the gall-bladder. Chronic pancreatitis produces enlargement of the organ, and the enlarged area is hard and feels like a malignant growth. This condition is more common than is the acute or subacute form. Robson and Moynihan have operated upon 30 cases. The disease is frequently associated with gall-stones or with stones in the pancreatic duct, and occasionally with ulcer of the stomach or of the duodenum. In some cases symptoms of the condition come on acutely. Pain, nausea, and vomiting occur, and jaundice develops rapidly, as it does after the passage of a gall-stone. It is noted, however, that the pain is not in the region of the gall-bladder, but is in the middle of the epigastrium, and it passes to the left rather than to the right. The tenderness, too, is in the middle of the epigastrium and not in the gall-bladder region. There is either constipation or diarrhea. A series of these attacks may occur, the jaundice growing worse after each attack. In some cases, however, the condition comes on gradually and insidiously, the pain slowly developing, but no violent seizures taking place. There are rigidity of the rectus muscles, rapid loss of flesh, anemia, sometimes bronzed skin, usually vomiting, and considerable flatulence. The gall bladder is enlarged and commonly palpable.

In some cases it is possible to palpate the inflammatory mass. There may be irregular fever and chills with episodes of subnormal temperature. None of the above indications are conclusive signs of disturbed pancreatic function. Signs of disturbed function of the gland are of great importance in making the diagnosis, and these signs are glycosuria and impaired power of digesting fats and proteids (Walko, in "Arch. f. Verdauungskrankheiten," 1907, xlii). Fatty stools containing bile and unsaponified neutral fat are very significant.

The jaundice in chronic pancreatitis results from compression of the duct by the hyperplastic mass, or blocking of the duct by a stone. Stenosis of the duodenum may occur. In jaundice from chronic pancreatitis capillary hemorrhage is particularly common (Robson). Mayo Robson attaches much importance to the Cammidge reaction. In the Jefferson hospital we regard it as often of decided use, but we do not as yet attach as much importance to it as

puted; but sometimes diarrhea occurs, and the movements may even contain blood. If the tumor presses upon the common bile-duct, jaundice will develop. The patient loses flesh markedly and with considerable rapidity, and he becomes very weak. In rare instances fat is present in the stools, and in other unusual cases sugar is found in the urine. A test should always be made with salol, to see whether pancreatic ferment is present in the intestine (page 1019). In the beginning the pancreatic cyst is behind the stomach; but it enlarges and, as a rule, pushes the stomach upward and to the right side, and the transverse colon downward. The cyst approaches the surface of the abdomen below the greater curvature of the stomach (Robson and Moynihan). The same authors tell us that in rare cases the cyst appears at the upper border of the stomach, and that in others it inserts itself between the layers of the transverse mesocolon. In the case upon which I operated it had worked its way through the subperitoneal tissue into the right loin, and had been looked upon by Professor Montgomery and myself as a hydro-nephrosis. As a rule, the pancreatic cyst is immovable; but in rare instances it is movable. When a hand is placed in the loin and another on the abdomen, ballotement may be appreciated. If the distended stomach or colon overlies the tumor, there will be a tympanitic percussion-note; but when the tumor reaches the abdominal wall, there will be a dull percussion-note. On inquiring into the history of these cases, it will frequently be found that there has been a severe injury to the upper abdomen.

Treatment.—Exploratory incision makes the condition clear. In the majority of cases the cyst is incised, emptied, and stitched to the wall of the abdomen. This operation may be done in two stages—first, exposing the cyst and fixing it to the abdominal wall; and, second, when adhesions have formed, opening it. As a rule, however, it is performed in one stage, the abdominal cavity being carefully protected with gauze. Some authors advocate exposing the cyst, opening and evacuating it through the abdominal wound, and draining through the loin. Complete extirpation is usually impossible because of the adherence of the cyst. If the cyst is movable, extirpation may be carried out; but the safest operation consists of incision and drainage.

Tumors and Other Growths of the Pancreas.—The pancreas may be affected with sarcoma, carcinoma, adenoma, tuberculous disease, or syphilis.

Treatment.—Attempts have been made to remove tumors of the pancreas. After an exploratory incision has determined the condition, the pancreas is exposed at the point at which the tumor projects. This is usually done by an opening in the gastrocolic omentum. If the tumor is in the tail of the pancreas, however, the exposure may be effected in the flank. When the tumor has been exposed, an attempt may be made to enucleate it. Tumors of the splenic portion of the pancreas have been removed. Total pancreatectomy or complete resection of the head of the gland should not be attempted.

In a large tumor of the head of the pancreas palliate the condition by cholecystenterostomy. Villar reports 13 cases of partial resection of the pancreas for tumors with 5 recoveries from operation ("French Surgical Congress of 1905").

INJURIES AND DISEASES OF THE SPLEEN.

Wounds of the Spleen.—A wound of the spleen causes great hemorrhage, and if surgical aid is not soon at hand, will inevitably produce death. It is caused by a bullet or a stab and, as a rule, other viscera are also damaged. Immediate operation is indicated.

Rupture of the spleen is unusual if the organ be healthy, but does occasionally occur from crushes. It is rarely found unassociated with other injuries. The spleen may be dislocated as well as ruptured. An enlarged spleen is particularly liable to rupture not only from a crush, but from a kick, a blow, or a fall. Rupture of the spleen produces pain and rigidity in the left hypochondriac region and the signs and symptoms of intra-abdominal hemorrhage. There is tenderness over the spleen, pain over the heart, and great shortness of breath. The bleeding is profuse, but sometimes slow. The splenic blood contains numerous leukocytes and clots rapidly, hence the bleeding may be arrested for a time, and if it should be the patient will not bleed to death rapidly and reaction will generally occur (Ballance). The blood in some cases clots so rapidly that it gathers in the left loin, and is not commonly diffused throughout the abdomen. It gives rise to an increasing area of dulness on percussion in the left flank, which, Ballance points out, does not shift when the position of the patient is shifted, as it does in bleeding from other intra-abdominal structures. In some cases, however, the blood remains fluid and spreads throughout the belly, and then there is rising dulness in each flank. The case reported by Le Dentu and Mouchet shows that the blood may remain fluid ("Bull. de l'Académie de Med.," June 16, 1903). In some cases the signs of hemorrhage are late and they may even be deferred until the fourth day (Eisen-drath, "Annals of Surgery," Dec., 1902). Exploratory incision will be required to certainly recognize the condition. In Elder's table there are 5 uncomplicated cases, not a case was operated upon (operation was not the rule until 1890), and 84.6 per cent. died. Eisendrath has collected 30 cases operated upon 56 per cent. recovered and 44 per cent. died*. Févret† has collected 56 ruptures of the spleen. In 46 cases operation was performed and the mortality was 50 per cent. E. Berger ("Archiv für klinische Chirurgie," Bd. 28, Heft 3) collected 168 fatal cases of rupture of the spleen 145 died during the first day and every one died from hemorrhage. After the first day 23 died. In 90 per cent. of the entire series hemorrhage caused death; in 10 per cent. infection was responsible for death. The same author collected 67 cases treated by splenectomy and 38 of them recovered. Hemorrhage is the great danger in ruptured spleen—hemorrhage of the parenchyma rather than from the great vessels. The parenchyma is friable and contains multitudes of capillaries and veins, there is no muscular tissue, divided vessels do not tend to contract, and the capsule is thin. (The elder Senn, in "Jour. Am. Med. Assoc.," Nov. 21, 1901.)

Treatment of Wounds and Rupture.—The treatment is evident from the previous remarks. It is as follows. Open the abdomen immediately, the patient being surrounded with hot bottles and hot salt solution flowing

* Darse, N. Eisendrath, Jour. Am. Med. Assoc., Oct. 25, 1902.

† Rev. de Chir., Nov., 1901.

into a vein. Explore the spleen and other viscera. If the spleen is damaged, we may do splenectomy (total or partial), may use the suture, the cautery, or the tampon, and any other visceral injuries are, of course, attended to.

The usual operation has been total splenectomy. In partial splenectomy only the injured part is excised and the wound margins are sutured.

The arrest of hemorrhage by suture is known as *splenorrhaphy*. *Lamarchia*, in 1896, was the first to perform this operation. The tear or wound is sutured with catgut and the suture line is covered with omentum. *Berger* collected 14 cases of suturing with 2 deaths, but these were injuries of less severity than those requiring splenectomy. In some cases the tampon can be used. *Berger* collected 10 cases with 1 death. Another method is to crush the splenic structure slowly with broad forcipressure forceps and suture the crushed margins with catgut. *Senn* followed this plan. *George Ben Johnston* (paper read before "Johns Hopkins Med. Soc.," March 2, 1908) has collected 150 cases of splenectomy for wounds or ruptures, with 99 recoveries and 51 deaths, a mortality of 34 per cent.

Abscess of the spleen is a rare condition which is usually metastatic in origin. It may follow typhoid, may develop during pyemia, or may result from injury. Chronic suppuration may be due to tuberculosis or actinomycosis. Pain is felt, and enlargement is noted in the splenic region, and the symptoms of pyemia exist. The abscess may become adherent to the belly wall, may become encapsuled, or may rupture into a viscus or the peritoneal cavity. Fluctuation can seldom be obtained. What is known as a tropical abscess (*Fontoyant and Jourdrau*, in "Archiv. Prov. de Chir.," No. 11, 1902) may develop during a malarial attack as a result of severe exertion. There are severe pain in the left hypochondrium, dyspnea, and dry tongue. There may or may not be fever. The pus may be sterile.

The treatment of abscess of the spleen consists in incising the abdomen at the outer edge of the left rectus muscle, suturing the spleen to the abdominal wall, opening the abscess, and providing for drainage (*Tédénat**). If the abscess is adherent to the abdominal wall, incise it directly. There are 9 recorded cases of splenectomy with 1 death (*George Ben Johnston*, *Ibid.*).

Enlargement and Tumors of the Spleen. The spleen undergoes hypertrophy in the course of infectious disease, from amyloid disease, from malaria, from splenic anemia, from tuberculosis, from leukemia, and from Hodgkin's disease. Secondary cancer is seen after cancer of the stomach. Genuine primary tumors are extremely rare. Fibroma, enchondroma, lymphangioma, angioma, and sarcoma occasionally develop. *Jepson and Albert* reported a case of primary sarcoma of the spleen and collected 31 others from literature ("Annals of Surgery," July, 1904). Primary carcinoma is usually medullary and is sometimes melanotic. Secondary carcinoma and secondary sarcoma are more common. Secondary cancer, as stated above, is seen after cancer of the stomach. Hydatid cysts, dermoid cysts, lymph cysts, serous cysts, and blood cysts occasionally develop. There are on record 12 cases of splenectomy for sarcoma: 9 recovered and 3 died (*George Ben Johnston*, *Ibid.*).

Treatment. The condition may become clear only after exploratory laparotomy. For some tumors splenectomy is indicated. A hydatid cyst is

* *Rev. de Gynéc. et de Chir. Abt.*, July, August, 1901.

treated as is a cyst of the liver (page 1016). A blood cyst is sutured to the incision in the abdomen and is drained.

Splenoptosis, or Wandering Spleen.—The spleen may wander into any part of the general peritoneal cavity. This condition is seldom met with except in women. It is most common in women who have borne children. A wandering spleen may undergo atrophy, engorgement, or axial rotation (J. Bland Sutton). The spleen may be healthy or enlarged from malaria or leukemia. As a matter of fact, it is usually diseased. The organ when displaced drags upon the stomach, producing dilated stomach; it may interfere with the bile-duct, causing jaundice; it may cause intestinal obstruction by forming adhesions, or may cause uterine retroflexion or prolapse by passing into the pelvis.

J. Bland Sutton says this condition may endanger life, as it may lead to rupture of the stomach, intestinal obstruction, splenic abscess, or splenic rupture.* A wandering spleen can be identified by the fact that it has a notch upon its edge, and can be pushed about the abdomen. When this condition exists, the spleen may be missed from its normal situation. Always examine the blood in order to determine if leukemia or malaria exists.

Treatment.—Greiffenhagen advocates suturing the organ in place (splenopexy). Most surgeons prefer to perform splenectomy. In a case with leukemia the operation is very successful. Splenectomy for wandering spleen is rarely followed by serious blood-changes or other trouble. The reason is that a wandering spleen is usually a diseased organ, having undergone hypertrophy or fibroid change, and other structures have taken on splenic function. Splenectomy should not be undertaken if leukemia exists. In such a case surgeons usually apply a support and employ medical treatment for the existing disease or endeavor to suture the organ in place. If the spleen were enlarged by malaria, I would perform splenectomy (as I did in one case). If the spleen were healthy, I would surround it with gauze exactly as is done with the kidney in a case of movable kidney. If the spleen were enlarged by leukemia, I would not operate.

OPERATIONS UPON THE ABDOMEN.

Abdominal Section (Celiotomy; Laparotomy)—There are many different methods of opening the abdomen. The plan selected depends upon the nature and the situation of the disease, and upon the inclinations and the custom of the operator. The abdomen may be opened to attack a recognized seat of disease or to determine what the disease is and where it is situated. Abdominal section performed for the latter purpose is spoken of as exploratory section or exploratory incision.

Of recent years, exploratory operations have become extremely common and many abdominal conditions would be unrecognized without such exploration, or would be recognized at so late a period as to be beyond the reach of surgery by the time the diagnosis had been made. This is notably true of the surgical diseases of the stomach. The surgeon should, however, not be too radical in employing exploratory operations. The fact that he

* Brit. Med. Jour., Jan. 16, 1897.

explore with such comparative impunity does not release him from the obligation to endeavor by every proper method to make a diagnosis before resorting to operation. I fancy that of recent years the belief that it is almost waste of time to make prolonged efforts to diagnosticate many intra-abdominal troubles because the solution is so much easier by section, has become common as to have led young and unskilled operators to perform section in cases in which the diagnosis might have been made without this procedure.

Before opening the abdominal cavity for exploratory purposes or to gain access to some area of abdominal or pelvic disease the patient is carefully prepared as for any other operation. In an appendicitis case the patient is moved with the utmost care and is prepared for operation most gently, because of the possible danger of rupturing an abscess. In an emergency case no prolonged or complicated method of cleansing can be employed. The abdomen and loins are scrubbed carefully with soap and water, special attention being given to the umbilicus; the pubic region is shaved, the soap-suds are washed away with sterile water, the surface is gently scrubbed with alcohol and then with a hot solution of corrosive sublimate (1 : 1000), and covered with gauze wet with the sublimate solution. As previously stated (page 59) we no longer regard it as necessary to "prepare" the abdomen the day before. The patient can be prepared antiseptically the morning of operation, or can be shaved just before etherization, and be cleaned down under ether. The instruments required depend upon the nature of the case. As a rule, there are required scalpels, scissors, a dry dissector, pairs of dissecting forceps, hemo-static forceps, pedicle forceps, Hagedorn clips, calyx-eyed intestinal needles, a needle-holder, drainage tubes, gauze sponges, gauze for sponging, silk, catgut, silkworm-gut, the Paquelin cautery, electric light, also an instrument and a saline solution for hypodermoclysis or intravenous infusion. Always count the instruments, sponges, and pads, write down the number, and count them again after operation. This rule is adopted so that no instrument, sponge, or pad will be left in the abdomen. The abdominal pads and sponges are not used when dry. Dry sponges injure the peritoneum and favor the subsequent development of adhesions (Sanger). The pads and sponges should be wrung out in hot normal salt solution before being used.

Operation.—An anesthetic is given. In some cases the patient is placed supine; in others, is put in the *position of Trendelenburg* (Fig. 529). In the Trendelenburg position the pelvis is elevated, the intestines fall toward the epigastrium, are removed from the necessity of being handled and from danger of being bruised, the pelvis is thoroughly exposed, and work comes easier and safer. This position should not be used if there is myocardial disease, as the increased pressure in and flow of blood in the inferior cava may cause fatal acute dilatation of the heart (Kraske, of Freiburg, in *Proceed. of German Surg. Congress*, 1903). The position is of little use in very fat people (Trendelenburg), and in such a subject may cause intestinal obstruction (Kraske). When this position is employed, the table should be lowered as soon as possible, because aortic hemorrhage may occur (von Eiselberg). The normal position

should not be suddenly assumed, as this may cause intestinal obstruction the omentum being mixed with coils of intestine, pulling the colon (Pasteau, in "Bulletins and Mém. de la Soc. Anat. de Paris," July, 1891). The position should not be used in a pelvic abscess (König), as it may lead to a flow of pus from the pelvis into the far more dangerous regions.

Volvulus of the ileum and also volvulus of the large intestine have been cured by the use of the position. If the Trendelenburg position was employed, before closing the belly return the omentum to its proper position and spread it out (Lauenstein). In every abdominal operation the patient is carefully protected from cold, the extremities and the chest are covered with blankets, sterilized sheets are placed well around the field of operation. The skin is sterilized immediately before operating. The surgeon

Fig. 529.—The Trendelenburg position.

steadies the skin of the belly with the fingers of his left hand, and, holding the knife free in the right hand, makes an incision. For purposes of exploration the incision is made about two inches in length, and it is lengthened if it is necessary. The abdomen may be opened in the median line above or below the umbilicus. This incision is advantageous for operations on the stomach, for general exploration, and for certain procedures upon the small intestine, and the left lobe of the liver. The closure of such an incision, however, lacks strength, as compared with the closure of an incision where the muscles will overlies the scar through the peritoneum and the transversalis fascia. Incision through the semilunar line is practised by a number of operators. A favorite incision is through the rectus muscle. The fibers of the muscle are separated, the structures beneath it are divided, and, after the completion of the operation, the deeper structures are sutured and the parts separated muscle are allowed to fall together. The scar resulting from an incision is well supported and solid, hence the likelihood of hernia developing is diminished. A favorite method with some is to open the sheath of the rectus muscle, retract the entire muscle aside, incise the posterior part of the sheath and the structures back of it, and, when the operation has been completed, allow the entire muscle to come back into place, and thus obliterate the deep-seated scar. When the abdominal trouble is in a region that admits of it, I almost invariably go through the rectus muscle or retract the entire muscle. Besides these methods, there are special incisions, such as for particular cases: An incision along the costal margin, for reaching the gall-bladder; an incision shaped like the italic letter "J," for the same purpose; special incisions for certain operations upon the stomach, for abdominal nephrectomy, etc. Some operators have even used a transverse incision in certain pelvic operations.

In an operation through the median line the first cut goes to the aponeurosis of the external oblique muscle. Clamp the vessels. Do not cut the linea alba below the umbilicus, but go right through or between the recti muscles. Above the umbilicus the linea alba is very distinct and the surgeon often cuts through it. Divide the transversalis fascia, beneath the

is a little fat, and expose the peritoneum. The latter structure is recognized by its glistening appearance, by the ease with which it can be pinched up between the finger and thumb, and by the readiness with which its opposed surfaces may be made to glide over each other. On identifying the peritoneum, catch it at each side of the incision with forceps, raise a fold, nick it with a knife, and open it with scissors to the length of the external wound. To prevent stripping of the peritoneum a good plan is to anchor it to the belly-wall with a stitch on each side of the incision. Through the wound thus made the abdomen and its contents are explored, the trouble located, and determination made as to whether or not further operation is advisable, and, if it is advisable, what form it shall take. It may be necessary to enlarge the wound. This is done by placing the index and middle fingers of the left hand in the belly, with their pulps against the peritoneum, in the line where the surgeon will cut, to serve as supports to the scissors and as guards to intraperitoneal structures. The scissors are introduced and the wound is enlarged upward, around the umbilicus if necessary. As soon as the incision is complete it is a good plan to push a large pad into Douglas's pouch and leave it there until the operation is finished, when it must be removed. Slender adhesions are stripped off with the finger or are pushed off with gauze; firm adhesions are tied in two places and cut between the ligatures.

The toilet of the peritoneum is important after the operation is completed. Following a clean laparotomy, when but little blood has flowed into the cavity, flushing is not required; if much blood has flowed or if septic matter has passed into the peritoneal cavity, after removing the sponge from Douglas's pouch flush the belly thoroughly with hot normal salt solution, empty out most of the fluid, but let a pint or more remain in the abdomen. In flushing the abdomen bear in mind Monks's observations as to the mesentery. It is a sort of shelf. If we follow down the left side of it with the finger the finger must enter the left iliac fossa; if we follow down the right side of it the finger must enter the right iliac fossa. Hence in order to flush the right cavity carry the nozzle down the right side of the mesentery to its root, and in order to flush the left fossa carry it down the left side of the mesentery to the root (Monks, "Annals of Surgery," Oct., 1903). The retention of the saline fluid in the belly minimizes shock. It is absorbed with great rapidity after the operation if the patient is placed with his head lower than his feet, because in this position the saline fluid gravitates to the diaphragmatic region, where absorption is very active; in fact, in one hour the peritoneal cavity can absorb from 3 to 8 per cent. of the body weight. If there is wide-spread infection with stomach-contents or feces, eviscerate, wipe out the peritoneum with pads soaked in hot normal salt solution, and wipe the intestines carefully, slowly returning them as they are wiped. Extravasated septic matter is apt to collect in the peritoneal fossae and between the liver and diaphragm, and these regions must be carefully wiped or irrigated. In cases of septic and purulent peritonitis flushing, evisceration, and wiping with gauze are not advisable (page 1006). In some cases it is desirable to drain through a lumbar incision. Rutherford Morison has pointed out that a lumbar opening into the right kidney pouch will drain a fossa which holds

over a pint of fluid, and which, when the patient is recumbent, is the most dependent portion of the peritoneal cavity. In some cases a drainage opening is made on each side of the belly or above the pubis or through the vagina. In septic cases it may be advisable to drain with several pieces of iodoform gauze instead of inserting tubes. After most laparotomies drainage is not needed, but it should be used when stomach-contents were extravasated, and it must be used if feces or urine were extravasated, in certain non-septic cases, and when hemorrhage has been severe. We may drain with a rubber tube, strands of gauze, or a glass tube. If a glass tube is used, it is introduced at a lower angle of the wound and reaches the bottom of the pouch of Douglas. This tube is repeatedly emptied during the progress of the case by means of a syringe. Before closing the wound arrest hemorrhage and count the instruments and sponges to know that no instrument or sponge has been left in the belly.

It is highly important that an abdominal incision shall be accurately closed, for any failure of neat approximation will, in all probability, result in the formation of a hernia through the cicatrix. Various methods have been employed. Probably the majority of operators use layer sutures, sewing up the peritoneum with a continuous suture of catgut, and the neurotic layers with the same material or with chromicized catgut, and close the skin with either interrupted sutures of silkworm-gut or a subcutaneous stitch of catgut, silkworm-gut, or silver wire. Other operators close the peritoneum with a continuous suture of catgut, then pass silkworm-gut sutures through all the other structures, leaving them for the time unput in layer sutures of catgut or of chromicized catgut, and then tie the silkworm-gut sutures. A layer suture makes a beautifully neat approximation, and is frequently quite satisfactory; but I have become persuaded that the dead space, so often left unobliterated when this method of suture is employed,—a space in which blood and inflammatory exudate may gather—is a danger to the future integrity of the wound. The combination of a dead space with catgut, a material that is always somewhat uncertain, is an unfortunate one from the surgical point of view. Recently I have turned to the use of the through-and-through suture in many cases, according to the method of Dr. Joseph Price. This suture is inserted with a straight needle, is composed of silk or of silkworm-gut, is put in close to the margin of the skin, gathers up a great deal more muscle than skin, and then close to the margin of the cut peritoneum and transversalis fascia. When these sutures are adjusted, the peritoneal edges are brought into accurate and firm apposition, the peritoneal surface is overlaid with abundant muscle, the skin edges are brought into neat approximation, and the formation of a dead space is rendered impossible. When passing the sutures have a gauze pad under the wound and be very careful not to include bowel or omentum. It is necessary to tighten and tie most carefully to prevent omentum being caught in the loop of the stitch. After closing a laparotomy wound with aseptic gauze and wood-wool and apply a flannel binder. In infected cases the wound is often kept open.

If a two-inch incision has been closed without drainage and peritonitis has taken place, the patient can usually get out of bed in seven or

A large incision offers greater danger of subsequent hernia, and the patient should be kept in bed for two or three weeks. If the wound has been kept open for drainage, a prolonged retention in bed may be necessary. I get patients up at an earlier period than used to be my custom, but I do not get them up as do Kummell and others in from one to three days (see Kummell, in "Zentralblatt f. Chirurgie," 1908). To get them up reasonably early lessens constipation, favors an early return of appetite and strength, and diminishes the risk of postoperative thrombosis and embolism and of bronchitis. We must bear in mind that if there is myocardial degeneration very early getting up may prove disastrous, or even fatal, and that in septic diseases there is often myocardial degeneration (see E. W. Foote, in "Progressive Medicine," June, 1909). In a case in which an incision of considerable length has been made, an abdominal support should be worn for a variable time. It limits the movements of cough, laughter, etc., and reminds the patient of the necessity of caution in lifting, hurrying, etc.

After-treatment.—The after-treatment depends somewhat on the case, but certain general rules can be laid down. The late J. Greig Smith said many wise things, and among them this: "A golden rule in the treatment of cases of celiotomy is to let the patient alone. Everything approaching to meddlesomeness is to be condemned. The patient must not be upset by fussy applications of tentative therapeutics; when an emergency arises, it is to be met, promptly and decisively, by a method which has been approved trustworthy" ("Abdominal Surgery"). In many cases, immediately after the operation the patient must be treated for shock by methods previously set forth. The treatment of vomiting resulting from the administration of an anesthetic is discussed on page 1197. If vomiting persists during the third or fourth day, it is probably due to the development of inflammation which has caused intestinal paresis; and if it is so produced, medicine is practically useless. In this condition there is usually marked tympanitic distention, and vomiting is, in a sense, a relief. Nothing should be given by the mouth, and the patient should be fed entirely by enemata. The insertion of a rectal tube and its retention for a considerable time may afford relief. Lying on the side is more comfortable than recumbency. Washing out the stomach from time to time gives great comfort and is often of real service.

In the average case of celiotomy, in which persistent vomiting does not occur, the question of feeding is of much importance. Usually, for the first twelve or twenty-four hours, nothing is given by the mouth but small quantities of hot water. The day after the operation, if everything is satisfactory, food is given to the patient. In many cases, however, food is not given by the stomach for forty-eight hours and the patient is fed by the rectum during the wait. He should not be given milk, because it will not be easily digested, may lead to nausea, and causes flatulence. Peptonized milk, if the patient will take it, does not possess these hurtful qualities. At first albumin-water or liquid beef peptonoids should be given and later Valentine's meat-juice, beef-jelly, broth, etc. Food is given every third or fourth hour, and stimulants are administered if required. After the first twenty-four or forty-eight hours considerable quantities of plain water or

Poland water should be taken, when possible, to favor elimination by the kidneys. Hot coffee is not only a stimulant, but is an excellent diuretic. The urine is always scanty after an abdominal operation, and a normal daily amount is not voided for ten days or more. Solid food is not given for seven or eight days. The patient is apt to suffer greatly from thirst, in spite of the hot water given during the first twelve to twenty-four hours. It does not do to give any considerable amount of hot water, and cold water and ice are inadmissible and tend to induce nausea and vomiting. Thirst can be much mitigated by enemata of water. J. Greig Smith recommends an enema composed of from 4 to 20 ounces of tepid water and some brandy. Usually, after the first twenty-four hours, a sufficient amount of liquid can be given to keep the patient free from actual distress.

The bladder must be watched to see that retention does not occur. If retention occurs, a clean catheter must be used at regular intervals. If tympanitic distention occurs after forty-eight hours, a saline purgative should be given and it should be followed by an enema of turpentine (page 1000). The rectal tube is frequently of signal service in such cases. If obstruction develops, it is treated as directed on page 976.

In any ordinary case after operation the bowels should be moved after forty-eight hours as a prophylactic measure against distention, peritonitis, and obstruction. From four to eight one-dram doses of Epsom salts are given in hot water, the solution having been filtered through gauze. The operation is followed by the administration of an enema consisting of soap, water, and half an ounce of castor-oil. Should opium be given? Never as a routine, and not to secure sleep; but if the patient is in pain which not only harasses him but causes him to turn and shift in torturing restlessness, or possibly two hypodermatic injections each containing $\frac{1}{4}$ gr. of morphine can be given with confidence that the good will overbalance the harm.

Operation for Appendicitis.—Before operating try to locate the situation of the appendix, and the relation the area of infection bears to the ascending colon. The incision should be over the seat of disease. In the rare left-sided cases and in median cases the incision is median. In cases where the appendix is posterior the cut may be in the loin. In one case I opened a purulent collection through the rectum. In the vast majority of cases the incision is made in the right iliac region.

In acute appendicitis when there is not thought to be a distinct abscess the incision usually made is two inches internal to the anterior superior iliac spine and perpendicular to a line drawn from the spine to the umbilicus (Fig 530). The skin incision is usually three inches in length, the upper third of the incision being above the omphalo-spinous line; the incision in the peritoneum is about two inches in length, but if there are many adhesions, it may be necessary to make it much longer. The oblique incision may be carried out as advised by McBurney, the muscles being separated by blunt dissection. By this method very few nerve-fibers are divided, and hence the operation is not followed by marked muscular wasting, a condition which strongly predisposes to hernia. Further, Van Hook points out,* the oblique incision enables the surgeon to reach

* Jour Amer. Med. Assoc., Feb 20, 1897.

the ordinary areas of appendix trouble, the wound is parallel to the lines of transverse abdominal muscles and does not tend to gape. In an acute case I make an oblique incision, but in chronic cases I make a transverse incision. In an interval case I make a transverse incision.

In an interval case I make a transverse incision. In an acute case I make an oblique incision, but in chronic cases I make a transverse incision.

The anterior layer of the rectus abdominis sheath is opened. The rectus abdominis is retracted, and any extension of the posterior layer of the sheath with the transverse fascia and peritoneum is removed.

I used *Davis's transverse incision* (Figs. 531 and 532) in many interval cases with satisfaction. G. Davis, in "Anger's," Jan., 1906). This incision does not divide the rectus abdominis and it divides the rectus abdominis in the direction of its fibers, hence the rectus abdominis is not injured. The rectus abdominis is divided at the base of the appendix. Davis describes his incision as follows ("Annals of Surgery," Jan., 1906):

In many cases the incision is made directly transverse, one and a half inches long. Its center is to be on the semilunar line on a level with the umbilicus. The aponeurosis of the external oblique is divided along the line of the skin incision, but obliquely to the direction of its fibers. The aponeurosis of the internal oblique and transversalis muscles are parted—not along the same line as the structures above. The peritoneum is then divided along the incision carried inward, first through the anterior layer of the rectus. A blunt retractor three-quarters of an inch wide is inserted and the muscle drawn toward the median line. This exposes the transversalis fascia and peritoneum posteriorly, which are then also divided. A triangular opening with its base of three-quarters of an inch and its sides of about an inch long which is ample for simple cases.

Difficult Cases.—If the case is a difficult one, the outer end of the incision is prolonged to the anterior spine or even above and inwardly through

Fig. 530.—Resection of the vermiform appendix, incision through the abdominal wall: *a*, External oblique muscle; *b*, internal oblique muscle; *c*, aponeurosis of external oblique; *d*, aponeurosis of internal oblique; *e*, peritoneum; *f*, outer border of rectus abdominis muscle (under it the deep epigastric vessels) (Kocher).

the sheath of the rectus to within an inch of the median line. This give an opening four to five inches long according to the size of the patient sufficiently large to insert the hand if necessary and through which the appendix can be extracted under almost all circumstances."

After opening the peritoneum examine very gently to detect the situation

Fig 531.—Davis's small transverse incision for simple cases.

Fig 532.—Davis's large transverse incision for difficult cases.

of the appendix, and if there are or are not adhesions. In a very chronic case and in a very acute case there will probably be no adhesions. If there have been previous attacks. Surround the region of infection with strips of iodoform gauze, each strip being two and one-half inches wide and sixteen inches long, and four layers in thickness. The edges of the wound

should be lifted up by retractors and the strips inserted around the cut, between the parietal peritoneum and intestines and to a distance of three inches from the wound. Strips of gauze are passed, when possible, below the appendix to prevent entrance of infected material into the pelvis, and a piece is pushed upward toward the liver (Van Hook). Over the iodoform gauze which it may be necessary to leave in place after the operation gauze pads are packed. The appendix is sought for by finding the colon. The colon is found by following the parietal peritoneum with the finger. The course of the finger is first outward, next backward, and finally inward; the first obstruction it encounters is the colon. The fact that it is the colon can be confirmed by finding the longitudinal bands. The anterior longitudinal band leads directly to the appendix. Pass the finger down to the head of the colon, find the appendix, usually posterior and internal, and lift it and the head

Fig. 533.—Radical operation for appendicitis (Kocher).

of the colon into the wound. In some cases it will be advisable to deliver the head of the colon from the belly (Fig. 533), in other cases this will not be necessary. If adhesions exist, they must be gently and carefully separated. Barker's method (Fig. 535) is a very satisfactory mode of removing the appendix. It is done as follows: Turn up a cuff of peritoneum, pull down the other coats, ligate at the base, cut through the tube, let the musculomucous stump retract, and tie or suture the peritoneal cuff over the stump. Another method, which is the one I usually employ, is as follows: Pass a ligature through the meso-appendix as shown in Fig. 534, at A, tie the ligature, and cut off the meso-appendix below the threads. Crush the stump of the appendix with strong straight hemostatic forceps. This divides the mucous membrane, submucous tissue, and muscular coat, and leaves the peritoneal coat undivided. Remove the forceps. Sur-

round the appendix with a catgut ligature and tie the ligature in the groove produced by the crushing. When the ligature is tied, peritoneum is brought against peritoneum (Fig. 534). Cut off the appendix between the ligature and a clamp with the cautery, a knife, or scissors. Disinfect the stump of appendix with pure carbolic acid. The stump beyond the ligature contains mucous membrane and muscle, which are lifted out with forceps and scissors. Suture the fringe of the meso-appendix and invert. Fig. 534 shows an older method still used by many. The meso-appendix is tied off by one ligature, the appendix is not crushed, but is tied off by another ligature, and both structures are cut off below their respective ligatures. The stump is disinfected with pure carbolic acid or the cautery, inverted, and the fringe of the meso-appendix is sutured. This method does not entirely remove the appendix, but inverts glandular tissue into the wall of the bowel. The stump may not be completely aseptitized by the carbolic acid and hence may lead to postoperative abscess, dense adhesions, or fecal fistula, or the undestroyed lymphoid structure may cause future trouble, even persistent ill health (Joseph Price). Some remove

Fig. 534 — Ligation of appendix and meso-appendix.

Fig. 535 — Barker's technique of operation for removal of the appendix.

the appendix by an elliptical incision around its base, and close the wound by Lembert sutures. This method, of course, removes the appendix completely. Dawbarn surrounds the appendix with a continuous Lembert purse-string suture of silk. This is inserted in the superficial layers of cecum, half an inch from the appendix. The appendix is divided so as to leave a stump never shorter than half an inch. The lumen of the stump is gently stretched by inserting a pair of mouse-toothed forceps and opening blades. The stump is then invaginated into the cecum—that is, it is turned "outside in." The sutures are tightened, and while this is being done, mouse-tooth forceps used in effecting inversion are withdrawn. Finally sutures are tied (Robt. H. M. Dawbarn, in "Internat. Jour. of Surg.," May 1895). In this method the stump is not ligated and hemorrhage is liable to take place into the gut. Deaths from such hemorrhage are on record. I retained bit of appendix drains into the colon. I believe it is a mistake to trust to simple ligation and to fail to bury the stump left after appendectomy.

If a surgeon follows this plan in any large number of cases, he will be apt now and then to have a case in which the ligature slips and feces pass into the peritoneal cavity, or cases of temporary fecal fistula, or cases of intestinal obstruction from adhesion of some portion of the bowel to the exposed stump (see Murat Willis, in "Annals of Surgery," July, 1908). I do not believe that a buried stump increases postoperative pain.

If there is no pus or no extravasated feces, if the peritoneum is not seriously affected, if the appendix is not gangrenous or perforated, and if there is no pus within the appendix, remove the pads, irrigate with hot salt solution, remove the strips of gauze, and close the wound. If any of the above conditions were found, remove the infected pads, but leave the iodoform strips in place to limit infection and secure drainage. Pass sutures through the wound edges, tie some of the sutures and leave some untied until gauze is removed at a later period (Van Hook).

If an operation is performed in a distinct interval, pus is absent and the surgeon can proceed without apprehension. If there is any question of the presence of pus, surround the region with gauze, as suggested above, before breaking down adhesions and liberating the appendix. An interval operation should not be performed until three weeks after an attack. In an interval case McBurney proceeds as follows: He makes the skin incision in the direction of the fibers of the external oblique muscle, separates the fibers of this muscle by blunt dissection, retracts them, separates the fibers of the internal oblique and the transversalis muscles in the same way and retracts them, and opens the transversalis fascia and peritoneum. No muscle fibers are cut and hernia is not apt to follow. Such a wound is closed as follows: a continuous catgut suture for the peritoneum, sutures of kangaroo-tendon for the transversalis fascia, the muscles are restored to place, the aponeurosis of the external oblique is sutured with kangaroo-tendon, and the skin is closed by a subcuticular stitch.

If an abscess is believed to exist, make an incision parallel with Poupart's ligament and over the area of dullness on percussion (Willard Parker's oblique incision). If the abscess is adherent to the anterior abdominal wall, such an incision will not enter the free peritoneal cavity. If, after opening the abdomen, an abscess is thought to exist, although it is not adherent to the anterior abdominal wall, surround the abscess with gauze before opening it, as directed under acute appendicitis. The gauze is placed under the margins of the incision in the peritoneum all around the appendix area; a piece is carried toward the pelvis and another piece toward the liver. Overlay this gauze with gauze pads (Van Hook). Adhesions are broken through with the finger, and when pus appears, it is at once wiped away. Remove the appendix in most cases, but not in all. If the appendix lies loose in the abscess-cavity, if it is sloughed off or but loosely attached to the abscess-wall, remove it. If the appendix is firmly fixed in the abscess-wall and must be dug out of a mass of inflammatory material, do not remove it. To remove it under these circumstances may rupture the wall and disseminate the pus into regions not protected by pads and gauze. Deaver and others tell us always to remove the appendix. I do not believe this to be a safe rule to follow. To insist on removing the appendix may cause death. When the appendix is left, it

phlebitis, hepatic suppuration, metastatic abscesses, endocarditis, and gangrene of the bowel. In a further report from September 1, 1902, to September 1, 1903, Deaver reports 566 cases in the German Hospital, with an aggregate mortality of 5 per cent. In cases with diffuse peritonitis the mortality was 31 per cent. In abscess about a necrotic and perforated appendix it was 12 per cent. In early appendicitis or when disease was confined to the appendix it was 0.8 per cent.

Appendicostomy (Weir's Operation).—This operation was devised by Weir, of New York, in 1902. It consists in opening the abdomen, finding the appendix, fastening this structure to the skin, closing the rest of the wound, opening the appendix to see that it is patent, and applying a temporary ligature to prevent leaking. The temporary ligature is removed in a day or two, and a few days later the adherent and open appendix is used as a route for the introduction of irrigating fluids. The operation is of the greatest value in chronic ulcerative colitis, as it enables us thoroughly to irrigate the large bowel. Daily a large tube is passed into the rectum and a small tube into the appendix. The fecal matter is washed out of the bowel with salt solution 1, and then a 1:5000 solution of silver nitrate or bismuth and starch water (5 j to the 3) is used to irrigate. It is used for the same purpose in some cases of tuberculous rectal or anal fistula. A most extraordinary suggestion is that appendicostomy be performed in epileptics, so that the opening may be used to flush the bowel, a suggestion which I will not act upon. When the fistula exists, it does not leak to any appreciable degree. When we wish to close it, we insert within the lumen of the tube the Paquelin cautery at a red heat. This destroys the mucous membrane and the fistula closes. (Robt. Weir in "Med. Record," August 9, 1902).

Enterorrhaphy, or Suture of the Intestine.—Surgical opinion has greatly altered in regard to this operation since the day when John Bell wrote his famous attack on Benjamin Bell. John Bell said: "If in all surgery there is a work of supererogation, it is this operation of sewing up a wounded gut." To-day we know that if in all surgery there is a proceeding of imperative necessity, it is the sewing up of a wound in the intestine. To perform this operation take fine sterile silk and thread a thin, round, straight, calyx-eyed

Fig. 536.—Eye of the calyx-eyed needle.

Fig. 537.—Enterorrhaphy: A, Lambert's suture; a, Dupuytren's suture.

needle with it (Fig. 536). The needle is very useful, as it can be threaded rapidly by pushing the calyx eye down upon the silk thread while the latter is kept taut. Lambert's suture (Figs. 537, A, 543, and 544) was devised in 1823. Lambert used it on animals, but never on man. It is inserted at right

serous membrane. A Lambert suture is added (Fig. 541). As at present used, the Czerny suture is carried to, but not through, the mucous membrane. Gussenbauer's suture is similar to the Czerny-Lambert suture, except that it applies the Czerny and the Lambert with one suture, and this suture does not pass through the mucous membrane (Fig. 546). In Connell's suture

Fig. 541.—Czerny-Lambert suture.

Fig. 542.—Czerny-Lambert suture as at present used.

(F. Gregory Connell, in "Phil. Med. Jour.," Jan., 1899) the knots are placed within the lumen of the bowel (Plate 10). Connell's very useful and ingenious stitch seems to be a modification of a stitch described by Frederick Holme Wiggin ("Med. Record," Nov. 19, 1898). *Wölfler's suture* unites broad layers of the serous coat, the knots being tied internally (Fig. 545). Senn says that after suturing a large wound of the stomach or of the intestine a strip of omentum ought to be laid over the wound and fastened by catgut sutures (*omental graft*). These grafts adhere and are a safeguard against leakage. (For other methods of enterorrhaphy see *Intestinal Resection and Anastomosis*.)

Operations upon the Stomach.—A patient must be carefully prepared for an operation upon the stomach. The Johns Hopkins method, founded on the researches of Harvey Cushing regarding sterilization of the stomach, is to be used. During the two or three days immediately preceding operation clean the mouth and teeth several times during the day with a carbolic solution. Give only sterile water and sterile liquid food by the mouth, and for twelve hours before operation give no food whatever. During the two or three days before operation wash the stomach with boiled water night and morning. I do not wash immediately before operation, as it sometimes leads to annoying vomiting and thus may interfere with anesthetization. After operation give no food whatever for thirty-six hours. Small quantities of hot water are allowed as soon as the patient recovers from ether. During the first twenty-four hours give an enema of hot salt solution and coffee every five hours and then alternate nutritive enemata with salt enemata. After thirty-six or forty-eight hours usually begin to give food—at first small doses of albumin-water, and, if this is tolerated, broth and milk. Solid food should not be given for two weeks.

If the patient is advanced in emaciation and much exhausted we should not wait for thirty-six hours to feed him, but should give milk and broth as soon as the patient recovers from ether. The bowels should be moved by enema the day after the operation. If the enema fails, calomel is given (gr. 3 or 4).

Digital Dilatation of Pylorus for Cicatricial Stenosis (Loreta's Operation, or Pylorodiosis). Place the patient recumbent and administer ether. Make a vertical incision in the linea alba or through the

right rectus muscle. The median incision begins one inch below the ensiform cartilage. The cut in either case should be five inches in length. When the peritoneum has been opened, the stomach is drawn out of the wound, adherent omentum is separated, and the pylorus is carefully examined. The stomach, after being surrounded with gauze pads, is opened near the center of its anterior surface, "but rather nearer to its pyloric end" (Jacobson).

Fig. 543. Lembert's suture.

Fig. 544. Lembert's suture closed.

Fig. 545. Wölfer's suture.

Fig. 546. Gussenbauer's suture.

Insert the index-finger through the stomach wound and into the pylorus and follow that with the middle finger. The pylorus can be well dilated by separating the fingers. If the stenosis is so tight as to prevent the entry of a finger, first introduce a pair of hemostatic forceps and open the blades a little when they are within the lumen of the constricted area. The wound in the stomach is closed by a continuous silk suture of the mucous membrane and two layers of Halsted sutures, to invert and approximate the peritoneal surfaces. After closure of the stomach wound the abdominal wound is sutured.

1. The first step is to identify the problem.

2. The second step is to define the problem.

3. The third step is to analyze the problem.

4. The fourth step is to develop a solution.

5. The fifth step is to implement the solution.

6. The sixth step is to evaluate the solution.

7. The seventh step is to monitor the solution.

8. The eighth step is to maintain the solution.

9. The ninth step is to improve the solution.

10. The tenth step is to document the solution.

33. The thirty-third step is to communicate the solution.

34. The thirty-fourth step is to review the solution.

35. The thirty-fifth step is to update the solution.

36. The thirty-sixth step is to test the solution.

37. The thirty-seventh step is to deploy the solution.

38. The thirty-eighth step is to support the solution.

EXPLANATION OF PLATE 10

Intestinal suture, all knots inside (Connell).

a. Suspending loops 2, 3, and 4 are made with one thread inserted at a point two thirds of the distance from mesenteric to convex border. The needle with suture is passed through the four walls of the cut ends, and that portion of suture within each lumen drawn up to a sufficient length, then cut, and the contiguous threads tied at the point indicated by the arrows; thus having as a result four suspending loops dividing the circumference of each cut end into thirds. Instead of employing four suspending loops which divide the circumference of the bowel into thirds, we may use but two loops, and thus divide the circumference into halves, or, if available, the "holder" devised by Dr. E. H. Lee can be recommended highly, and will be found a most efficient aid in maintaining the cut edges in apposition. (The description of the instrument will be found in the "Annals of Surgery," January, 1901.)

b. Loop 2 has been cut away, and loop 1 takes its place in one hand of the assistant with loops 3 and 4 held in the other hand, thereby bringing into apposition that portion of the walls to be included in the second third of the suture. The operator continues the suture to the points of insertion of loops 3 and 4, where again a back stitch is taken, to fix the suture and prevent a purse-string contraction of the same. The white elevation in the center of illustration, representing mesentery, shows that that portion of the intestinal wall not covered by peritoneum, at the mesenteric border, has been secured in the suture.

c. The needle, after having entered the lumen, is passed out again on the same side $\frac{1}{2}$ inch distant, then over to the opposite cut end, where it is inserted from without in, and again emerges from within out, on the same side. This step—the taking of a bite—is repeated alternately on opposing margins until the necessary number of stitches have been inserted. It will be observed that when the needle enters the lumen the last time, it makes what might be termed a half-stitch, as it does not return again through the wall, but having reached the point where the suture was commenced, the free end and the needle end will complete the last stitch, when tied, on the mucosa. The needle at this point is then brought out of the lumen at the angle of wound alongside of the free end of the suture. The cross-over stitches are next carefully drawn up, thus bringing into contact the opposing serous surfaces at every point except where the suture ends still protrude.

d. The eye-end of threaded needle is made to emerge alongside of the suture ends, and is then withdrawn a little, which causes its thread to form a loop, through which the assistant passes the ends of the suture. The operator next withdraws the threaded needle, at the same time bringing with it the suture ends, and they present externally at the point of withdrawal of the needle. The serous coats throughout the entire circumference are now in apposition, and the suture ends can be tied.

e. By slight traction on the suture ends the opposing mucous surfaces are brought in close contact, the suture ends are then tied firmly, and deep between the serous coats, thus tying the knot upon the mucous coat, and the ends then cut off short.

Divulsion by the fingers or by an instrument is no longer practised, because experience has shown that the constriction is sure to return.

Pyloroplasty (Heineke-Mikulicz Operation).—The first operation was performed by Heineke in 1886. Early in 1887 Mikulicz, not knowing of Heineke's antecedent operation, did the same thing. Open the abdomen in the middle line, or, better, through the right rectus muscle. Draw the pylorus as well as possible, and pack warm moist gauze pads around it; make an incision through the stricture and in a direction corresponding to the long axis of the stomach and bowel (Fig. 547). Catch an aneurysm needle under the upper margin of the incision and draw it up, and an aneurysm needle under the lower margin and draw it down. The effect of traction is to convert the transverse wound into a vertical one. The sutures are applied so as to

Fig. 547.—Heineke-Mikulicz's pyloroplasty. The incision.

Fig. 548.—Heineke-Mikulicz's pyloroplasty. The axis of the incision is changed by traction from horizontal to vertical; sutures in position; only one of the two rows of sutures is shown.

maintain the wound in a vertical line (Fig. 548). The mucous membrane is sutured with a continuous suture of silk, and interrupted Lembert or Halsted sutures of silk close the peritoneal and muscular coats (Figs. 548 and 549). Pain for twenty-four hours, because there is danger of leakage. A. W. Mayo and Eason insert a bone bobbin and apply the sutures. The operation of pyloroplasty shows a mortality about the same as or slightly less than gastro-enterostomy. In the cases it is a very satisfactory procedure, but there are objections to it, and in 30 per cent. of cases it fails to give relief (Wm. J. Mayo). The outlet is not at the most dependent part of the stomach, hence the stomach may not empty itself. Furthermore, as Finney points out, it cannot be performed if there are firm adhesions or active ulceration, and the scar may contract and give rise to stenosis. Again, it is difficult to suture so as certainly to provide against leakage. The Mayo reported 27 pyloroplasties without a death, but 7 cases required secondary operations ("Annals of Surgery," Nov., 1905). Pyloro-

Fig. 549.—Heineke-Mikulicz's pyloroplasty. after tying the sutures.

bleeding; excise as much scar-tissue as possible on either side of the incision, and trim off the redundant mucous membrane. Insert a continuous catgut suture on the posterior side of the incision and carry it through all the coats (Fig. 554). Straighten out the anterior sutures and tie them (Fig. 555). The Mayos report 58 Finney operations with 4 deaths and 2 secondary operations (Wm. J. Mayo in "Annals of Surgery," Nov., 1905).

The mortality is greater than after gastro-enterostomy, due probably to the necessity of separating adhesions and setting the duodenum free. The opera-

Fig. 555.—Finney's pyloroplasty completed by tying the anterior sutures.

tion should be restricted to cases in which adhesions are not widespread and firm and in which the gastrohepatic omentum is of fair length. In properly selected cases it is an excellent operation.

Pylorectomy (Excision of the Pylorus).—The removal of a portion of the stomach is a partial gastrectomy, and pylorectomy is a partial

Fig. 556.—Billroth's method of pylorectomy.

Fig. 557.—Pylorectomy.

gastrectomy in which the pylorus and also a portion of duodenum are removed.

The experiments of Gussenbauer and von Winiwarter on dogs in 1876 lead them to suggest this operation. It was first performed by Péan in 1879. It was next performed by Rydygier in 1880. Billroth did the first successful pylorectomy in 1881. The operation is usually performed for cancer, but some-

Figs. 556 and 557. In Mayo's method, after exposing the stomach ligate the gastric artery close to the stomach, tie the lesser omentum in several segments close to the liver and divide it, and tie the pyloric artery. Apply two clamps to the duodenum and have them an inch apart, and divide the duodenum by means of the cautery (Fig. 558).

Close the right end of the duodenum by means of a continuous catgut suture, remove the clamp, and invert the closed end by a purse-string suture (Fig. 559). Pass a hand from above back of the stomach and lift the great omentum forward. Tie the right gastro-epiploic artery close to the stomach. Tie the left gastro-epiploic artery distinctly to the left of any enlarged glands in the great omentum. Tie the great omentum in several segments. Divide the great omentum, leaving

any enlarged glands attached to the portion of the stomach it is the intention to remove. The stomach is to be divided to the left of all lymphatic glands in which the cancerous region drains. The clamps are applied as shown in Fig. 558. The stomach is divided between the clamps with a cautery, and as the division is being carried out catch the stump here and there with hemostatic forceps to prevent it slipping through the clamps. Slipping is disastrous and will cause leaking and entrance of air into the stomach, and entrance of air is apt to be followed by pulmonary difficulty.

A row of locking stitches is passed through all the coats of the stump. The stitches are tied and a second row is passed and tied (Fig. 559). The clamp is removed and the stump is buried by Cushing's right angled suture or Dupuytren's suture. A gastrojejunostomy is then performed to the posterior wall of the portion of stomach which remains.

Such a patient is usually much dehydrated, and if he is, salt solution should be given intravenously during the operation, and an enema of warm salt solution should be administered every six hours for several days after the operation. Active stimulation is usually necessary and 8 ounces of coffee should be given by rectum at the completion of the operation. The patient must be placed erect or semi-erect in bed as soon as the effects of the ether pass away. Twelve hours after operation begin to give small amounts of hot water by the mouth. Nourish by the rectum from four to six days, when fluid food may be given by the mouth, starting with small doses of albumin-water, and if this is tolerated, giving dessertspoonful doses of peptonized milk every hour.

Fig. 559.—Pylorectomy by the Mayo method. End of divided duodenum buried by a purse-string suture. Row of lock stitches inserted in stomach stump (Mayo).

Total Gastrectomy.—The entire stomach was first removed by Conner, of Cincinnati, in 1883. The first successful operation was performed by Schlatter, of Zürich, in 1897. Total gastrectomy will rarely be required, but in certain unusual cases it will be proper to perform it. In some cases the duodenal end can be sutured to the divided esophagus; in others it will be necessary to close the end of the divided first portion of the duodenum, and anastomose the esophagus to the jejunum.

The cases suitable for total gastrectomy are those in which the entire viscus, or almost the entire viscus, is cancerous, the stomach being still freely movable, and the glands not so much implicated as to forbid attempts at removal. It is a remarkable fact, first demonstrated in Schlatter's case, that an individual can digest food very well without a stomach. This statement is true only if the stomach function has been gradually abolished by disease. During this period the functions of the stomach have been assumed to a greater or less degree by other parts. In a recent injury of the stomach complete removal would almost certainly be followed by death, as in such a case other parts would have had no chance to learn how to assume gastric duties. The reported cases of total gastrectomy show 10 deaths out of 27 cases; but, as Robson truly says, if all cases were reported, the mortality would probably be found to be 50 per cent.

Gastrotomy.—This term is used to designate the operation of opening the stomach for the accomplishment of some purpose, and immediately closing the incision in the gastric wall when that purpose is accomplished. Gastrotomy may be performed to permit of the removal of foreign bodies, of exploration of the stomach and its extremities, of division of the pyloric orifice, of the treatment of bleeding, of an esophageal stricture, or a stricture of the cardiac orifice of the stomach, or of the removal of a foreign body lodged in the esophagus. The first case on record was in 1602 when Mathis removed from the stomach of a juggler a knife which had been accidentally swallowed.

The patient is prepared as for pylorotomy. The incision may be vertical in the middle line or identical with the incision for pylorotomy. If a large foreign body can be felt, the incision is made directly over it. When the peritoneal cavity is opened, the surgeon decides as to the point where the stomach is to be incised, and draws this portion out through the wound, packing gauze pads under and around it. The stomach is opened by means of scissors, the cut being at a right angle to the long axis of the viscus (Jacobson). Bleeding vessels are ligated with catgut. The purpose for which the stomach was opened is now to be carried out, the interior of the stomach and the surface of the extruded portion are irrigated with hot salt solution, the mucous membrane is sutured with a continuous suture of silk, and two rows of Halsted sutures are inserted. The abdominal wound is closed, drainage being employed for twenty-four hours.

Gastrostomy is the making of a permanent gastric fistula, through which opening the patient can be fed. Gastrostomy was first proposed by Egebert in 1837 (Keen), and was first performed by Sédillot in 1842. In 1875 Sydney Jones operated upon the twenty-ninth case and obtained the first recovery (Keen). Up to 1884 the estimated mortality was 80 per cent. At present the mortality in malignant cases is from 20 to 25 per cent., and

in non-malignant cases from 8 to 10 per cent. Gastrostomy is employed in cases of esophageal obstruction or obstruction of the cardiac end of the

Fig. 560.—Witzel's method of gastrostomy. Application of sutures in wall of stomach, embedding tube obliquely therein.

Fig. 561.—Sutures tied completely embedding tube obliquely therein.

stomach. In many cases of malignant disease the operation is performed late, and if performed when the patient is greatly emaciated and exhausted,

Fig. 562.—Kader's method of gastrostomy. Tube in place and first row of sutures inserted.

Fig. 563.—Kader's method of gastrostomy. First row of sutures tied and second row inserted.

the operation has, of course, a high mortality. An early operation is far safer and confers the maximum of relief. The operation should be per-

This cone is puckered by the insertion of two drawing-string sutures of chromicized catgut through the serous and muscular coats. A cuff of gastrocolic omentum is sutured by silk around the neck of the puckered cone. The stomach is sutured to the belly-wall with silk, the sutures including the omental cuff, the serous and muscular coats of the stomach, and the structures of the belly-wall, except the skin. The skin is partly sutured. The stomach may be opened at any time.

Gastro-enterostomy or gastro-jejunostomy is the establishment of a permanent fistula between the stomach and the small intestine, in order to side-track the pylorus. The operation is performed for cancer of the pylorus, for non-cancerous stenosis of the pylorus, in some cases of ulcer of the stomach, and for tetany. Anterior gastro-enterostomy was proposed

Fig. 565

Fig. 566

Figs. 565, 566. —The Seabanejew-Frank method of gastrostomy in carcinoma of the esophagus.

by Nicoladoni in 1881 and was first performed by Wohler the same year. In Wohler's early operations the jejunum was so placed that the proximal end was to the right of the anastomosis opening. Hence peristalsis in the stomach was from left to right and in the jejunum from right to left, and this was supposed to be responsible for the common occurrence of regurgitant vomiting. It was sought to prevent this by altering the direction of the loop (Lücke), then by entero-anastomosis (Braun), and finally by a posterior anastomosis. Posterior gastro-enterostomy was first proposed by Courvoisier in 1883. His suggestion was that the posterior surface of the stomach be reached through the transverse mesocolon. His plan necessitated a transverse division of the mesocolon, but it was found that this impaired the blood-supply of a part of the colon and might lead to gangrene. Von Hacker, in 1885, devised an improved posterior operation. As a matter of fact, the transverse mesocolon has a marginal artery, unlike other parts of the colon, and the danger of

gangrene from a transverse incision is probably not very great. In the earlier operations by the posterior method a long loop was used and results were not notably better than after the anterior operation. In 1890 Czerny and Peterson advised the making of the jejunal opening close to the duodenojejunal flexure. The results from this operation are vastly better than from the anterior operation. Posterior gastro-enterostomy has been signally improved in technic by the Mayos, Moynihan, and others. In the earlier operations of anterior gastro-enterostomy the mortality was 40 per cent. In non-malignant conditions the mortality after gastro-enterostomy is now very low (under 3 per cent.), the hyperacidity of the gastric juice disappears, and the functions of the stomach are restored. In malignant cases the mortality is about 20 per cent., but even in such cases, if operation is done early, life may be prolonged and made comfortable for months. Wm. J. Mayo makes the following report upon 421 cases of gastrojejunostomy: "Benign, 307 cases, 19 deaths (6.18 per cent.). In the last 140 there were 4 deaths, a mortality of 2.85 per cent., the last 80 gave but 1 death. Malignant, 114 cases, with 21 deaths (18.5 per cent.). Of these 114 cases, 61 were in connection with pylorotomy and partial gastrectomy, with 8 deaths (12.6 per cent.). The very unfavorable cases of cancer obstruction were subjected to gastro-enterostomy, so that this operation gives a higher mortality than radical excision. In the last 40 gastrojejunostomies for malignant disease the mortality was 8 per cent. In the 421 gastrojejunostomies there were 21 reoperated cases (5 per cent.);" ("Annals of Surgery," Nov., 1905). In about 5 per cent. of cases of gastro-enterostomy for benign disease secondary operation has been required. In Kronlein's clinic, 51 cases of malignant disease subjected to gastro-enterostomy showed an average duration of life of 192 days, 470 days after operation 17 cases were living. The causes of death, according to Mayo, are, exhaustion, exhaustion with vomiting, pneumonia, and detachment of the anastomosed intestine.

Treatment After Gastro-enterostomy.—On returning the patient to bed at once establish continuous enteroclysis with one-half strength salt solution, the reservoir being only 6 inches above the level of the bed. This is Murphy's plan. As soon as patient is out of ether place him semi erect. Mayo begins in from sixteen to twenty hours to administer by the mouth one ounce of hot water every hour, and if it is well tolerated, the amount is quickly increased, and in thirty-six hours liquid food is given and, if tolerated, is continued.

Complications Following Gastro-enterostomy.—Among them are *lung complications*. These are not due to the anesthetic, for they tend to occur even when local anesthesia has been employed. They are not due to the epigastric incision interfering with cough and expectoration for they are not nearly so common after operations upon the gall bladder (Wm. J. Mayo). Mayo says that the latest theory is that some of the venous blood returning from the stomach does not pass through the liver, and infected emboli are deposited in the lungs. The *suture line may leak* after gastro-enterostomy because of imperfect suturing, or the anastomosed intestine may become *detached*; 20 per cent. of the deaths among Mayo's cases resulted from this cause. *Contraction of the anastomosis opening* may gradually take

place. This has been held by some to be particularly common in cases of dilated stomach, shrinking of the stomach being the efficient cause; but evidence upon this point is not conclusive. In cases in which the pylorus is not obstructed shrinking often occurs, but it rarely takes place when the pylorus is obstructed. In some cases after operation a *spur* forms in the jejunum because of angulation; in other cases adhesions produce obstruction; and in rare instances ulceration takes place in the jejunum. The most common complication after gastro-enterostomy is *persistent vomiting*, which may or may not be expressive of the formation of a vicious circle.

Peptic Ulcer of the Jejunum. The first case was reported by Braun in 1890. F. Gregory Connell has collected 38 cases and reported one of his own, in all ("Surg., Gynecol., and Obstet.," Jan., 1908). Connell points out that in many of the reported cases acute perforation occurred. Most of the reported cases, it is found, suffered from non-malignant trouble and had hyperacid gastric juice. It very seldom occurs after operations for cancer. Most of the reported cases happened after the anterior operation and when the anastomosis was very near to the pylorus. It has happened, however, in 9 cases after the posterior operation, and cases have been reported following both the anterior and posterior methods associated with entero-anastomosis. It is probable that more cases seem to follow the anterior method because in late years it has been the operation commonly performed. In most of the reported cases the ulcer was single; in 3 out of 24 cases it was multiple. It is usually in the distal loop, but may be in the proximal loop. It may be situated at the anastomosis level, a little way below it, or even 5 or 6 inches below it. The ulcer may appear a few days after the operation, weeks after, months after, or even years after. The condition results from hyperacid gastric juice passing directly into the jejunum before it has been neutralized by admixture with bile and pancreatic juice. It is possible that the condition is predisposed to by a twist in the jejunum and by such a small anastomosis opening that hyperacidity was not corrected.

There may be no symptoms at all until there is a severe hemorrhage or perforation, or symptoms similar to those which called for the gastro-enterostomy may return. Connell's table shows that acute perforation took place in 14 of the 39 reported cases. In chronic cases treatment is first medical; if this fails, operation is indicated. In perforation, operation must be immediate.

The Vicious Circle and Regurgitation.—Vomiting may occur after the performance of gastro-enterostomy. It may soon cease, may be productive of disastrous consequences, and may be expressive of an existing complication of great gravity. In some cases of gastro-enterostomy vomiting arises because the anastomosis has been made high up on the anterior wall and the stomach is not drained. In other cases ether induces vomiting, and the mechanical efforts force the contents of the duodenum and even of the jejunum into the stomach. The true "vicious circle" is a condition in which the contents of the stomach pass through the anastomosis opening into the duodenal side of the loop of intestine, mix with the duodenal secretions, and return to the stomach (Fowler, in "Annals of Surgery," Nov., 1902). The following conditions are often classified under the same head, but each is called by

Moynihan has confirmed these experiments by clinical observation. It has been held that the cause of this condition is the making of a loop with a long loop between the duodenojejunal flexure and the opening into the jejunum, the loop being unable to propel its contents forward and tending by its weight to produce a bend or kink at the junction. This is a very doubtful theory.

Persistent vomiting may be due to spur formation, which directs the contents into the duodenal side of the loop. It is in some cases

Fig. 567.—Gastro-enterostomy (after Lucke).

Fig. 568. Implanted jejunum and jejunum (Wolfer).

or twisting of the distal loop, in others, to failure of peristalsis of the loop; in still others, to contraction of the opening in the stomach. See also Dr. J. B. Murphy's article on Gastro-enterostomy in the Breslau Clinic; article by C. J. Bland in "Annals of Surgery," Aug., 1908). I cordially agree with Herbert J. Patterson, viz: "Most, if not all, fatal cases of regurgitation after gastro-enterostomy are due to mechanical obstruction at the afferent opening." (Lectures delivered before the "Royal College of Surgeons" of London, 19, 21, and 23, 1906). In order to lessen the danger of vom-

stomach-contents, and usually, but not always, pass into the efferent loop. In all these operations there is great danger of the development of a vicious circle.

Lucke devised an operation with the idea of preventing such a complication. In the Lucke operation the direction of peristalsis in the efferent loop is the same as in the stomach (Fig. 567). McGraw points out that the crossing of the loop which is effected is dangerous. The Wölfler-Lucke operation is shown in Fig. 577. Wölfler devised the operation pictured in Fig. 568. Von Hacker's posterior operation is thought by some to be less apt than the anterior method to be followed by the vicious circle (Fig. 578). Kocher devised an operation in which a valve is formed, but, as Fowler points out, this valve does not prevent filling of the duodenum and imbibition of the material by the stomach; and, further, that the valve does not work when the parts become cicatricial (Fig. 571).

The combination of gastro-enterostomy with entero-anastomosis does tend to prevent the vicious circle. This operation is shown in Figs. 575 and 576. I do not believe it should ever be a primary operation. It permits acid gastric juice to flow directly into the jejunum and keeps away the bile which would normally protect mucous membrane. Hence such an operation exposes the patient to the danger of jejunal ulceration. Another defect in such an operation is that there is still a communication between the stomach and the efferent loop. Fowler's operation (Fig. 579) corrects this defect. McGraw's operation (Figs. 572 and 573) tends to prevent the formation of a vicious circle. It seems certain that the danger of the formation of a vicious circle is greatest after a long-loop anterior operation and least after a short-loop posterior operation. The shorter the loop, the less the danger, hence the latter is the operation of choice. The safest operation of all is the short-loop operation of Moynihan or Scudder (page 1083), or the "no-loop" operation of the Mayos (page 1086).

Fig. 569. — Billroth's method of gastro-enterostomy

Treatment of Persistent Vomiting after Gastro-enterostomy. If vomiting persists in spite of gastric lavage and rectal feeding after the operation of gastro-enterostomy with a long loop without entero-anastomosis, open the abdomen again and perform anastomosis between the afferent and efferent loops of intestine. This was suggested by Braun in 1892, and both he and Jaboulay performed it in the same year. The operation has saved lives. In a short-loop operation we should assume that the jejunum has been twisted, open the abdomen, and endeavor to correct the condition. Herbert L. Patterson (Ibid.) points out that slight cases of regurgitant vomiting not immediately following an operation may be due purely to constipation, and may be recovered from if care is taken to secure daily a free bowel movement. In Patterson's opinion constipation causes reversed peristalsis, and as both the duodenal "siphon-trap" and the pyloric sphincter are put out of service, regurgitation takes place from the efferent loop into the stomach.

Anterior Gastro-enterostomy. — Senn's Method. — A median incision is made through the abdominal wall, from below the xiphoid cartilage to the

Diseases and Injuries of the Abdomen

An opening is made in the lower part of the anterior wall of the continuous catgut suture. The contents of the jejunum are forced below the point where an incision is to be made. The duodenal loop should be from 12 to 14 inches in length. A rubber tube is fastened to the bowel above this point, and another below it; an incision is made in the long axis of the bowel, and the margins of the wound are sutured in the manner as the stomach-wound. Bone plates are introduced into the stomach and intestine, and the ligatures are tied as in intestinal anastomosis. Cut rings or rubber rings may be used.

Mayo's Anterior Method (Fig. 570).—Open the abdomen, and pick up the jejunum about 14 inches from the point at which it emerges from under the mesocolon. Effect the union to the inferior border of the stomach close to the greater curvature and at the lowest portion of the stomach pouch. When the anastomosis is completed, the stomach pouch is funnel-shaped. The usual custom has been to place the opening higher on the anterior wall. It sometimes led to the formation of a pouch on the anterior wall, and did not drain the stomach, and caused vomiting. After the performance of gastro-enterostomy the edges of the omentum are caught up on each side of the anastomosis and are sutured to each other and to the stomach-wall one inch above the opening. The edges are then united together in a downward direction for about three inches so as to form an apron over the anastomosis, yet not connected with it. Catgut is used for suturing. If leakage occurs, the omentum is raised and the anastomosis is re-

Fig. 570—Mayo's method of gastro-enterostomy, showing proper and improper locations of openings. a, proper position, leaving no pouch; b, usual position, forming intra-gastric pouch ("Annals of Surgery").

adjacent and "available." If leakage does not occur, the omentum turns to its normal position (Wm. J. Mayo, in "Annals of Surgery," Aug. 1902).

Kocher's Method (Fig. 571).—After opening the abdomen, lift up the omentum, pull up a loop of intestine, and find the point where the jejunum appears from under the mesocolon. Select a loop sixteen inches from the origin of the jejunum and prepare to attach it to the stomach. Wash

level that the intestine should be applied to the stomach in such a manner that the direction of peristalsis in the bowel must correspond to the direction of the stomach-tide. This can be accomplished by having the proximal portion of gut to the left, and the distal portion to the right. The operation is to be so performed that after its completion the stomach-contents pass to the distal portion of the gut, and the intestinal contents do not tend to enter the stomach. In order to accomplish this Kocher hangs the intestine to the stomach-wall in such a manner that the proximal portion of the loop is superior and ascending, and the distal portion is anterior and descending. The bowel is hung to the stomach by a continuous serous suture of silk, the ends of which are left long. The intestine is opened by a curved incision, the continuity of which is downward. The stomach is opened so that the convexity of the cut is upward. The valve-like function of the bowel-wall is sutured to the stomach below the incision in that position. The two openings are well approximated by sutures.

Operation by McGraw's Elastic Suture (Figs. 572-574).—The elastic suture was introduced by Silsbee in 1862 and was first used for intestinal anastomosis by the same surgeon. McGraw perfected the operation in 1891 (see Dudley Tait, "Annals of Surgery," Feb., 1906). The operation may be anterior or posterior. The intestine and stomach are sutured together by Lembert stitches. An elastic cord, which is 3 to 5 mm. in

diameter, is passed through the stomach and then the bowel, in the long axis, and is tightly tied, and the knot is fastened with a silk thread. Another row of Lembert sutures buries the elastic cord from sight. The cord is removed through in from forty-eight to seventy-two hours and makes the anastomosis. Thus the danger of infection is greatly lessened, for when the anastomosis opening is formed, it is completely encompassed by firm adhesions. Further, the danger of the formation of a vicious circle is greatly lessened, because there is no communication between the stomach and bowel for between forty-eight and seventy-two hours, the period in which vomiting of the type previously described is most apt to occur. The method is not suitable for absolute pyloric occlusion. In this condition it is imperative to give nourishment early, and, again, an ordinary gastro-enterostomy allays autointoxication and this operation cannot until the ligature cuts through. It is particularly valuable in the performance of lateral intestinal anastomosis.

Jaboulay's Gastro-duodenostomy.—This operation was devised by Jaboulay in 1892. It aims to obviate some of the objections to pyloroplasty and at the same time to retain the advantages this operation possesses over

FIG. 571.—Kocher's method of gastro-enterostomy. *a*, Places of posterior annular suture through entire wall of stomach and intestine. *b*, places of anterior annular suture through the entire wall. *c*, valve at the jejunum by arch-formed incision. *d*, posterior annular suture of the serosa. *e*, thread ends for continuing anterior suture of the serosa.

gastro-jejunostomy. Jaboulay's gastro-duodenostomy has never become popular with surgeons, and Finney's method is much more satisfactory (page 1066).

Posterior Gastro-enterostomy (Fig. 578).—In a thin subject with a long mesocolon posterior gastro-enterostomy is to be chosen, but if the mesentery is

Fig. 574.—McGraw's method of lateral anastomosis. The operation completed (Walker)

short or contains much fat, or if the vascular loop coming from the superior mesenteric artery, and which supplies the transverse colon with blood, is small, so that on opening the posterior layer of the gastro-colic omentum it would be close to the artery, the anterior operation is employed (Wm. J. Mayo, in "Annals of Surgery," Aug., 1902). If a Murphy button is used, the posterior operation

Fig. 575.—Jaboulay's method of gastro-enterostomy.

Fig. 576.—Braun's method of gastro-enterostomy.

is selected. The operation is commonly performed as follows: After the abdomen has been opened, the stomach and omentum are raised; a portion of the upper jejunum is seized, emptied, and a site selected for the clamp. This site must be within 5 inches of the flexure. If there is a broad mesocolic band

preventing a near approach to the flexure the band must be divided. A clamp is applied on the side opposite the mesenteric attachment. A spot is selected on the transverse mesocolon where there are no vessels, and an opening is made through the mesocolon with a dry dissector. The posterior wall of the stomach is pulled into the opening and sutured to its edges. This prevents downward displacement of the stomach and obstruction of the loop of gut. A portion of the posterior wall of the stomach is pulled out into a cone and clamped. Openings are made and the sutures applied as directed on page 1083. Regurgitation is less common after posterior than after anterior gastro-enterostomy. In 250 posterior operations in Czerny's clinic there was not one case of regurgitant vomiting. One hundred and seventy cases were button operations and 45 were by sutures alone (Peterson). Von Hacker had one instance of regurgitation in 60 posterior operations.

Operation by the Murphy Button.—Gastro-enterostomy may be quickly performed by the use of a large-sized Murphy button. Murphy says that in some reported cases the button has slipped back into the stomach, but this accident can be prevented by the use of an oblong button and by making the anastomosis on the posterior stomach-wall. The same surgeon advises us to

Fig. 577.—Woelfer-Lacke method of gastro-enterostomy

Fig. 578.—Von Hacker's posterior gastro-enterostomy

scarify the peritoneum to hasten union, and says supporting sutures about the button are not required, except when considerable tension exists. There is no question that an anastomosis on the anterior wall, accomplished by a Murphy button, can be speedily performed. Anastomosis on the posterior wall cannot be performed so speedily, and it sacrifices to some extent the great advantage of the button operation—that is, speed. In spite of the reported cases we can positively assert that the danger of the button producing grave trouble is slight. In some cases it drops into the stomach and remains there, but seems to do no harm. In other cases it takes a long time to pass. In one of the author's cases it did not pass until the eighty-sixth day. If it does not pass in two or three weeks, the rectum should be explored with the finger from time to time to see if it is lodged there. The x-rays may determine whether

the button is in transit. If the wall of the stomach is thick, the incision should be made in the stomach-wall before the suture is passed, and this suture should pick up only a small portion of the stomach-wall, otherwise the button may be retained in place for a very long time (Wm. J. Mayo). "In many cases in which the button passes, vomiting with symptoms of obstruction may appear in the second or third week while it is in transit. Gastric lavage and rectal feeding for a day or two cause these symptoms to subside" (Wm. J. Mayo, in "Annals of Surgery," Aug., 1902). Mayo considers the suture operation as good as the button, and thinks the results are about the same. Mikulicz says that in the suture operation entero-anastomosis is necessary, but not in the button operation, because the button, while in place, prevents angulation. The last-named surgeon uses the button in malignant cases and the suture in benign cases. Czerny is an advocate of the button. Every button should be tested before it is used. Mayo finds nearly 20 per cent. of buttons imperfect and dangerous.

Fowler's Method (Fig.

579).—Anastomose the posterior wall of the stomach to the jejunum and do an entero-anastomosis between the afferent and efferent loops of jejunum. Pass a No. 20 silver wire two or three times

around the afferent loop of jejunum and draw it sufficiently tight to occlude the lumen without strangulating the wall of the gut. The ends are twisted, cut short, rolled into a flat coil, the cut ends being in the coil. (See Geo. Ryerson Fowler on the "Circulus Vitiosus" following gastro-enterostomy, "Annals of Surgery," Nov., 1902.) This operation positively prevents the entrance of material from the duodenal loop into the stomach and also drains that loop.

Moynihan's Method.—This is the plan I usually employ. It is easy, rapid, and clean. Make a 4-inch incision 1 inch to the right of the middle line and above the umbilicus. Open the anterior sheath of the rectus and separate it from the front of the muscle as far as the middle line. Draw the entire muscle outward, open the posterior portion of the sheath, and then open the belly. Inspect and feel the entire stomach. Lift the omentum and transverse colon out of the abdomen and make the mesocolon taut by raising the stomach and colon with the left hand. Find "a bloodless spot in

Fig. 579.—Fowler's method of gastro-enterostomy.

the arch of the middle colic artery," pick up a bit of the under surface of mesocolon with a pair of hemostatic forceps, lift it from the posterior stomach wall, and open the lesser sac of peritoneum with the scissors. Enlarge opening by dilatation or tearing until it admits three fingers. Inspect and feel the posterior stomach-wall. Place the stomach in its natural position mark with the thumb the lowest part of the posterior stomach wall.

Fig 580.—Moynihan's clamp for gastric and intestinal operations (made by Down Brothers, London)

omentum, and transverse colon are returned to the abdomen and the clamps are surrounded with gauze. Each clamp holds a fold $\frac{3}{4}$ to 4 inches in length. Pagenstecher's celluloid thread is used for suturing. The first line of suture is passed as shown in Fig 581. In front of these sutures an incision is made into the stomach and jejunum, the serous and muscular coats being first

again turn the viscus over. From the spot marked by the thumb a fold is made. The fold is oblique and its upper end is to approach the cardia and lesser curvature. A stomach clamp (Fig 581) having a rubber tube bent over the blade is applied obliquely so as to grasp the base of this fold. In applying the clamp the tip should point toward the right shoulder and the handle toward the outer side of the left hip, and the lower portion of the stomach is grasped. The tip of the blade of the clamp is placed at the tip of the fold (Fig 581). The clamp is now put in a horizontal position. The duodenal flexure is found with the finger. The jejunum is identified and its position is noted. The jejunum is picked up and "drawn tight" and its position is noted which reaches the greater curvature of the stomach when the jejunum is in its natural position. The distance noted is 5 inches from the flexure. The jejunum above the spot is clamped. The anastomosis is made. The clamp is applied in the side of the gut opposite the mesentery. The surgeon must be sure that the jejunum is not twisted around its longitudinal axis. If the clamps are not rightly applied they must be placed so that after the anastomosis the jejunum lies in its natural position without a twist. The clamped gut is placed by the side of the clamped stomach, a bit of gauze is put between them (Fig 582). The stomach (except the clamped portion)

Fig. 581.—Moynihan's method of gastro-enterostomy. The oblique application of the clamp to the stomach (Moynihan).

Fig. 582.—Moynihan's method of gastro-enterostomy. The strip of gauze between the clamps (Moynihan).

Fig. 583.—Moynihan's method of gastro-enterostomy. The first layer of serous suture (Moynihan).

and an ellipse of mucous membrane being removed (Fig. 584). The next row of sutures is inserted as shown in Fig. 585. When this row is completed the clamps are removed and the long suture of the first row is picked up again and the operation is completed (Fig. 586). Finally, the edges of the mesocolic opening are sutured to the jejunum. The parts are cleansed with salt solution, the suture line is inspected, the parts are returned to the belly, and the abdomen is closed. (See Moynihan's "Abdominal Operations.")

The No-loop Operation of the Mayos.—(Figs. 587-589).—In this operation the gastric opening, which is placed in the line advised by Moyni-

Fig. 584.—Moynihan's method of gastro-enterostomy. Removal of the ellipse of mucous membrane (Moynihan)

Fig. 585.—Moynihan's method of gastro-enterostomy. The inner suture continued (Moynihan)

han, extends one-fourth or one-half inch into the anterior wall of the stomach and thus the lowest part of the opening will be the lowest part of the stomach (Fig. 587). The incision in the intestine begins from 1 to 3 inches from the origin of the jejunum, the measure being made on the anterior surface (Fig. 588).

The object is to get as short a piece of jejunum as can be attached without tension. The operation is described as follows (Wm. J. Mayo "Annals of Surgery," Nov., 1905).

"(a) The abdominal incision is made 4 inches in length, $\frac{1}{2}$ inch to the right of the middle line, the fibers of the rectus muscle being separated. The lower end of the external wound lies opposite the umbilicus. This opening

also enables inspection of the duodenum and gall-bladder and is reliable against hernia when closed.

"(b) The transverse colon is pulled out and the mesocolon made taut by traction upward and to the right, in this manner bringing the jejunum into view at its origin.

"(c) About 3 to 4 inches of the jejunum opposite the mesentery are drawn into a slightly curved clamp. The handles of the clamps should be to the right, to enable a short grasp on the intestine. Three-fourths of the circumference of the bowel is pulled through; the posterior border is not included, to prevent entanglement of the suture with the redundant posterior mucous membrane. The holding clamps are applied sufficiently tight to check hemorrhage and prevent extravasation of intestinal contents.

"(d) The ligament of Treitz is a short muscular mesentery covered by a variable peritoneal fold (so variable for a reliable landmark) extending upward from the origin of the jejunum on to the mesocolon. This peritoneal fold lies at the base of the arterial loop of the middle colic artery which supplies the transverse colon. The mesocolon is opened within the vascular loop and the posterior inferior border of the stomach pushed through. A small separation

of the greater omental attachment to the stomach enables the anterior gas-

Fig 587. Mayo's method of gastro-enterostomy. Showing posterior wall of the stomach drawn through a rent in the transverse mesocolon. Note slight separation of gastroduodenal omentum from its attachment to the stomach, permitting anterior wall of stomach to appear and insuring drainage at lowest level. Black lines mark site of proposed anastomosis; the jejunum shows at its origin.

Diseases and Injuries of the Abdomen

all to be drawn out posteriorly. The posterior gastric wall is drawn into the clamp, with the handles to the right, in such a manner as to just expose the anterior wall at the base.

Fig. 588.—Mayo's method of gastro-enterostomy. Forceps in place and anastomosis half completed by suture.

Fig. 589.—Mayo's method of gastro-enterostomy. Completed operation from behind margin of mesocolon attached by several interrupted sutures to line of union.

"(c) The two clamps are laid side by side and the field carefully protected by moist gauze pads. With fine celluloidal linen thread on a straight needle the intestine is sutured to the stomach from left to right by a Cushing suture at least $2\frac{1}{2}$ inches.

"(f) The stomach and intestine are incised $\frac{1}{2}$ inch in front of the suture line and the redundant mucous membrane excised flush with the retracted peritoneal and muscular coats. With a No. 1 chromic catgut on a straight needle the posterior cut margins of the entire thickness of the gastric and jejunal wall are united by a button-hole suture from right to left; at the extreme left the suture changes to one which passes through all the coats, of each side alternately, from the peritoneal to the mucous, then directly back on the same side from the mucous to the peritoneal. This acts as a hemostatic suture, and also turns the peritoneal coats into apposition. It passes around the anterior surface and is tied to the original end, which has been left long for the purpose. If silk or linen is used for this suture, it may hang *in situ*, suppurating for months.

"(g) The clamps are now removed and the linen thread continued around until it is tied to the original end, firmly catching the blood-vessels in sight along the suture line. The parts are carefully cleansed and inspected. If

Fig. 590. - Bitcher's method of gastroplication.

Necessary, a suture or two is applied to accurately coapt or to check the bleeding.

"(h) The margins of the incised mesocolon are now united to the suture by 3 or 4 interrupted sutures, and the parts returned into the abdomen."

In this operation the greatest care must be taken to avoid twisting the gut around its longitudinal axis.

Gastro-anastomosis or **gastrogastrostomy** is an operation performed for hour glass contraction of the stomach, a condition which occasionally ensues on the healing of an ulcer. In this operation an anastomosis is effected between the pyloric and cardiac pouches. It was devised and practised by Wollfer in 1894. I have practised it twice with success. Watson folds the two stomachs over each other, using the narrow isthmus as a hinge; sutures the pouches together and leaves the ends of the sutures long. He incises the anterior wall of the anterior stomach in order to obtain access to the double septum between the two pouches. He makes an anastomosis opening through the double septum, sutures the edges, and closes the wound

in the anterior wall of the anterior stomach. Wölfler made a vertical cut in each pouch and united these openings to make an anastomosis. The best plan is to apply clamps on each side of the isthmus and operate as we would for gastro-enterostomy.

Fig. 591.—Hour glass stomach. The application of clamps and the method of suture in gastrogastrostomy. The details are the same as in the operation of gastro-enterostomy. Martin.

Gastroplication (Brandt's Operation of Stomach-reefing for Dilated Stomach).—Apply sutures in the anterior wall so as to form reefs, then tear through the great omentum and apply sutures in the posterior wall. The sutures pass through the serous and muscular coats. A continuous suture may be used on the anterior wall and another on the posterior wall, or numerous interrupted sutures may be inserted. This operation is of questionable value, and must never be used if stenosis of the pylorus exists, and stenosis of the pylorus is the most common cause of gastric dilatation.

Bircher's method of gastroplication is shown in Fig. 590.

Gastropexy (Duret's Operation for Gastropptosis).—It has been shown by Duret that dyspepsia of a peculiarly severe type may be produced by prolapse or downward displacement of the stomach. In this condition he advised the following operation: Perform a median laparotomy, but do not incise the peritoneum in the upper portion of the wound. Expose the stomach and fix it by means of a silk suture to the undivided but exposed peritoneum. The suture should be parallel to the lesser curvature and near the pylorus should be horizontal.* The operations of Duret, of Rovsing, of Hartman and

* *Rev. de Chir.*, June, 1896.

of Eve, of London, fix and distort the stomach. This seems to me an objectional procedure and liable to be followed by pain. To fix an organ which undergoes active peristalsis must surely be productive of difficulty. Byron Davis advises the suturing of the gastrohepatic omentum near its attachment to the lesser curvature to the stomach-wall as high as possible. Beyea has devised an operation which is free from the objections which may be urged against Duret's operation.

Beyea's Operation for Gastropptosis.—Insert three rows of interrupted silk sutures through the gastrohepatic omentum and the gastrophrenic ligament. Each suture is passed from above downward and the row begins at the right and passes to the left (Fig. 192). When the sutures are tied, a fold

Fig. 192 — Beyea's operation for gastropptosis: 1, Position of one suture of first row, 2, one suture of second row, 3, one suture of third row. Others of each row introduced at intervals to and including the gastrophrenic ligament.

or plication is formed in the ligaments, the supports of the stomach are shortened, and the viscus is elevated to a normal position without any disturbance of its physiological mobility ("Univ. of Penna. Med. Bull.," Feb., 1903).

Duodenostomy and Jejunostomy.—It has been suggested that one of the above operations should be performed in a case of pyloric obstruction in which pylorotomy is not feasible. Duodenostomy is an easy operation because of the mobility of the pylorus and first part of the duodenum, and it is not only easier, but is safer, than jejunostomy, because it makes the fistula above the opening of the common bile-duct ("Bull. et Mém. de la Soc. de Chir. de Paris," No. 39, 1901). Cackove advocates the operation in some cases of gastric ulcer with repeated hemorrhages and some cases of gastric cancer. In the latter cases he asserts that the mortality is about the same as from gastro-

enterostomy and the prolongation of life is greater ("Arch. f. klin. Chir. Bd. lxx, Heft 2). Hartman's case of duodenostomy lived two months. The operation was performed for extreme cicatricial stenosis of the pylorus due to swallowing hydrochloric acid. Moynihan points out that if the operation is done at all, the indication for jejunostomy is cancer involving the entire stomach or leather-bottle stomach. He operated on 2 cases. One lived one month and one seven weeks (B. G. A. Moynihan, "Brit. Med. Jour.," June 1902).

Jacobson disapproves of both procedures, and objects particularly to duodenostomy, because it involves a portion of the intestine which is difficult to deal with, and because important fluids escape constantly from the fistula.

The same author objects to jejunostomy because of the inevitable leakage of nutritive fluids.

Reported cases of duodenostomy and jejunostomy certainly do not indicate that the operations prolong life to any considerable degree.

Enterectomy, or Resection of the Intestine with Approximation by Circular Enterorrhaphy.—How much of the intestine can be removed without the patient dying from lack of nutrition? The question is not settled.

It has been stated that the removal from an adult of more than one and two-thirds feet produces intestinal disturbance, and that a child tolerates the removal of a piece relatively larger better than does an adult. Certainly it is that great lengths have been successfully removed, and the patients have not only lived, but have been well nourished. Ruggi removed eleven feet successfully. Hayes removed eight feet four and one-half inches from a child of ten years of age, and the patient was well eight months later. Dresser reported 26 cases in each of which more than three feet three inches had been removed (Alexander Blaney, in "Brit. Med. Jour.," Nov. 10, 1901). Blaney adds 7 cases from literature, and tells us that in 9 of the 33 cases death occurred soon after operation.

Alexander Blaney, in the previously quoted article, reviews the subject of the resection of great lengths of intestine. He tells us that how much remains after a resection is important but uncertain. It is uncertain because, as Treves has shown, the length of the intestine varies from fifteen feet six inches to thirty-one feet ten inches.

Resection of the jejunum is much more dangerous than resection of an equal length of ileum. If resection is employed, all diseased or injured bowel must be removed irrespective of ultimate bad consequences (Blaney). The operation is performed as follows: After opening the abdomen isolate the loop of intestine we intend to resect. Push a rubber tube through the mesentery close to the bowel, above the seat of operation, and pass a rubber tube through the mesentery below the seat of operation. Empty this segment of bowel by squeezing and stroking, tighten the rubber tubes, and clamp them to keep the bowel empty (Fig. 503). Instead of tubes, strips of iodoform gauze may be used to encircle the bowel. The diseased intestine is resected, each incision being carried through a healthy segment, and care being taken that the cuts are so arranged that at each end a blood-vessel from the mesentery reaches the edge of the cut bowel. Otherwise repair can scarcely

* Jacobson's "Operations of Surgery."

occur. The lumen of each end of the divided gut is irrigated with salt solution. The divided surfaces are approximated by a double row of sutures—a continuous suture for the mucous membrane, and Lembert's, Dupuytren's, or Cushing's suture to effect inversion. Thoroughly satisfactory approximation can be effected by one row of Halsted sutures. If a redundant fold of mesentery is left, it can be stitched at its raw edge (Fig. 504). Many surgeons remove a V-shaped piece of mesentery and tie the divided mesenteric vessels (Fig. 503). The tubes are removed, and the wound is cleansed, closed, and dressed.

Senn effects invagination by means of a bone ring (Fig. 597).

If the two segments of bowel are unequal in size, the narrow part of the bowel should be cut obliquely and the larger part should be cut transversely. To meet this complication Billroth devised *lateral implantation* (Fig. 626). Suppose the cecum has been resected; its lower end is closed by Lembert sutures, an opening is made in the long axis of the periphery of the colon opposite the attachment of the mesocolon, and the end of the ileum is sutured into this incision. This is called *end-to-side approximation*, or implantation. It is used in the sigmoid, in the cecum, and in any intestinal segment in which the circulation is deficient. Eugene A. Smith ("Amer. Med.," May 10, 1902)

Fig. 591.—Excision of bowel, first step (Esmarch and Kowalzig).

Fig. 594.—Excision of bowel with enterorrhaphy and stitching of the redundant mesentery, second step (Esmarch and Kowalzig).

sums up the advantages of end-to-side approximation as follows: The strain of peristalsis is less than in end-to-end union; the circulation of each end of the bowel and the parts of bowel adjacent is better; each cut edge of mesentery is free to recover its circulation, and there is no dead space at the mesenteric border to lead to leakage.

Senn advises the insertion of an anastomosis ring in the ileum, the invagination of the colon as the ring is pulled into place, and firm suturing of the line of junction. By Senn's method the ileum may be implanted into the end of the colon or into a slit in the wall of the large bowel after the end of the colon has been closed. In some cases, where one portion of bowel is larger than the other, lateral anastomosis is the preferable method. For a full week after an intestinal resection the patient is fed chiefly by nutrient enemata. During the first twenty-four hours nothing is given by the stomach but small amounts of hot water, and for the next six days but a little liquid food is allowed to be swallowed.

Fig. 595.—Resection of intestine. *a* & *b* The two halves of the button. *c*, the two portions clamped together; *d*, introduction of the sutures for feeding each half of the button in place. The lower figure shows the completed union of the intestine by the Murphy button; the slit in the outside has been closed by linear union (after Zuckerkandl).

Fig. 596.—Comparison of old (*a*) and new (*b*) Murphy buttons.

use of *Murphy's button* permits of rapid approximation after resection

Fig. 597 — Senn's modification of Jobert's invagination. A, Upper end lined with ring. B, Sutures in place. C, Lower end.

(Fig. 595, *b* and *c*). This button closely approximates the portions of the intestine within its bite, rapid adhesion taking place. The diaphragm of tissue undergoes pressure-atrophy and liberates the button, which is passed per anum. It is claimed that the button-opening contracts but slightly. For end-to-end or side-to-side approximation of the small intestine a No. 3 button is used. For similar operations on the large intestine a No. 4 button is employed (Murphy). After the resection one half of a but-

tered into each segment, and is held in place by a purse-string suture which passes through all the coats (Fig. 595). The redundant mucous

is tucked in or so that it will be exposed between the surfaces. The surfaces are

trouble does not of necessity follow. But in some cases its retention leads to trouble, and obstruction ensues. If the caliber of the button blocks the dislodgment, obstruction follows; hence the rule to give saline purgatives the day after the operation.

Fig. 599.—The segmented ring of Harrington and Gould.

Some surgeons have sought to make a button which would come apart and be absorbed after it had accomplished its purpose. The best of the appliances is Frank's coupler, which is made of bone, the compression being furnished by rubber. In this apparatus, however, the amount of pressure obtained is always uncertain and the rubber is apt to wear out. The button gives a lower mortality than the suture operation, and many surgeons now use it who once condemned it. Czerny is a strong advocate of the button.

Fig. 600.—End-to-end union with aid of segmented ring. Continuous suture beginning at one side of the handle (Harrington and Gould).

After intestinal resection Halsted performs circular enterorrhaphy by means of mattress sutures (Figs. 605 and 606).

Harrington and Gould use a segmented aluminum ring. This ring collapses into small segments after the anastomosis has been effected. By its use the authors believe that the operation is made more rapidly and safely ("Annals of Surgery," Nov., 1904). During the suturing the ring is held by

means of a handle, which, after the anastomosis has been effected, is removed. The ring in the handle is shown in Fig. 599 and the operation in Figs. 600, 601.

Maunsell has devised a most ingenious method of circular enterorrhaphy. The two portions of bowel are attached by two fixation sutures which penetrate all the coats (Fig. 598). An incision one and one-half inches in length is made

Fig. 601.—End-to-end union with aid of segmented ring. Handle unscrewed, suture completed (Harrington and Gould).

Fig. 602.—Robson's decalcified bone bobbin.

Fig. 603.—Allingham's decalcified bone bobbin.

Fig. 604.—Harris's method of circular enterorrhaphy.

through the wall of the proximal segment of gut, about one inch from its edge. The fixation sutures are brought through this opening, traction is made on them, the distal portion of the bowel is invaginated into the proximal portion, and the ends emerge from the opening, their peritoneal surface being in contact (Fig. 598). Sutures of silk are passed through both sides of the area of invagination, the threads are caught up in the center, cut, and tied on each side. The fixation sutures are cut off. The invagination is reduced by traction. The longitudinal cut is closed by Lambert sutures.

Fig. 605.—Use of Halsted's inflated rubber cylinder in circular enterorrhaphy.

A. W. Mayo Robson performs circular enterorrhaphy and brings the ends of the gut together over a hobbin of decalcified bone (Fig. 602). All ham uses a bone hobbin the shape of two cones joined at their apices. The hobbin is decalcified, except an area at the center (Fig. 603). Köcher performs circular enterorrhaphy as follows: A fixation suture is introduced through the bowel at the mesenteric attachment and another is inserted

Fig. 606.—Suture of the mesentery after circular enterorrhaphy (Halsted).

at an opposite point. The intestinal ends are approximated by a continuous silk suture which passes through all the coats, but which includes more of the serous than of the mucous coat. The suture-line is overlaid by a continuous Lambert suture which includes the serous and a portion of the muscular coat. Harris removes a portion of mucous membrane from the distal end by means of a curet. Three needles are threaded with fine silk. The first needle is pushed through

the bowel-wall to one side of the mesentery. The point of the needle

Fig. 607.—Moynihan's method of end-to-end anastomosis (Moynihan)

Fig. 608.—Moynihan's method of end-to-end anastomosis continued

Fig. 609.—Moynihan's method of end-to-end anastomosis continued.

takes up a portion of the distal end transversely. The needle is used as a lever to invaginate the distal end into the proximal end. The same procedure is carried out with the other needles. When invagination is effected the needles are pulled through and the threads are tied. The end of the bowel is now turned to the invaginated part by interrupted inversion sutures or by a continuous version suture broken once (Fig. 604).*

In doing an end-to-end approximation I prefer to use the clamps of Moynihan, as shown in Figs. 607, 608, and 609. We thus are able to hold the parts and keep them clean, rapidly make an even and secure stitch line, and have no free-edged septum.

Fig. 610.—Laplace's forceps for intestinal anastomosis.

* Chicago Med. Recorder, Jan., 1897.

Some surgeons employ inflatable rubber cylinder anastomosis (Halsted, Downes, and others). The Treves, but was subsequently abandoned by him. The use of the inflatable rubber cylinder enables the operation more quickly and to dispense with clamping of the intestine; makes easy the adjustment of intestine of unequal size; and renders it performed rapidly, evenly, and securely.* Three preselected portions of bowel and a V shaped piece of mesentery incision being so made as to leave an edge to supply each end of the divided intestine, are ligated and the ends of the bowel are pulled together by two stitches, two of which are tied. The collapsed intestine is introduced into the bowel by means of forceps and is inflated (Fig. 605). Twelve mattress sutures are inserted, the

Fig. 611.—End-to-end anastomosis with the aid of Laplace's forceps.

Fig. 612.—Senn's bone operation of the intestine.

drawn and the sutures are tied, the stitch is drawn. The slit in the mesentery is sewed in such a way that the vessels which nourish the bowel are not interfered with.

Connell has devised a method which places the suture within the lumen of the intestine (F. Gregory Connell, "Medicine," April, 1905). The placing of the knots within the lumen of the gut avoids the danger of the placing of the knots outside: there is no foreign body; the suture passes between the neighboring organs are few; the serous approximation is more secure; the septum is smaller and the operation is simpler. The suture is shown in Plate 10.

Laplace has devised forceps which greatly facilitate the operation. It is easy to obtain an even suture line, and which is not liable to tearing. When suturing is finished, the small opening through which the intestine is introduced being closed with a stitch (Figs. 610, 611). By this method the operation can be neatly and rapidly performed.

* Phila. Med. Jour., Jan. 8, 1905.

formed, a considerable area is exposed to infection, the tissues of the diaphragm are bruised and may slough, the raw ends may grow together and

Fig. 613.—Method of passing the silk sutures in inserting the rings of Abbe.

Fig. 614.—O'Hara's anastomosis forceps (about one-third original size).

Fig. 615.—Showing the manner of placing forceps in resection of bowel, dotted lines show the incision to be made (O'Hara).

cause obstruction, and it seems probable that considerable contraction will follow. Another objection is that an infected instrument is withdrawn from the bowel and may contaminate the peritoneum. O'Hara's forceps (Fig. 614) permit

of rapid and accurate suturing, but possess the same disadvantages as Laplace forceps. In one case within my knowledge absorption of the raw edges of the septum followed its removal. Figs 615 and 616 show the use of O'Hara's forceps. Of the various methods of anastomosis, I prefer the clamp and suture as employed by Halsted.

Fig. 616.—End-to-end anastomosis. Forceps brought together and held by sutures introduced, some of which are tied (O'Hara).

Fig. 617.—Showing relative size of incision and method of introducing suture with Murphy's button.

the operation of Halsted (although distention by an inflated balloon is a necessary adjunct), or the operation with the Murphy button.

Lateral Intestinal Anastomosis.—Approximation of the ends of the intestine by other methods than by end-to-end junction or implantation is preferred in most cases of resection to close each end of the divided intestine in the form of lateral anastomosis. By this operation we can obtain a permanent opening as we desire. Again, after lateral anastomosis

a better blood-supply than after end-to-end suturing, because in the form

Fig. 618.—Suturing intestines in apposition before incision (Abbe).

Fig. 619.—Showing the four-inch incision and sewing of the edges (Abbe).

operation the mesenteric vessels are not interfered with. Further, in lateral anastomosis there is little tendency to cicatricial contraction. Lateral anastomosis may be performed in some cases without a preliminary resection for the purpose of short circuiting the fecal current, throwing a diseased portion of the bowel out of action, and thus avoiding obstruction (Fig. 612). This operation has the disadvantage that the diseased structure is not removed.

Operation with Rings.—In this operation a portion of bowel above the obstruction and a loop below the obstruction are brought into the wound. These segments are emptied, and are kept empty by fastening around them rubber tubes or iodoform

Fig. 620.—Halsted's operation for lateral anastomosis, showing four steps of same (Jesett, from Halsted).

strips. Two tubes are needed for each loop of bowel. Pack in gauze pads. Make an incision in one loop, in the long axis of the bowel, on the surface away from the mesentery, permit the contents to escape externally; irrigate this segment with saline solution; and introduce the bone plate of Senn (Fig. 612, A) or Abbe's catgut ring (Fig. 613). Calyx-eyed needles are used to pass the silk, and the threads of the ring are carried through the coats of the bowel and are gathered together in the bite of a pair of forceps. The other loop of intestine is treated in a similar manner. The two segments of intestine are so brought together that the two wounds are opposite each other, the posterior

sutures being tied first, the upper next, then the lower, and finally the ant-threads. The ends of the threads are cut off and the entire anastomosis is surrounded by a layer of Lembert or Halsted sutures or is encircled by Cushing's suture. Fig. 612, B, shows an intestinal anastomosis partly finished, and Fig. 612, C, shows an anastomosis complete. Fig. 613 shows the passing of the sutures when the catgut rings of Abbe are employed. After an intestinal resection each end can be closed and anastomosis effected as described above. Lateral anastomosis can be accomplished with a Murphy button, the intestine being prepared for the button as is shown in Fig. 617.

Fig. 621 - Represents the ends of the intestine in position and grasped by the artery forceps. The first row of sutures has been partially applied, the septum partly away, and the second row of overhand sutures being applied. *a, b*, are the two ends of the intestine; *c*, the first row of sutures (Cushing); *d*, the second row of sutures (overhand); *e*, the septum; *f* and *g*, the mesentery. (Shelton Horsley).

Abbe's method of anastomosis without mechanical aid is as follows:

Fig. 622.—Operation nearly completed. The septum has been cut away and the row of overhand sutures has been brought almost to its point of commencement. The cut also shows the first row of sutures (Cushing) as it should be continued after the overhand sutures are finished. (J. Shelton Horsley.)

After resecting the bowel and mesentery and closing the ends of the bowel he places the extremities side by side and applies two rows of a Dupuytren suture, one-quarter of an inch apart. These rows of sutures are an inch longer than the slit in the bowel will be (Fig. 621). The thread at the end of each row being left long. An incision is made in the bowel, one-quarter of an inch from the sutures, both rows of threads being on the same side of the cut. This incision is four inches long. The other portion of the bowel is then incised in the same way. The adjacent cut edges are united by a whip stitch which goes through all the coats, and the free cut edges are stitched in the same

manner (Fig. 619). The surgeon now utilizes the long threads of the first sutures, and brings the serous surfaces of the opposite sides together by means of Dupuytren's suture. Halsted performs anastomosis as follows: He places the two portions of bowel with their mesenteric borders in contact. Quilted sutures of silk are introduced, tied, and cut off (Fig. 620, A). At each end of this row of sutures two quilted sutures are introduced, tied, and

Fig. 623.—Lateral anastomosis with the aid of Laplace's forceps.

(Fig. 620, *b*). A number of quilted sutures are introduced, as is shown Fig. 620, *c*. The intestinal openings are made with scissors, and the ones last introduced are tied and cut off (Fig. 620, *d*).

J. Shelton Horsley has suggested an ingenious method of intestinal anastomosis which secures for the sutured portion a greater diameter than that normal to the intestine.* After resection of the intestine and a V shaped piece of mesentery, the ends of the bowel are placed side by side, the openings being in the same direction, and are clamped in place (Fig. 621). The first stitch approximates the two limbs of the bowel at the mesenteric attachment, is carried obliquely for about 3 inches to the border opposite the mesenteric attachment, and continued over the other limb (Fig. 621). The septum is removed, a margin being left one-third of an inch wide. The edge of the shelf made by cutting the septum is sutured. When the suture reaches the end of the shelf, it is continued by invaginating about the rest of the resected ends (Fig. 622).

Fig. 624.—Withdrawal of Laplace's forceps.

Bodine's method of intestinal anastomosis is referred to on page 1112. Dr. J. C. Bodine, of Philadelphia, has devised an operation in which temporary approximation is effected by means of forceps, the instrument being withdrawn before the abdomen is closed. Junction of two segments of intestine

*New York Polyclinic.

Laplace's forceps, O'Hara's forceps, the decalcified bone plates of Senn, the catgut rings of Abbe, the segmented ring of Harrington, the catgut strands inside of rubber tubing of Brokaw, Chaput's button, Allingham's bone bobbin, Robson's bone bobbin, Frank's coupler, Clark's bobbin, tubes or plates of potato or carrot, and rings or plates of leather, all have their adherents. Of mechanical appliances, the best are Murphy's button, the bone ring, Moynihan's forceps, and the inflatable rubber cylinder. Of recent years many surgeons have abandoned all mechanical aids, and have returned to closure by simple sutures. The ideal operation is without mechanical contrivances. But such devices are time-savers, and to lessen the time of operation will often save life. Further, Moynihan's forceps prevent fecal extravasation and consequent infection. What method to follow must be determined in each particular case by a study of the necessities of the situation. Nevertheless, it may be possible to formulate a few general rules: If the condition of the patient is excellent and the bowel is in a fairly healthy condition, well

Fig. 626—Operation of complete exclusion of the cecum: *a* and *b*, lines of incision; *f* is implanted into *c*, *e* and *d* are sutured to the abdominal wall.

above and well below the seat of trouble, end-to-end approximation should be performed by circular enterorrhaphy with the aid of Moynihan's clamp, or each end can be closed after resection and a lateral anastomosis be effected with the aid of the clamp. If the condition of the patient is such as to make haste necessary, use a Murphy button. If the bowel below the seat of trouble is much contracted and haste is necessary, do not use a Murphy button, but use Senn's bone plate or Robson's bobbin. If haste is not imperatively necessary, do enterorrhaphy. If the surgeon is obliged to join a very much distended bowel to a very much contracted bowel, perform end-to-end approximation (implantation) with the bone plate of Senn or by simple suturing, or else effect side-to-side junction by the method of Abbe or of Moynihan.*

Local Intestinal Exclusion.—This operation was introduced by Salzer in 1891. It excludes the fecal current from a portion of the intestine. In complete exclusion the intestine is cut through above and below the diseased portion and the ends of the healthy gut are united to each other or the end of one portion of gut is implanted into the side of the other. Both ends

* See the discussion of this subject by the late J. Greig Smith in his "Abdominal Surgery."

abdominal wall as well as the omentum. The liver and spleen, under surface of the diaphragm, and parietal peritoneum about the liver and spleen are usually rubbed harshly with a piece of gauze. Drainage is not to be used. It does not appear to contribute any favorable chances and it exposes the patient to the danger of infection.

The operation ought to be performed early, before the onset of chronic inflammation of the peritoneum. In a great majority of cases the operation proves futile, and not uncommonly death soon follows from complications or because the disease is very far advanced. In exceptional cases the operation proves of distinct benefit. The operation shows the least mortality and the greatest number of apparent cures when the liver is large; the greatest mortality and the fewest cures when the liver is contracted. The greatly lowered vital resistance of these patients is the imminent danger (Greenough). Renal disease, cardiac disease, other grave complications, and the absence of sufficient functioning liver substance to maintain life contraindicate operation (Greenough, in "Am. Jour. Med. Sciences," Dec., 1902).

Harris, in the paper previously quoted, collected 46 cases. Twenty-three of these were instances of alcoholic cirrhosis. Thirty per cent. were dead within fourteen days; 52 per cent. were dead within two months; 56 per cent. were dead within six months. Ascites had returned in all of those who died late. At the end of one year or longer 13 per cent. had recovered from ascites. The remaining 30 per cent. were either unimproved or were said to be improved with some ascites.

Of the group of mixed cases constituting the remainder of those Harris collected, 10 per cent. were dead in four days, 25 per cent. were dead in four months. In 40 per cent. no improvement took place. In 10 per cent. the report was too early to give any information. About 15 per cent. were free of ascites after one year or longer, and 5 per cent. were cured of intestinal hemorrhage, ascites never having been present. Greenough collected 105 operations; 42 per cent. were improved; 58 per cent. were not improved; 29.5 per cent. died within thirty days. Two years after operation 9 cases were apparently in good health ("Am. Jour. Med. Sciences, Dec., 1902).

Operation for Intussusception. Air distention and hydrostatic pressure are uncertain; in an advanced case may rupture the gut; even in a recent case may fail or may reduce the bulk of the intussusception, but not its apex. Russell ("Intercol. Med. Jour. of Australasia," March 20, 1902) alludes to the uncertainty of the method. He used hydrostatic pressure in 5 cases. Two died and two recovered. In one case the method failed and operation was then performed. It is safer and better to operate early, but if the conservative plan is tried and fails, operation should certainly be done at once, because an early operation enables the surgeon easily to effect reduction, and also because early complications are unusual. The incision is made in the mid-line above the umbilicus. The surgeon endeavors by manipulation to reduce the intussusception by pushing it back, not by pulling it out. If the intussusception is gangrenous, perform intestinal resection and circular enterorrhaphy. The same rule maintains when malignant disease of the gut exists (D'Arcy Power). It is inadvisable to make an artificial anus. Maunsell's operation is suited to cases of irreducible intussusception. It is performed as follows: A longitudinal incision is made

in the intussusciens. The intussusception is gently pulled upon and is caused to protrude from this opening. Two straight needles threaded with horse-hair are passed so as to transfix the base, and one-fourth of an inch above the needles the intussusception is cut off. The needles are carried completely through, the sutures are hooked up in the middle and cut, and the two ends are tied on each side. These sutures unite the intussusception to the intussusciens. The two surfaces are now carefully approximated by sutures. The sutures are cut. The stump is replaced. The longitudinal incision is closed with Lembert sutures.*

Russell reports 16 cases operated upon: 12 recovered and 4 died. In every one of the 4 fatal cases the diagnosis was not made until the disease had lasted several days. In 2 of the successful cases the diagnosis was made late ("Intercolonial Med. Jour. of Australasia," March 20, 1902). If operation is done in the first twelve hours the mortality, even in infants, will scarcely exceed 15 per cent. If gangrene exists the mortality is enormous (at least 90 per cent.).

Senn's Operation for Fecal Fistula.—Suture the opening transversely with Czerny sutures of silk in order to prevent infection. Cleanse the surface thoroughly. Open the abdomen and separate the edges of the bowel from the parietes. Deliver the portion of bowel which contains the fistula and apply Lembert sutures over the Czerny sutures. Another method is to open the abdomen above the fistula, insert the fingers, cut out the skin and tissues around the fistula in an elliptical course, leaving them attached to the bowel, draw the bowel from the abdomen, pack gauze around, remove the tissues adherent to it, and suture the fistula transversely (Hearn).

Enterostomy is the making of an artificial anus. If performed in the large bowel, it is called *colostomy*. In some cases of intestinal obstruction it is necessary to open the small intestine, and if this is required, the artificial anus should be made as near as possible to the cecum. The nearer to the stomach it is made, the more apt is the patient to die of lack of nourishment. The anus may be made in the middle line or in the right iliac region. The bowel is fixed and opened as directed under colostomy. In acute intestinal obstruction it may be necessary to open the bowel at once. In such a case Paul's tube is very useful. Paul's tube is made of glass, is bent to a right angle, and has a rim near each end. The large tube is used in the colon, the small tube in the small intestine. A small opening is made in the intestine, the tube is introduced, and is tied in place by a silk suture which surrounds all the coats of the bowel, a gush of feces is caught in a basin, a rubber tube is fastened to the glass tube, and fluid feces are collected in a bottle and beneath an antiseptic fluid.† In from three or four days to a week the tube becomes loose and can be removed. Stewart's method of enterostomy was outlined on page 977.

Inguinal Colostomy. Maydl's Operation (Fig. 629).—In this operation a vertical or oblique incision four inches long is made over the portion of colon to be incised. In all cases where it is possible, do a left inguinal colostomy. In right inguinal colostomy it is difficult to deliver the bowel as in a left inguinal colostomy, because of shortness or absence of mesocolon at this point of the

* L. P. King Proc. Quarterly Med. Jour., Jan., 1897.
† Proc. in Liverpool Med.-Chir. Jour., July, 1892.

colon. Right inguinal colostomy has been performed for chronic amebic dysentery. It puts the colon at rest and permits of free irrigation. It is kept open until the dysentery is well. Appendicostomy has replaced it for dysentery.

Fig. 627. Stevenson's bag for inguinal colostomy.

It has also been employed for the treatment of ulceration of the colon. After the incision on the left side the colon usually bulges into the wound, but if it does not, it may easily be found by following with the finger the parietal peritoneum outward, backward, and inward, the first obstruction it encounters

Fig. 628. —Stevenson's bag applied.

being the mesocolon. Draw the colon out of the wound until its mesenteric attachment is level with the abdominal incision. Push a glass bar through a slit in the mesocolon near the bowel, and wrap the ends of the bar with iodo-

form gauze to prevent slipping. Instead of the bar, a bridge of skin can be made under the two skin edges. The two parts of the flexure are stitched which penetrate to and catch the submucous coat (Fig 629) coat of the bowel to the parietal peritoneum. Whenever twenty-four to forty-eight hours before opening the gut, by the cauterizer or by scissors. If the artificial anus is to a transverse incision through the bowel. Cut one-fourth of the colon when it is first opened, and entirely across at a later time. If the artificial anus is to be temporary, the incision should be made in the transverse colon. This operation has great advantages: it is quick, certain, readily performed, and absolutely prevents fecal accumulation below the opening, and absolute fecal incontinence. In many cases the bowels

Fig 629.—Inguinal colostomy, after Zuckerkandl.

colostomy should reach to and remain at the level of the condition impossible of attainment by hanging the loop out of the body or piece of gauze, because a spur thus formed is rigid and is inevitably dragged below the skin-level. If such a thing has taken place, some fecal matter will pass into the artificial anus. Bodine opens the abdomen, sutures the incision to the skin, seeks for the lesion, and draws it with six inches of the incision. He lays the limbs of the loop side by side, and unites the two segments close to their mesenteric attachment by a silk stitch, beginning at the point where excision is to be made. The loop is dropped into the abdomen until the beginning of the lesion is with the skin, and at this point it is fastened to the abdominal wall with a continuous catgut suture. The protruding lesion is cut off (Fig 630). The artificial anus is thus established. To close the artificial anus, divide the septum with scissors (Fig 631) and close the abdominal wound.*

Lumbar Colostomy. Lumbar colostomy is a modification of the inguinal colostomy. It does not completely intercept the fecal current, but it relieves the patient in a condition of wretched discomfort because of fecal accumulation. A patient who has had lumbar colostomy

times a day, however, comfortable, no warning, there will be no long as it is covered with gauze by a firm bandage permanent.

Bodine's (Fig 630).—Bodine's colostomy permits of the fecal matter being performed and the surgeon maintains

* New York Polyclinic, Feb. 15, 1897.

either obtains little benefit because the feces pass into the bowel below the opening which was made to intercept them or else they pour out of the opening uncontrolled, making the poor unfortunate a living horror to himself and others. It is rarely performed at the present day.

The Healthy Gall-bladder.—A healthy gall bladder has a capacity of about 1 ounce, and its hue is bluish. If a gall-bladder contains calculi or has contained them, its hue is grayish white or yellowish (Moynihan).

Congenital Absence of the Gall-bladder.—When the gall-bladder is shrunken and buried in adhesions, it is very hard to find at operation. Sometimes it is not found and one may jump to the conclusion that it is congenitally absent. This is occasionally, but very seldom the case. Gray collected 39 instances of congenital absence of the gall-bladder ("Trans. of Chicago

Fig. 630.—Rodier's method of colostomy, showing one side of the loop after it has been sutured, passed back into the cavity, and sutured into the abdominal wound. The lesion is left protruding, and the dotted line indicates where the protrusion is to be clipped off.

Fig. 631. Rodier's method of colostomy, showing the septum to be divided in restoring the fecal current. Grant's clamp in position for the division. In permanent colostomy this septum remains as a rigid and effective spur.)

Path. Soc., 1902). When it is absent the subject seems to get along perfectly well without it.

The Incision for Operations upon the Gall-bladder and Bile-ducts.—I have employed several methods, but for some years have been most content with Bevan's incision (Fig. 632). The primary portion of the incision is shaped like the italic letter *f*. It is by the side of or through the right rectus muscle, and is shown by the double line in Fig. 632. The primary incision is used for exploration and cholecystotomy. The primary incision is from three to four inches long, and the extended portions, shown by heavy lines in Fig. 632, are added if required (Arthur Dean Bevan, "Annals of Surgery," July, 1899). This incision gives most satisfactory exposure, its edges can be separated without tension, and it injures but few of the nerves of the abdominal walls.

I believe it to be superior to Kocher's incision (Fig. 632), which cuts the

and the peritoneum to be incised in the same direction as the skin and anterior wall. The upper end of this diagonal incision through the posterior wall extends into the short, transverse incision across the linea alba. When this last cut is made the incision pulls open and gives ready access to the right upper abdomen. This incision does not damage the intercostal nerves, hence muscular atrophy is avoided. The opening through the different planes of the abdominal wall are not continuous, hence closure will be more solid. The opening in the posterior portion of the rectus sheath is protected by uninjured muscle.

Cholecystostomy or, as many call it, **cholecystotomy** is the operation of opening and draining the gall bladder in order to remove gall-

Fig. 611.—A, anterior wall of sheath of rectus muscle; B, posterior wall of sheath; C, rectus muscle; D, intercostal nerves. The direction of the incision through the skin, fat, and anterior wall of the sheath of the rectus muscle (Collins).

stones or secure the removal of infectious material. In the hands of the Mayos, operations for stone exhibit a mortality of less than 1 per cent.; Kocher's mortality is 2 per cent. When death follows an operation on the gall-bladder or ducts, in about one half the cases it is due to duct infection and is preceded by grave nervous symptoms (Mayo). Cholecystostomy is performed in cases of acute cholecystitis, in hydrops, and in empyema of the gall-bladder; in gall-stone cases in which jaundice has lasted for four weeks or more, and in colic of the gall-bladder with fever, the colic having recurred a second or third time (Carl Beck). The operation completed in one stage is performed as follows. The patient is placed recumbent with a sand-pillow under the back and

the incision is made. The peritoneum is opened. If the gall bladder is distended, it is surrounded with pads and aspirated, and is then opened. Gall stones are removed by forceps, the scoop, or irrigation. The gall ducts are examined by the fingers external to them, and are sounded, if possible. If a stone is wedged in the duct, try to manipulate it back into the gall bladder. If this fails, introduce an instrument from the gall bladder and break the stone, if this fails, open the duct, remove the stone, and close the incision in the duct (A. W. Mayo Robson). The only way to be certain that stones have been entirely removed from the cystic duct is to insert a finger and draw it out. Sounds are unreliable. After the removal of all stones and fragments pass a rubber tube which has no side perforations into the gall bladder, cut it off level with the cutaneous surface, purse up the cut in the gall bladder and the tube by means of a catgut suture, and suture the gall bladder to the abdominal aponeurosis. If sutured to the skin, a permanent biliary fistula is apt to follow. It will seldom follow if the gall bladder is sutured to the aponeurosis. The gauze is now removed and the drainage tube can usually be dispensed with in from one week to ten days. It should not be dispensed with until the bile becomes sterile.

Some surgeons have advocated immediate suture of the gall bladder after removing a stone (*ideal cholecystotomy*). I believe this is never advisable when the stones are active for harm, because small calculi may be in the ducts, and minute fragments of stone are often left in the bladder, and the drainage will remove them and relieve the diseased condition of the gall ducts and bladder. In Kocher's 31 operations by this method, gall stones were removed in 3 cases. Further, the operation with immediate suture is decidedly more dangerous when infection exists. The Mayos only employ it in latent cases of gall-stone disease when the existence of stones is discovered during the performance of an abdominal operation.

It is advised by some that the operation of cholecystostomy be performed in two stages. First, the bladder is exposed and sutured to the parietal peritoneum. When adhesion takes place, the gall bladder can be opened with less risk of infecting the general peritoneal surface. Riedel advocates operation in two stages, and so did Christian Fenger in certain cases. The two-stage operation is objectionable because it does not permit of satisfactory exploration of the ducts. The *biliary fistula* which is left by cholecystostomy usually closes spontaneously, but may not. If it does not close and the secretion is pure mucus, it is evident that the cystic duct is absolutely blocked and cholecystectomy should be performed.

If the secretion from a persistent fistula is bile and if the common duct is obstructed, separate the edges of the gall bladder opening from the parietal peritoneum, endeavoring to avoid entering the abdominal cavity, and close the fistula with Lembert or Halsted sutures. If the secretion is bile and the common duct is obstructed permanently, perform *cholecystenterostomy*. In 214 cases of cholecystotomy for stone in the gall bladder, in the cystic duct, or both, the Mayos had 2 deaths (Wm. J. Mayo, "Annals of Surgery," June, 1902). At the end of 1907 Hans Kehr placed his mortality at 2 per cent. ("Jour. de Chir.," Oct., 1908).

Cholecystenterostomy consists in making an anastomosis between the gall bladder and intestine, preferably the duodenum, or, if this cannot be

done, to the jejunum. It is employed in cases of irremovable obstruction of the cystic or common duct. It is done chiefly in cases of malignant obstruction. It is not a suitable operation for gall stones impacted in the common duct, because it does not remove the cause of trouble, infection of the bile-passages may follow, and the fistula is liable to contract. In those rare cases of common duct obstruction from gall-stones in which the gall-bladder is distended and the patient is desperately ill, it may be done (Robson). In such a case Robson attaches the gall bladder to the colon because the operation is easier and because he considers it as useful as the attachment to the duodenum. Cholecystenterostomy can be done most rapidly and successfully by means of a small Murphy button. Before the gall-bladder is incised it is aspirated. Murphy's operation is shown in Fig. 634, and is similar in per-

Fig. 634.—Showing method of holding parts while approximating a Murphy button in cholecystenterostomy.

formance to intestinal anastomosis. I believe that Brentano is right and that it is best to do posterior cholecystenterostomy, bringing the jejunum through an opening made in the transverse mesocolon.

Cholecystectomy is the extirpation of the gall-bladder. It was first performed by Langenbuch in 1882. Sometimes primary extirpation is performed; at other times cholecystectomy is performed as a secondary operation, cholecystostomy for drainage having been first performed. Its performance may be demanded by the existence of phlegmonous inflammation or gangrene, ulceration, "in chronic cholecystitis from gall-stones where the gall bladder is shrunken and too small to safely drain, and where the common duct is free from obstruction" (A. W. Mayo Robson), in empyema with greatly damaged walls, in fistula associated with irremediable obstruction of the cystic

duct, the common duct being free, in cancer, and in some wounds of the gall bladder. Objections to the operation are that drainage can only be obtained by putting a tube into the hepatic or the common duct and that, should renewed drainage be subsequently required, the necessary operation will prove difficult and dangerous (Maurice H. Richardson, "Medical News," May 2, 1903).

After opening the abdomen the gall-bladder is found and is drawn into the wound. If it is distended and tense or if it is thought "to contain infectious fluid" (Lilienthal), it is packed about with iodoform gauze and emptied by an aspirating trocar. "When the walls are very friable, it is even wise to incise and empty the viscus, closing the opening by ligature or clamp before proceeding with the extirpation. The gall-bladder is usually quite a tough organ, and in the majority of cases it may be grasped with an ovarian ring-clamp applied near its fundus, which at the same time closes the aspiration puncture" (Lilienthal, "Annals of Surgery," July, 1904). The peritoneum which covers the gall-bladder must be divided just below the liver, the gall-bladder is dissected from the liver until the cystic duct is reached, the cystic artery is tied and divided, and if the liver ducts are healthy, the cystic duct is ligated with silk and divided, the stump is touched with pure carbolic acid and is covered with a layer of peritoneum fastened by sutures of fine silk. In cases free from infection it is not necessary to drain the bile-ducts. In cases with cholangitis external drainage is necessary and it is obtained by incising the hepatic duct and inserting a drainage-tube, or, better, by leaving the stump of the cystic duct open. Wm. J. Mayo reports 33 cases of cholecystectomy with 1 death ("Annals of Surgery," June, 1902). Howard Lilienthal reports 42 cases with 1 death ("Annals of Surgery," July, 1904). Hans Kehr's mortality at the end of 1907 was 3.6 per cent. ("Jour. de Chir.," Oct., 1908).

Removal of the Mucous Membrane of the Gall-bladder.—Mayo has suggested the removal of the fundus and of all the mucous membrane of the gall-bladder as an occasional substitute for cholecystectomy. In this operation we are enabled to drain the cystic duct and through it the hepatic ducts. A serious objection to the operation is that, as glands pass from the mucous coat to and through the muscular coat, it is impossible absolutely to remove the mucous membrane of the gall bladder alone (Lund Ries).

Drainage of the Hepatic Duct.—This operation is employed for certain hepatic infections. It was first performed by Cabot in 1897. If the cystic duct is dilated throughout, it may be carried out through that. At opening the gall bladder a tube is passed through the cystic and into the hepatic duct. It is often done after opening the common duct, a tube being carried up into the hepatic duct. The hepatic duct may be exposed and opened directly, a tube being carried into it for a short distance and sutured to the edges of the incision in the duct by catgut. The tube should be surrounded by iodoform gauze.

Choledochotomy is the operation of incising the common duct for the removal of a stone. It is also called choledocholithotomy. It was first performed by Courvoisier in 1890.

Cases upon which this operation is done are often deeply jaundiced and there is grave danger of infection and of fatal oozing of blood. In one of my cases this happened. The patient was laboring under stones in the com-

common duct, associated with cancer of the head of the pancreas. In every case in which operation is contemplated for obstruction of the bile-ducts, take the coagulation time of the blood. Normal coagulation time (taken by Wright's coagulometer) is from three to six minutes. Prolongation to seven or eight minutes calls for pre-operative treatment to hasten coagulability. If jaundice exists, it is customary to endeavor to prevent hemorrhage by employing Robson's plan: Give by the mouth from 30 to 60 grains of chlorid of calcium three times a day during the twenty-four or forty-eight hours preceding the operation, and 60 grains by enema three times a day for the forty-eight hours following the operation. I have followed this course in a number of cases, but am not convinced of its value. Instead of this method we may follow the plan of giving thyroid extract (gr. v three times a day) for several days preceding the operation.

The plan I now pursue I am certain does reduce the coagulation time distinctly. I give an injection of diphtheria antitoxin (horse serum) the day before operation and another the morning of the operation.

When ready to operate, a sand-bag should be placed under the lower ribs. This will bring the liver at least two inches nearer to the abdominal wound. The abdominal incision must be longer than that employed for cholecystostomy. The pylorus and stomach are drawn to the left, the colon and omentum are drawn downward, and the liver and ribs are lifted strongly upward. Gauze packs are inserted.

The operator should now, after having separated adhesions, have a good view of the common duct within the free border of the lesser omentum, and on inserting his left index-finger into the foramen of Winslow, or on grasping the duct between the index-finger and thumb, he can, without difficulty, bring the duct well within reach, the concretion making a distinct projection.* A longitudinal incision is made, the stone is removed, and a probe is introduced into the duct to determine whether other stones are present.

Stones in the second and third portions of the duct are often missed and the second portion of the duodenum should always be palpated with the utmost care. If the lowermost stone removed from the common duct is faceted we should always search most carefully to find a concretion which is lower still (F. Gregory Connell, "Annals of Surg.," April, 1908).

If a calculus is found in the lower part of the common duct the surgeon tries to push it up so that he may reach it. This can usually be accomplished. If he fails to push the stone up into reach, he must try and force it into the duodenum. This attempt will sometimes, but seldom, succeed. If it does not succeed he must perform a transduodenal or a retroduodenal operation. Only in cases so shocked that further operation is impossible is it proper to do cholecystostomy or cholecystenterostomy. If either of these palliative operations is performed a radical operation must be done later.

Many surgeons suture the incision in the duct. This procedure is rendered easier by the use of Halsted's hammer, which draws the duct toward the surface and keeps it under control (Fig. 635).

Interrupted sutures of fine catgut are used. The muscular and serous coats may be included in each suture, and over this layer Lembert or Halsted sutures are applied. A drainage-tube is inserted and a piece of iodoform

* A. W. Mayo Robson's "Treatise on Diseases of the Gall-bladder and Bile-ducts."

Fig. 535.—Suture of duct over Halsted's hammer

or inserts a rubber drainage-tube into the opening and carries it into the hepatic duct, or makes an incision into the right loin after Rutherford Morison, and carries a tube into the right kidney pocket, the most dependent part of the peritoneal cavity when the patient is in the prone position. Personally I always drain the duct, when I have opened it for stone removal, by carrying the tube up to the hepatic duct. The same reasons which cause us to drain the gall-bladder after removing stones should influence us in this case.

Robson ("Lancet," April 12, 1902) has performed the operation of cholecystotomy 60 times. In 10 cases of stone in the common duct he dilated the stone back into the gall-bladder and removed it through the gall-bladder by means of a scoop. The above maneuver is impossible if the cystic duct is dilated. In 30 cases he crushed the stones between his fingers and thumb, but this is only possible when the stones are soft, and an objection that it may leave fragments. If a stone is lodged in the common duct and cannot be manipulated back into the gall-bladder, cho-

stone in the hepatic duct. The operation was first performed by Kocher in 1889. There were 7 cases on record in 1903 (Delagenière, in "Bull. et Mem. de Chir. de Paris," No. 10, 1903).

Duodenocholedochotomy (*McBurney's Operation; the Transduodenal Route*).—This operation is seldom necessary. In the more than 2000 operations performed by the Mayos on the gall-bladder and ducts, this operation was only required in 4 cases. I have never performed it. In 1891 McBurney proposed this method for the removal of gall-stones impacted near the papilla ("Annals of Surgery," Oct., 1898). McBurney's original suggestion was to open the duodenum, dilate or incise the papilla, remove the stone, and suture the duodenum. If the stone is located in the diverticulum of Vater it may, in some few cases, be removed by simply stretching the opening of the duct with forceps (Collins's method). If this is not possible, the opening in the papilla may be enlarged by cutting or the duodenal mucous membrane over the stone may be incised (McBurney's plan). When the stone is not impacted at the outlet, but is lodged a little higher up, and when dense adhesions render access by the ordinary supraduodenal route difficult or impossible, the anterior wall of the duodenum may be opened longitudinally, the posterior wall of the duodenum and the common duct incised over the stone, the stone removed, the duodenum and common duct sutured together (Kocher's method, or *internal choledochoduodenostomy*), and the anterior wall of the duodenum closed. (See Charles Otto Thienhaus, in "Annals of Surgery," Dec., 1902.) After finding and removing a stone by the transduodenal route we must make a careful search to see no stones are left before closing the duodenal incision. Robson opposes the transduodenal route and says he has abandoned it because of the danger of sepsis. Thienhaus ("Annals of Surgery," Dec., 1902) opposes this view of Robson and shows that in 29 operations by the transduodenal route there were but 2 deaths.

Connell ("Annals of Surgery," Jan., 1908) has collected 77 cases in which stones were removed by the transduodenal route. There were 10 deaths. In 2 of these cases duodenal fistula preceded death.

Retroduodenal Choledochotomy. In this operation the second portion of the common duct is incised back of the duodenum without opening the gut. That this may be done the duodenum must first be drawn toward the midline of the body, and this can be done only by "mobilizing" the duodenum, incising the posterior layer of the parietal peritoneum one inch to the right of the descending portion of the duodenum. After freeing the gut and retroperitoneal structures the duodenum becomes sufficiently free to lift toward the left with a rotation. We thus expose the posterior aspect of the duodenum, the head of the pancreas, and the common duct.

The duct is opened, the stone removed, the duct sutured, and a drain inserted.

This operation has been successfully performed by a number of surgeons, but there is a great objection to it. In nearly all cases the common bile-duct passes through the pancreas rather than back of it. Bungner found this to be the case in 55 out of 58 dissections ("Gray's Anatomy," Seventeenth American edition, p. 1352). Hence, incision of the common duct in this situation means in nearly all cases incision of the pancreas and all the grave dangers of leaking of pancreatic fluid. The transduodenal operation is a much better procedure.

Total Splenectomy.—This operation is performed for wounds and rupture of the spleen, tumors, cysts, floating spleen, and non-leukemic splenic hypertrophy. Twisting of the pedicle of an ectopic or wandering spleen calls imperatively for operation. It should not be performed for hypertrophy in leukemia.

In view of the bone-marrow changes in splenomyelogenous leukemia, we cannot hope to cure a patient by removing the spleen. In a leukemic patient the operation has a very high mortality from shock and hemorrhage. (Geo. Ben Johnston ("Annals of Surgery," Jan., 1908) has collected 49 splenectomies in leukemia with only 6 operative recoveries (a mortality of 87.7 per cent.). One of the 6 cases lived eight months, 1 lived four years, and it is claimed that 1 was cured.

Splenectomy has been performed for malarial hypertrophy (ague cake). The operation has been advocated on the theory that by removing the spleen we would get rid of the lurking place of the malarial parasites, but they also lurk in the bone-marrow and in the capillaries of the liver. The operation should not be performed for malarial spleen unless the organ is movable, unless it greatly interferes with the patient's comfort or occupation, or unless we fear rupture, and then, if it is done, it is for the movability, the discomfort, or the danger, and not for the malaria. It is to be noted that the operation does not cure the malaria. Johnston (Ibid.) collected 58 splenectomies performed for malarial hypertrophy since 1900. There were 50 recoveries and 8 deaths. To these he adds 3 successful ones of his own, making 61 cases, with 8 deaths (a mortality of 13.1 per cent.).

A number of operations have been done for splenic anemia or its terminal stage, which is known as Banti's disease. It is improbable that splenic disease is the cause of the anemia, but it is much more probable that some underlying condition causes splenic enlargement and anemia. The operation does not seem to be founded on sound pathologic indications, although it is proper to state that Cushing's case was alive and well eight years after the operation.

Johnston (Ibid.) has collected 61 splenectomies for splenic anemia or Banti's disease. There were 49 recoveries and 12 deaths, a mortality of 19.7 per cent.

Johnston (Ibid.) notes 12 splenectomies for sarcoma of the spleen with 9 recoveries. One lived eight and one-half years and died of heart disease. Three are known to have died from recurrent sarcoma.

It is stated that there are on record 4 splenectomies for cancer. Moynihan doubts the diagnostic accuracy of the three earlier reports. Mary A. Smith records a case of colloid cancer occurring in a woman who had been operated on ten years before for ovarian cyst associated with pseudomyxoma of the peritoneum. The pathologist reported that the growth in the spleen was a metastasis of colloid carcinoma. This patient died seven months after the splenectomy from peritoneal and omental cancer ("Annals of Surgery," Jan., 1908).

In Johnston's (Ibid.) table of 708 splenectomies for various causes the mortality is 27.4 per cent. In the cases operated upon from 1900 to 1907 inclusive the mortality is 18.7 per cent.

In order to remove the spleen make an incision from the anterosuperior spine of the ilium to the ribs, open the peritoneum, and divide adhesions.

between ligatures. If the spleen is adherent to the pancreas, it may be necessary to remove a fragment of the last-named organ. It is a very undesirable thing to have to do, and I lost a case from pancreatic leakage after having done it. Ligate the suspensory ligament and divide it. Bring the spleen well out of the wound. Surround it with gauze pads. Transfix the pedicle with stout silk. Tie it firmly, leaving the ends of the ligature long for a time, and cut through the pedicle beyond the ligature. Ligate the vessels separately with catgut. Cut off the long ends of the silk ligature and drop the pedicle back, unless apprehensive of bleeding, when it may be fastened to the surface. The wound is closed without drainage. Traction upon and ligation of the vessels in the pedicle may cause profound shock by injuring the splenic plexus, which is in close relation with the solar plexus (Jordan, in "Lancet," Jan 22, 1890).

Changes After Splenectomy.—About two weeks after the removal of a normal spleen certain definite changes happen in adults, but not in children. These changes last for several weeks and are manifested by enlargement of the lymph-glands, tenderness of bones, blood-changes, loss of weight, weakness, thirst, polyuria, abdominal pain, elevation of temperature, and rapid pulse.* Tizzoni says that these changes are not obvious in children, because in them compensatory organs act at once, whereas in adults compensatory organs act slowly and with painful effort. Such symptoms are noticed when the spleen is removed because of a wound or a rupture, but rarely after removal of a diseased spleen. It is likely that compensating organs become active when the spleen is diseased, and consequently are in full operation when such a spleen is removed. After partial splenectomy these changes are not noted (Jordan). Changes can be prevented after splenectomy by the administration of tablets of extract of spleen and red bone-marrow (Ballance).

The blood changes after splenectomy consist of diminution in hemoglobin and red blood-cells. The coloring matter and cells do not become normal for two or three months.

Splenopexy.—This is the operation of anchoring a movable spleen. It can only be used when the spleen is not enlarged and is not diseased. Rydygier in 1895 published the first case, although both Tullier and Kouwer operated before this date. Sutures should not be passed through the spleen; the structure is so soft the stitches are bound to loosen and the insertion will cause bleeding. A promising method is to create adhesions by the use of iodoform gauze, as is done for movable kidney, and as was done by Kouwer. Some advocate making a pocket outside of the peritoneum and bringing the spleen into this pocket, thus placing it extraperitoneal.

Abdominal Hernia or Rupture. A hernia is a protrusion of peritoneum liable to contain, containing at times, or permanently containing any viscus or part of a viscus from the abdominal cavity. MacCormac says the term implies that the protruded viscus is covered with integument; hence a protrusion of viscera through a wound does not constitute a hernia. A hernia has three parts—the sac, the sac-contents, and the sac coverings (Fig. 636). The sac is formed of peritoneum. A *congenital sac* is due to developmental defect, and may be in the inguinal region, the umbilical region, the lumbar region, or in the epigastric region as a result of a congenital slit in the transversalis

* Ballance, in Practitioner, April, 1898; H. Martyn Jordan, in Lancet, Jan 22, 1898.

fascia. It used to be stated that femoral hernia was never congenital but Russell and Coley both say that a femoral hernia may have a congenital sac. In 100 necropsies Murray found 20 potential femoral sacs (sacs into which hernia had not entered). An *acquired sac* is due to intra abdominal pressure bulging the peritoneal covering of an abdominal ring and converting it into a pouch. The sac comprises a *body*, a *neck*, and a *mouth*. A sac once formed is almost certain to persist, because it adheres by its outer surface to surrounding parts, and hence the sac of a hernia is usually irreducible even when the contents are reducible. The *neck of the sac* is due to the constriction through which the sac passes; it becomes furrowed and folded,

Fig. 616.—A diagrammatic representation of the coverings of a hernia (Sultani). a, The skin; b, the superficial fascia; c, the muscular layer—e, x, the cremaster muscle in an inguinal hernia; d, the transversalis fascia; c and d, have also been called the fascia propria hernia; e, the peritoneum—c, the sac of the hernia.

and the adhesion of these folds causes thickening and rigidity. Hernia of the bladder or of the cecum may have no sac or but a partial sac. A ventral hernia following an abdominal operation may be without a sac. The *contents of the sac* depend chiefly on the situation, a portion of the ileum being the usual contents. The colon, the stomach, the great omentum, the bladder, and other structures may enter the hernial sac. An *enterocele* contains only intestine; an *epiplocele* contains only omentum; an *entero-epiplocele* contains both omentum and intestine; a *cystocele* contains a portion of the bladder. The *coverings of the sac*, which vary with its situation, will be set forth during the consideration of special forms of hernia. In old hernia the layers are never distinct, fat and muscle waste, tissues adhere, and the skin stretches and atrophies. The sac of an old hernia occasionally becomes tuberculous, and the disease may remain local in

the hernia sac or spread to the general peritoneum. Renault tells us that *tuberculosis of a hernia* is made manifest by increase in size, pain on pressure, and loss of body-weight.

Causes of Hernia.—Hernia is a common trouble. According to Berger, in 1000 people 4.4 per cent. suffer from hernia. It occurs at all periods of life, and hereditary predisposition sometimes seems to exist. The male sex is three times as liable to hernia as the female sex. That increase of intra-abdominal tension is a common cause in children has been amply demonstrated. (See *Hernia in Childhood*, page 1152.) Excessive length of the mesentery has been assigned as a cause. In some instances a mass of fat forms (*fat hernia*) and advances before the hernia, and seems to bear a causative relation to it. Lucas-Championnière explains this as follows: when a person begins to take on fat, it is deposited not only under the skin, but also in the omentum, mesentery, and subperitoneal tissues. This semiliquid fat is easily

influenced by pressure. The deposit of fat within the abdomen lessens the size of that cavity; intra-abdominal pressure is increased, and fat protrudes at any weak spot in the wall. The protruding mass of fat adheres to and makes traction upon the peritoneum, and this membrane is drawn upon to form a sac, and the sac is surrounded by fat. This method of formation is frequently noticed in umbilical hernia, and occasionally in inguinal hernia. Any laborious occupation predisposes to rupture (muscular relaxation from ill-health, relaxation of abdominal walls following the termination of pregnancy, the removal of a large tumor, or tapping for ascites, and wound or abscesses of the abdominal wall). The common cause is repeated muscular effort which increases intra-abdominal tension (straining at stool, coughing, lifting weights, jumping, the sexual act, and straining during micturition). In 25 per cent. of cases the cause is supposed to have been lifting or carrying a weight (Coley). A hernia may appear gradually or suddenly. Berger and Coley state that nearly 70 per cent. of hernia in adult males appear gradually. The sac of an acquired hernia exists for a longer or shorter time before the hernia enters it. The sac of a congenital hernia is present at birth. The sac of an acquired hernia gradually forms. A sac may exist for years and yet remain empty. When bowel or omentum enters it from some strain or effort, the parts were long prepared to receive the extruded mass. This extrusion may occur gradually or it may occur suddenly. If it occurs suddenly, the sufferer believes that his hernia was formed then and there, but, as a matter of fact, the extrusion of bowel or omentum and its entrance into the sac are but the last of a long series of antecedent and preparatory changes. Finally, a hernia appears, and usually does so during effort. In rare cases traumatism may cause a hernia immediately, no sac existing before the accident. It does so in the inguinal region by stretching or tearing the internal ring, the inguinal canal at once enlarging. Such a condition is a true *traumatic hernia*, traumatism being the sole cause and not simply the exciting cause.

The old and erroneous idea was that a hernia was always formed by tearing of the peritoneum; hence the term *rupture*. This mode of formation is extremely unusual, but occasionally does occur. Coley saw such a case. An ordinary non-traumatic hernia, when the bowel suddenly and for the first time enters the sac, is the seat of some pain, but the pain is not disabling and the lump disappears on recumbency. In many cases the bowel or omentum gradually finds a way into the sac, and in such cases pain is usually trivial and often absent. In true traumatic hernia there are violent pain, collapse, vomiting, inability to walk and stand, and the mass does not return to the belly on recumbency, but must be reduced by taxis or operation. True traumatic hernia may occur anywhere in the abdomen, but are most common in the inguinal region, where they are direct hernia. (The relation born by accidents to the development of hernia is discussed by Paul Berger, in "Rev. de Chir.," April and May, 1906, and by Wm. B. Coley, in "Internat. Jour. of Surg.," Feb., 1908). All congenital hernia are due to structural defects. Hernia are divided clinically into *reducible*, *irreducible*, *incarcerated*, *inflamed*, and *strangulated*.

Reducible Hernia.—In this form of hernia the contents of the sac can be reduced into the abdominal cavity. At a known hernial opening the

patient has a smooth enlargement (narrower above than below), which began to grow above and extended downward. A distinct neck can often be felt. In enterocoele, straining, lifting, or standing enlarges the mass, the protrusion becomes smaller and may disappear on lying down, cough causes impulse or succussion, the protrusion is elastic, and may be tympanic on percussion, and on reduction the mass suddenly disappears and there is a gurgling sound. In epiplocele the mass is often irregular and compressible, and feels boggy rather than elastic; muscular effort does not have much influence in enlarging it; impulse on coughing is slight, percussion gives a dull note, and reduction is accomplished gradually and produces no gurgling sound. In entero-epiplocele some parts of the mass are smooth, elastic, and tympanic; others are dull on percussion, irregular, and flabby, but the diagnosis of this especial form is uncertain. The victims of reducible hernia complain of some pain on exertion, of dyspepsia, and often of constipation.

When a hernia is beginning to form, there is often *premonitory uneasiness*. The patient complains of muscular pain in the lower abdomen, and this condition may exist for weeks before it is recognized that a hernia is present. An inguinal hernia can be recognized before it protrudes from the external ring. The tip of the finger is inserted in the ring and the patient is asked to cough. If a hernia has entered the canal, succussion will be detected on coughing. In a healthy man the external ring should admit the tip of the little finger, but not the end of the index-finger. If the end of the index-finger can be made to enter the ring, that aperture is dilated, and even if there is no hernia in the canal, in future a hernia will probably descend. In a man, if the surgeon desires to examine the ring, he inverts the skin of the scrotum over the finger and carries the finger to or in the ring. When the hernia first appears, there may be pain, faintness, and some sick stomach; but often there is no pain or any discomfort.

Treatment of Reducible Hernia.—Palliative Treatment.—Prevent constipation, forbid sudden strains and violent exercise, and order a truss. The continued employment of a truss in young persons may bring about a cure. The day truss should be applied before rising in the morning and be removed after lying down at night, when a light truss should be substituted. A special truss is applied before bathing. In very fat people there is always trouble in adjusting a truss. A femoral hernia is more difficult to keep reduced than an inguinal hernia. In a hernia in which the gut is replaceable, but a portion of omentum is irreducible, it is difficult to maintain reduction of the gut with a truss, and an operation should be performed. In an oblique inguinal hernia the pad of the truss fits over the internal abdominal ring; in a direct inguinal hernia, over the external abdominal ring; in a femoral hernia, over the femoral ring at the level of Gimbernat's ligament. Mac Cormac's method of measuring for a truss is as follows: in either inguinal or femoral hernia start the tape from the *lower part* of the hernial opening, carry it up to the anterior-superior iliac spine of the same side, then take it around the body, one inch below the crest of the ilium, to the other anterior-superior iliac spine, and then to the upper part of the hernial opening.* A well-fitting truss will keep the hernia up even when the patient sits in a position to relax the abdominal walls and coughs and strains. A truss is

* Treves's "Manual of Surgery," "Hernia."

always uncomfortable at first, but a person usually becomes accustomed to it. It should be kept scrupulously clean, and borated talc powder should be dusted upon the skin under the pad at least once a day. A truss which does not keep the hernia up or which causes pain does harm. Too strong a spring tends to enlarge the hernial orifice, and thus aggravates the case. Even after an apparent cure with a truss the instrument must be worn for a long time.

Radical treatment of reducible and of non-strangulated hernia seeks to obtain cure by plugging the mouth of the sac or by obliterating the canal of descent. Radical operations should be performed when a strangulated hernia is operated upon, in ordinary cases of reducible hernia in which a truss is very painful or does not keep the bowel up, in most cases of irreducible hernia, and in any case of hernia in which there are occasional attacks of obstruction. It was formerly believed that a cure would fail if the subject was under three years of age, but Coley and others have proved that it is a very successful operation in childhood. It is rarely recommended under the age of four, because in two-thirds of the cases a truss will cure. It is advised after the age of four when a truss has failed, when there is irreducible omentum, or when there is a reducible hydrocele which prevents the truss from folding (Wm. B. Coley, in "Annals of Surgery," June, 1903). The radical operation is almost without danger in properly selected cases, and is one of the most successful of surgical procedures. We are justified in doing the operation upon an individual under fifty years of age and free from complications, purely to relieve him or her from the annoyance of wearing a truss. If, however, a patient is sixty years of age or over and a truss keeps the hernia up satisfactorily, the operation should not be performed unless it is demanded by some complication. Organic diseases of the heart, lungs, and kidneys are contraindications. Enormous herniae (Figs. 670 and 674) are unfavorable for operation. Restoration is difficult or impossible, the forcible handling produces much shock, and recurrence is to be expected. Restoration is difficult or impossible because the abdominal cavity has contracted and holds with difficulty or cannot hold the huge hernia. As J. L. Petit said, the hernia has *forfeited the right of domicile*. In an operation for an enormous hernia a great quantity of omentum will require removal, and it may be necessary to resect a considerable piece of intestine. If we decide to operate upon an enormous hernia, treat the patient some time before with the object of making him lose flesh. The absorption of mesenteric fat lessens intra-abdominal pressure. That operation may succeed in such cases is shown by Figs. 637 and 638. In any operation for the radical cure of inguinal hernia always remember that the bladder may be part of the hernia, and be on the lookout for it. Eggenberger's table of 6778 hernia operations shows 75 bladder hernias (1 per cent.). As a rule, it is covered with cellular fat, which differs in color and consistence from omental fat and from other fat which may be found about a hernia. The presence of a quantity of extra-peritoneal fat outside of the sac suggests the adjacency of the bladder and warns us not to tie off the sac very high up. It was the author's misfortune on two occasions to open a bladder in operating upon an inguinal hernia. In each case the bladder was sutured, and both patients recovered. It has been estimated that the mortality after this accident, even when the bladder is sutured, is from 6 to 16 per cent. Among other possible accidents which may

occur during hernia operations are: injury of an iliac vessel, of a femoral or of an epigastric vessel.

The success of an operation for the radical cure of a hernia depends upon the attainment of primary union. Primary union is favored by the

Fig. 637. Oblique inguinal hernia of large size (duration, sixteen years).

Fig. 638. The case shown in Fig. 637 six months after operation.

cleanliness, by wearing gloves while operating, by cutting the parts with a sharp knife instead of tearing them with a dissector, by removing some of the

perfluous tissue-fragments; by tying the stitches firmly, but not tightly (stitch causes necrosis and creates a point of least resistance); by careful dressing with pressure; and by keeping the patient recumbent for weeks.

Truss is not to be used after operation. Wm. B. Coley ("Annals of Surgery," June, 1903) has operated upon 1075 cases of inguinal and femoral hernia. In his report he does not consider operations performed within the last six months, and so presents a study of 1003 cases. Of these, 937 cases

Fig. 630. Hernia which has sacrificed "the right of domicile."

of inguinal, 66 cases were femoral. In the 1003 cases, 647 were traced and found well from one to eleven years after operation; 705 were well from months to eleven years; 460 were well from two to eleven years. If the patient is well one year after operation, he will probably remain well. Supported by Coley's study of relapses, an investigation which shows that 10 per cent. of relapses occur within six months of operation and 80 per cent. within the first year. Only 13 1/2 per cent. occur from one to two years, and only 6 1/2 per cent. after two years. Coley had 2 deaths in 1075 cases (an one-fifth of 1 per cent.). After Bassini's operation there are about 10 per cent. of relapses. Coley reports that from Dec., 1891, to Jan., 1900, there were 100 operations performed by Drs. Bull, Walker, and himself, in the Hospital for Ruptured

and Crippled, 2384 operations for the radical cure of hernia. Of these 2218 were inguinal (only 445 in females). In the 1773 male cases the typical or modified Bassini operation was done with 12 relapses or .68 per cent. (*Progressive Medicine*, June, 1909).

Lannelongue's Method.—Lannelongue has for certain cases returned to the old injection plan, using a 10 per cent. solution of chlorid of zinc instead of white oak bark. The hernia is first reduced and is held up by an assistant who closes the internal ring with a finger, and also holds the cord aside. Several injections of 10 minims each are thrown in the region of the internal pillar, the region of the external pillar, and into the canal behind and outside of the cord. The surgeon must be careful that no zinc solution escapes

into the subcutaneous tissue. The effect of the chlorid of zinc is to cause the formation of quantities of fibrous tissue. It is scarcely to be expected that a cure so produced will be permanent in an adult, though it may be in a child.

Fig. 640.—A, Hernia needles, B, binged hernia director.

Macewen's Operation for Inguinal Hernia.—The instruments required in this operation are scalpels, a blunt, straight bistoury, a dry dissector, a grooved director, scissors, a hernia director (Fig. 640, B), hernia needles (Fig. 640, A), dissecting forceps, toothed forceps, hemo-

Fig. 641.—Macewen's operation for radical cure of inguinal hernia: A, Stripping of the sac; B, purse-string suture; C, fastening the purse-string suture; D, passing and E, tying the sutures for the internal ring.

static forceps, an aneurysm needle, blunt hooks, half-curved needles, needle holder, and chromicized catgut sutures. The patient lies recumbent, the thigh being abducted and partly flexed and resting on a pillow beneath the knee. The bowel is reduced, and an incision three inches long is made in the direction of the inguinal canal, the center of the incision corresponding to the external ring. The sac is freed from its attachments below and is lifted up. The surgeon introduces a finger into the inguinal canal and separates the sac from the cord and from the walls of the canal, and then carries the finger through the internal ring and separates the peritoneum for one inch about the periphery of this aperture (Fig. 641, A). A chromicized catgut stitch is fastened to the lowest portion of the sac, and is passed through the sac several times, so that pulling on the stitch will purse the sac (Fig. 641, B). The free end of this stitch is carried through the internal ring into the belly, and is pushed out through the abdominal muscles one inch above the internal ring, the skin being pushed aside so as to escape perforation by the needle. The thread is tightened so as to fold up the sac and pull it into the belly. This plugs the ring (Fig. 641, C). The thread is handed to an assistant to keep tight until the sutures are introduced into the ring, when the sac is permanently anchored by taking several stitches in the external oblique muscle. A strong catgut suture is passed with a Macewen needle through the conjoined tendon from below upward, the ends of this suture being carried through Poupart's ligament and the outer border of the internal ring from within outward. This suture is tightened, and closes the internal ring. The external ring is sutured and the skin is stitched (Fig. 641, E).

In congenital hernia the sac is divided in its middle, and the lower part is closed by stitches of chromicized catgut, forming a tunica vaginalis. The upper part of the sac is slit posteriorly to permit the escape of the cord, and is closed by stitches of chromicized catgut. The operation is finished as in the acquired form (Fig. 642). After Macewen's operation the patient should stay in bed for at least three weeks, and must not work for eight or nine weeks. Workmen after this operation should always wear for a time a pad and a spica bandage. Children require no pad. Never apply a truss, as strong pressure will produce atrophy of the curative scar.

Bassini's Operation for Oblique Inguinal Hernia.—(See E. Wylls Andrews, in "Med. Record," Oct. 28, 1899, who describes from personal observation how Bassini does his operation. I have drawn upon his description in the following section.) Bassini's operation displaces the spermatic cord from the old canal and places it in a new canal, and this new canal is oblique. The instruments employed are the same as for Macewen's operation, excepting the special needles, which are not needed. Curved and rounded needles are employed to insert the stitches. The suture material is kangaroo-tendon or chromicized catgut. Silk or silver wire is apt to make trouble—it may be, long after the operation. The patient is placed supine with the thighs extended. An incision is made parallel to Poupart's ligament and extending

Fig 642. —Macewen's operation for the radical cure of congenital hernia.

from the external ring to a point external to the is about one and one-half inches above the ligament inches in length. By this incision the aponeurosis and the pillars of the external ring are exposed the aponeurosis is incised in the direction of its forward, and the inguinal canal is opened. The oblique is dissected up with a blunt instrument is exposed. We speak of this ligament as the the sac of the hernia, the cord, the cremaster is lifted up. Bassini employs blunt dissection. the knife. Masses of fat and usually the cremaster. The sac is isolated first at its neck and the neck aspect of the internal ring for the distance of an inch. The object of this stripping is to permit the removal

Fig. 643. A C Bassini's operation for the cure of inguinal hernia.

Fig. 644. Removal of the hernia sac and closure of the inguinal canal.

High removal obviates the leaving of a funnel-shaped toneum. Such a depression predisposes to relaxation of the fundus, the interior is investigated, and if the contents are restored to the abdominal cavity and the fundus is high up. If adherent masses of omentum are present, they are separated, bleeding is arrested, and the omentum is sutured unless it is in a hard and thick mass, when Bassini ties off the neck of the sac above the neck of the hernia with a strand of silkworm-gut. If the sac is large and thick, a strand of a ligature upon a needle, passes the strand through the wall of the neck of the sac, and passes it around over the first loop. (See E. Wyllis Anderson, 28, 1899.) Dr. Coley and many other operators place a catgut suture rather than with silkworm-gut or silk. They employ fine black silk, catching it to prevent it from passing through the wall of the neck of the sac. After lig-

sac is cut across and removed. The cord is now lifted out of the way (Fig. 643, A), the inner surface of Poupart's ligament is exposed by retraction, and the deep sutures are passed (Fig. 643, A). Bassini uses silk which has been boiled in glycerin. Most American operators use kangaroo-tendon or chromicized catgut. Bassini inserts first the sutures nearest to the pubes. The first suture—and sometimes also the second—includes part of the rectus sheath and rectus muscle. Each stitch includes the internal oblique and transversalis muscle in the upper edge and the shelf of Poupart's ligament below the lower margin, and from four to six stitches are passed behind the cord (Fig. 643, B). The last stitch narrows the internal ring so that it fits tightly around the cord (E. Wyllis Andrews, "Med. Record," Oct. 28, 1899). Coley's rule for passing this suture is to insert it so "that it just touches the lower border of the cord

Fig. 645.—The skin incision, retractors in the lower angle of the wound dislocating the opening in the skin and subcutaneous fat downward, exposing the aponeurosis of the external oblique and external ring. The dotted line within the wound represents the direction of the division of aponeurosis of external oblique (Bloodgood).

Fig. 646.—The aponeurosis of external oblique has been divided and retracted, uncovering the internal oblique muscle and inguinal canal. The lines on the muscle represent the direction and extent of the division. The dotted line in the inguinal canal is the direction and extent of the division of the coverings of sac (Bloodgood).

when the latter is brought vertically to the plane of the abdomen" ("Annals of Surgery," June, 1903). Coley always places a suture above the cord, and believes it tends to prevent relapse (Fig. 644). The sutures are tied from above downward. The cord is laid upon this new floor and the aponeurosis of the external oblique is sutured over it (Fig. 643, C). Coley uses a continuous suture of fine kangaroo-tendon and closes the skin with interrupted sutures of catgut. Drainage is not used. The wound is covered with a roll of iodoform gauze and some pieces of sterile gauze, and compression is made by strips of adhesive plaster, and a piece of adhesive plaster run from thigh to the other acts as a shelf for the testicles to rest upon. The adhesive plaster is overlaid with dry gauze, and this is covered with absorbent cotton and the dressing is retained in place by a firm spica of the groin (Coley's dressing). The wound is dressed on the seventh day and the patient is kept

in bed for two weeks and is allowed to get about in two and one-half weeks to three weeks, wearing a bandage until four weeks after operation.

In this operation some surgeons treat the sac as in Macewen's operation, carrying out the rest of the procedure as directed above. In a pure Bassini operation the funnel-shaped depression in the peritoneum at the point of emergence of the cord may remain and predispose to hernia, but the use of Macewen's plan for treating the sac obviates this.

Fig. 647.—The internal oblique muscle and the coverings of the sac have been divided, the sac with the veins and vas deferens are drawn out of the wound preparatory to the excision of the sac and the ligation and excision of the veins (Bloodgood).

Halsted's Old Operation (as described by J. C. Bloodgood, in "Johns Hopkins Hosp. Report," vol. vii).—The skin incision is not parallel to Poupart's ligament, but at an angle of 25 degrees to it (Fig. 645). Poupart's ligament is well exposed to within 2 cm. of the pubic spine. The aponeurosis of the external oblique muscle is divided. Free the lower border of the internal oblique muscle and divide the edge of the muscle at a right angle to its fibers (Fig. 646), and as far as possible from the linea semilunaris. The coverings of the sac near the neck are picked

up with mouse-toothed forceps and are divided. The division of the

Fig. 648.—The method of excision of veins in operations for hernia and varicocele. The vas deferens and its immediate vessels and the mesocord have not been disturbed (Bloodgood).

Fig. 649.—The insertion of the deep silver wire sutures, one above and four around the cord. The veins have been ligated and excised. The mesocord has been torn greatly in its center only (Bloodgood).

fascia is continued from the neck of the sac downward toward the pubes.

Fig. 650.—The method of transplanting the rectus muscle. The sac has been excised and the peritoneal cavity closed; internal oblique muscle has been divided, the rectus exposed and transplanted, at this stage the wound is ready for the deep sutures. This illustration shows how perfectly the transplanted rectus muscle lines the lower half of the wound (Bloodgood).

is used to tear the mesocord. The freed vas is lifted into the upper angle of the divided internal oblique muscle, and is held there until the sutures are inserted. The deep sutures of silver wire are next inserted. Usually five are needed. The upper one is passed first. These sutures are shown in Fig. 649. The cord emerges from the cut in the internal oblique muscle between the first and second sutures. Sutures No. 1 and No. 2 pierce the mesocord, but care is taken to see that they do not injure the vas or its vessels. Each suture is drawn upon and twisted about six times. The cut twisted ends are caught with forceps and turned.

The skin-wound is closed with a subcuticular stitch of silver wire. It is covered with silver-foil and dry gauze, and often a plaster-

The sac is then lifted from the inguinal canal and it brings with it "the larger bundle of veins and the vas deferens" (Fig. 647). The sac is separated from the veins and the vas with a knife or scissors, and the separation is carried to and beyond the neck of the sac. In "certain cases the larger bundle of veins is separated from the vas deferens, ligated, and excised" (Fig. 648). Whether the veins are excised or not, the sac is opened, its contents reduced, the opening into the peritoneal cavity closed with a continuous silk suture, and the excess of sac excised. During the entire operation the vas and its vessels "should be handled very little, and should not be torn from their bed in the inguinal canal." Every point of bleeding should be ligated. At this stage the vas is gently picked up and a blunt-pointed hook

Fig. 651.—The transplanted rectus included by the deep sutures. In this illustration the cord has been excised in order to demonstrate the operation more clearly (Bloodgood).

Fig. 632.—Exposure of the sac, the vas, and the spermatic veins (Halsted).

of-Paris bandage and splints are used, "the splints extending from just above the knee to near the costal margins."

The Modified Halsted Operation.—The operation at present performed by Professor Halsted and his assistants has been evolved from the former operation so long associated with his name, and has been greatly modified

by himself and by Dr. Bloodgood.

In this operation the skin and the aponeurosis of the external oblique are incised exactly as in performing Bassini's operation; and flaps of aponeurosis are raised. Next, the cremaster muscle and the cremaster fascia are incised in a line slightly above the center of the spermatic cord. The internal oblique muscle is then brought into distinct view at the side of the inguinal canal, and the hernia is carefully inspected (Fig. 652). If the veins are found to be large, they should be excised; but the surgeon does not lift the vas

Fig. 654.—Suture of the aponeurosis of the external oblique (Halsted).

from its bed, and even avoids touching it, if he possibly can, for fear that thrombosis may occur in its veins. The veins are tied above, well up in the abdomen; and below, well above the testicle, and excised between the ligatures. The sac is then ligated or sutured with a purse-string suture. One end of the thread that ties or sutures the sac is carried, by means of a long, curved needle, in an outward direction under the internal oblique muscle, through which it is then pulled. The other end of the thread is also pulled through the muscle, one-eighth of an inch from the first end, and these two ends are tied together. It will be observed that this treatment of the neck of the sac is somewhat similar to the method practised by Kocher.

The next step is to carry the inferior flap, composed of cremaster muscle and fascia, under the internal oblique muscle, and suture it there (Fig. 653). We next suture the internal oblique muscle and the conjoint tendon to Poupart's ligament, the lower edge of the internal oblique being tucked under the edge of the ligament (Fig. 654). In order to accomplish this, it may be necessary to release the muscle by incising the anterior rectal sheath. The incision in the external oblique is now closed with sutures that overlap the margins (Figs. 655 and 656), and the skin wound is also closed.

Fig. 656.—Suture of the margin of aponeurosis to Poupart's ligament (Halsted).

Halsted's Operation plus Bloodgood's Method of Transplanting the Rectus Muscle.—(See Jos. C. Bloodgood, in "Johns Hopkins Hosp. Reports," vol. vii.) When the conjoined tendon is very thin or obliterated, the ordinary operation is not enough. Insufficiency of the conjoined tendon is known to exist when a finger does not meet any obstruction after passing through the external abdominal ring, but can be introduced for some distance into the abdominal cavity (Bloodgood). To meet this condition of affairs, Bloodgood devised "a plastic operation on the rectus muscle, bringing this muscle down and suturing it with the other available tissue to Poupart's ligament and to the aponeurosis of the external oblique from the arch of the pubis up to the position of the transplanted cord" (Bloodgood, in previously mentioned report). The first steps of the operation are identical with those previously described, but before the insertion of the deep stitches the rectus sheath is exposed and divided in the direction of the muscle-fibers, from the pubic insertion upward for 5 cm. The muscle bulges from the cut and is caught with silk sutures (Fig. 650). Deep sutures are now introduced as in Halsted's operation, except that they include the rectus and its sheath (Fig. 651). The operation is completed as is Halsted's. I have performed this operation a number of times with entire satisfaction.

Fig. 650.—Ferguson's operation: the semilunar skin incision ("Journ. Am. Med. Assoc.")

Kocher's Operation.—Kocher exposes the aponeurosis of the external oblique, makes a small incision through the aponeurosis above and external to the internal ring, and draws the sac through this incision and sutures it in place.

Fig. 651.—Ferguson's operation: flap turned back exposing the aponeurosis and the sac of the hernia ("Journ. Am. Med. Assoc.")

Fowler's operation is as follows: an incision is made parallel with Poupart's ligament from the spine of the pubis to the level of the internal ring, and a flap is turned up. The inguinal canal is opened and the sac and cord are isolated. The sac is opened, its contents reduced, it is cut off, and its edges grasped with forceps. The deep epiga-

tric artery and vein are sought for, each is tied in two places and divided between the ligatures. The index-finger is introduced into the belly, and on this as a guide the floor of the canal is divided (transversalis fascia, subserous tissue, and peritoneum). The cord is placed in the peritoneal cavity. The edges of the opening are sutured so that broad serous surfaces are approximated, through and-through sutures being passed from side to side. The cord is brought out at the inner end of the incision, the lower angle of the cut being at such a level that the cord curves upward and forward as it leaves the abdomen. The inguinal

canal, the gap in the aponeurosis, and the skin-wound are closed.*

Ferguson's Operation.—

In studying a number of recurrences after operation A. H. Ferguson observed that a hernial protrusion is apt to return at the upper and outer portion of the scar, above the cord and near Poupart's ligament. When he operated upon relapsed cases, he discovered a slit of the aponeurosis of the external abdominal wall, through which the sac and some fat protruded. In order

Fig. 659.—Ferguson's operation: dealing with the sac and its contents ("Jour. Am. Med. Assoc.,").

to determine the cause of the failure of these operations, he thought it proper to make a semilunar incision, and raise a flap of skin, fascia, and aponeurosis of the external oblique.

On doing this, he was surprised to find an angle between the lower border of the internal oblique muscle and the inner aspect of Poupart's ligament absolutely unprotected by the internal oblique or the transversalis muscle. In some cases this angle extended upward and outward to the anterior superior iliac spine. He therefore determined positively that the cause of a rupture returning in this

angle after an operation for radical cure is deficient origin of the internal ob-

Fig. 660.—Ferguson's operation: suture of the slack in the transversalis fascia ("Jour. Am. Med. Assoc.,").

* *Annals of Surgery*, Nov., 1897.

lique muscle and of the transversalis muscle at Poupart's ligament. He is now persuaded that in all cases of hernia there is a deficient origin of these muscles, and he has demonstrated the same thing in a series of dissections in the inguinal region. Ferguson describes his operation as follows ("Jour. Am. Med. Assoc.," July 1, 1899): He begins his incision over Poupart's ligament, an inch and a half below the anterior-superior iliac spine, carries it inward and downward in a semilunar curve, and terminates it over the conjoined tendon, near the pubic bone. This incision goes down to the aponeurosis of the external oblique, and the flap, with its fat and fascia, is turned downward and outward (Figs. 657 and 658). The next step is to incise the external abdominal ring to the intercolumar fascia and separate the longitudinal fibers of the external oblique over the inguinal canal to beyond the internal ring, at a point nearly opposite the anterior-superior spine of the ilium. Any transverse fibers that may be encountered are severed. The separated aponeurosis of the external oblique muscle is then retracted. One has then brought into view the contents of the inguinal canal, the hernial sac and its adhesions, the spermatic cord, the ilio-inguinal nerve, the internal abdominal ring, the subserous fat, the cremaster muscle, the conjoined tendon, the internal oblique and its deficient origin at Poupart's ligament, the transversalis fascia, and the internal surface of Poupart's ligament. The sac is now dissected from the cord and the internal ring. It is opened and its contents are inspected and

Fig. 657.—Ferguson's operation. Suture of the internal oblique and of the transversalis muscle to the internal aspect of Poupart's ligament ("Jour. Am. Med. Assoc.")

not be touched unless a varicocele also exists. Any excessive quantity of subserous adipose tissue should be removed. The next step in the operation is to restore the structures to their normal position; and one should remember that in the transversalis fascia is the internal ring. In hernia the internal ring is large and the transversalis fascia bulges outward; one must, therefore, take up the slack in this fascia and make a well fitting ring for the cord, by means of a catgut suture, either interrupted or continuous (Fig. 660). After this has been accomplished, the internal oblique and transversalis muscle are sutured to the internal aspect of Poupart's ligament, after the lower borders of the muscles have been freshened and Poupart's

properly dealt with. It is tied high up and cut off, and the stump is dropped into the abdomen (Fig. 659). If the sac is congenital, it is divided into two parts: the distal portion is used to make a tunic for the testicle, and the proximal portion is treated as above directed. The cord is not disturbed, and it is beyond doubt that Ferguson is right in saying that the testicle frequently comes to harm after operations that disturb the cord. The veins in the cord should

ligament has been scarified. The sutures must be carried two-thirds of the way down Poupart's ligament, which is about the normal origin of this muscle in the female (Fig. 661). The next step is to suture the edges of the divided aponeurosis of the external oblique; this restores the external abdominal ring. The skin-flap is then carefully sutured.

Radical Cure of Direct Inguinal Hernia.—If the hernia goes through the conjoint tendon or pushes that structure before it the operation should consist in transplanting the rectus muscle as practised by Bloodgood (page 1138) and suturing the arched fibers of the internal oblique and conjoint tendon to Poupart's ligament and beneath the cord.

If the hernia passes around the outer edge of the conjoint tendon an overlapping operation, like the Mayo operation for umbilical hernia, should be performed (G. G. Davis, in "Annals of Surgery," Jan., 1906).

Radical Cure of Umbilical Hernia.—The results of operations for umbilical hernia have not been satisfactory. Recurrences are frequent. This is probably due to the fact that most of the subjects are fat, and that the muscles are thin and flabby. The usual operation may be thus described: Make a longitudinally elliptical incision through the skin around the mass. Encleave to separate the sac from the superficial tissue. If this cannot be done, open the sac and separate it from the contents. Even if the sac can be stripped from the skin, always open it and separate the contents. Return any bowel which may be present, and do not forget that there may be a small portion of bowel completely encased in omentum. Tie into segments and cut off the superfluous omentum and return the stump into the belly. Excise the umbilicus (*omphalectomy*). Suture the peritoneum with a continuous catgut suture. Close the musculofascial wall with two layers of interrupted kangaroo-tendon sutures or one layer of silver wire mattress sutures. Close the skin by interrupted sutures of silkworm-gut or a subcuticular stitch.

Mayo's Operation—This is a vast improvement on the older operation. It gives a firm cicatrix free from disastrous traction. Mayo believes that the defect in the old operation is that the recti muscles are naturally separated at the level of the umbilicus, and in bringing the recti together we have virtually performed muscle transplantation, and these thin muscles are of no great value

Fig. 662 —Mayo's operation for the radical cure of umbilical hernia. Exposure of hernia and lateral incision.

in preventing relapse, and in a large hernia it is not gap by muscle. Mayo now operates as follows: Two are made around the umbilicus and hernia and the exposed (Fig. 662). The surface of the aponeur-

cure of umbilical
second time

plished, the silver wire sutures are drawn so as to the pocket between the peritoneum and the under (Fig. 664). The free margin of the upper flap is the aponeurosis (Fig. 665), and the superficial incision

J. Mayo ("Jour. Am. Med. Assoc.," June 1, 1907) reports upon 88 operations for umbilical hernia by this method between 1894 and 1905. Seventy-five

were traced. One had a partial relapse. One was supposed to have a relapse, but operation disclosed a second opening above and outside of the closed umbilical opening.

Radical Cure of Femoral Hernia.—Cheyne ligates the sac, stitches the stump to the abdominal wall, dissects the external oblique muscle, stitches this flap to Poupart's ligament

Fig. 668.—Fabricius's operation for femoral hernia. Crural sheath is closed by suture. Sutures applied to Poupart's ligament and origin of peritoneal sac. Sutures are placed in position to approximate the points of the external oblique muscle.

wall, and thus fills up the crural canal. Bassini makes an incision in the external oblique muscle, ties the neck of the sac, and returns the stump into the belly. He attaches by suture the external oblique muscle to the pectineal aponeurosis as high up as

the cord or round ligament of the uterus is found. Superficial incision is made between the pubic portion of the fascia lata.

Fig. 669.—Outline of peritoneal lining of sac, utilized as a flap to cover posterior surface after it has been freed by dissection (Weir).

The Operation of Fabricius is performed as follows: An incision is made in the skin of the femoral region, the sac is exposed, isolated, its contents are reduced, its neck is cut off, and the stump is sutured (Fig. 666). An incision is made in the external oblique muscle so as to expose the femoral sheath and the vessels are retracted outward. The origin of the external oblique muscle is sutured to Poupart's ligament. The lower suture

is sutured to Poupart's ligament. The lower suture is sutured to Poupart's ligament. The lower suture is sutured to Poupart's ligament.

of the horizontal ramus of the pubes as well as the beginning of the muscle (Fig. 668). Care must be taken in passing some of them to avoid injuring the deep epigastric vessels. When these stitches are tied, the femoral canal is obliterated. The flap of fascia lata is sutured to the aponeurosis of the external oblique, and the skin is sutured.

Operative Treatment of Sliding Hernia of the Ascending and Descending Colon.—My personal experience consists of four cases of right and one case of left inguinal hernia. The sac is deficient posteriorly and externally (page 1155). In order to restore the bowel many operators have sought to force up the adherent bowel to the external ring, and others have stripped the bowel from the subperitoneal tissues in order to permit of reduction. This first plan should never be followed, as sutures will fail to hold the bowel up. The second plan is risky and may be followed by gangrene of the bowel. In my 5 cases I followed Wier's plan ("Med. Record," Feb. 24, 1900), and after dissecting up the peritoneum on each side to a little above the internal ring, freed the bowel from its bed, and covered the new surface with the peritoneal flaps (Fig. 669). The bowel was then restored and a radical cure was made.

Irreducible Hernia.—The swelling in irreducible rupture presents the usual evidences of hernia, imparts an impulse on coughing, but cannot be replaced in the abdomen. Sometimes a portion is reducible and a portion is irreducible. A hernia may become irreducible because of the size of the mass, because of adhesions, or because of excessive growth of omental fat. An irreducible hernia is liable to be bruised and to cause much distress and pain, and is always a menace to life because of the danger of obstruction and strangulation. It was formerly the custom to support a small irreducible hernia by a hollow, padded truss, but at present operation is advised. A large hernia of this variety, if operation is refused, must be carried in a bag truss. The patient must not take very active exercise, must keep the bowels regular, and must live upon a plain diet. Most cases of irreducible hernia should be treated by operation.

Incarcerated or Obstructed Hernia.—Obstruction takes place by the damming up of feces or of undigested food, the fecal current being arrested, but the blood-current in the wall of the bowel not being cut off. Incarceration is commonest in irreducible hernia, umbilical hernia, and during the existence of constipation. The hernia enlarges and becomes tender, painful, and dull on percussion; pressure diminishes it in size; it is irreducible, but still presents impulse on coughing. The abdomen is somewhat distended and painful; there are nausea, constipation, and not unusually slight vomiting. Constitutional disturbance is trivial and constipation is not absolute, gas at least usually passing. Vomiting is not fecal. The treatment is rest in bed in a position to relax the belly, an ice-bag over the hernia for a very few hours, and a little opium for pain. Do not give a particle of food for twenty-four hours; when the active symptoms subside, give an enema, and after this acts a dose of castor oil. Do not employ taxis, as bruising the bowel may produce strangulation. If improvement does not rapidly occur, operate. Prompt operation saves the patient from the danger of strangulation and cures the hernia.

Inflamed Hernia.—Inflammation of a hernia is local peritonitis due to injury of an irreducible hernia. The mass becomes tender and painful,

and perhaps heat is noted. In enterocoele much fluid forms; in epiplocele the mass becomes hard. The hernia cannot be reduced; there is constipation, often vomiting, usually elevated temperature, but the mass still shows impulse on coughing. Vomiting is not fecal. Some gas is usually passed through the bowels. Constitutional symptoms are slight. The *treatment* usually recommended is rest in bed with abdominal relaxation, an ice-bag to the tumor for a few hours, a small amount of opium by the mouth if pain is severe, an enema, and, after this acts, a saline. In an inflamed hernia there is great danger of strangulation, and operation should be performed in preference to relying upon the conservative plan.

Strangulated hernia is a condition in which, if the hernia contains bowel, not only is the fecal circulation arrested and gas prevented from passing, but the circulation of blood in the bowel-wall is also arrested. The bowel is irreducible and obstructed, and the blood ceases to circulate. If the hernia contains omentum, the omental vessels are tightly constricted. In both

Fig. 670.—Strangulated umbilical hernia containing nearly all the intestines and part of the stomach. Strangulation under bands within the sac.

bowel and omentum gangrene soon occurs, but sooner in bowel than in omentum. Strangulation is commonest in old inguinal ruptures in active, middle-aged men, and is more frequent in enterocoeles than in epiploceles. It is most common when the hernial orifice is small and is seldom seen in large ruptures.* Strangulation is much more dangerous if bowel is present in the sac than if only omentum is present. If the abdominal pressure is suddenly increased, as by a violent cough or a muscular effort, the hernial orifice is dilated for a moment, more intestine or omentum may enter the sac, and if it does, it may be caught and constricted by the now constricted hernial orifice and strangulation begins. Strangulation so caused is called *elastic strangulation*. A sudden increase of

* Strangulation developed in the large herniae shown in Figs. 637 and 670.

Intra-abdominal pressure may force a quantity of fecal matter into the herniated intestine. The sudden entry of a quantity of fluid and gas into the herniated coil causes *fecal strangulation*, the mechanism of which is obscure. By *retrograde strangulation* we mean a condition in which the end of a loop of bowel or a piece of omentum in a hernia re-enters the abdomen and then becomes strangulated, the balance of the hernia not being strangulated. Strangulation may be due to active peristalsis or to congestion, and it may arise from inflammation or from incarceration. The constriction may be at the neck of the sac, in the outside tissues, or even in the sac itself. In an hour glass hernia the constriction is in the body of the sac. In inguinal hernia a tight external ring is a common cause of strangulation and is the commonest cause in children. As Coley shows, the neck of the sac is very seldom the cause in children. Adhesions within the sac may cause strangulation. Spasmodic contraction of the tissues about the neck of the sack is an exploded hypothesis. The obstructed veins dilate and the blood in them ceases to move, the bowel becomes deep bluish and finally black, effusions of blood occur beneath the peritoneum, and the intestinal wall becomes edematous. Fluid transudes into the sac, and the fluid, at first clear, assumes a bloody hue, and finally becomes dry and foul. The peritoneum ceases to glisten, becomes dry and rough, and coated here and there with lymph. Strangulated omentum undergoes edema and hemorrhagic infarction and thrombosis occurs. When strangulation once begins, the hernia swells, a furrow forms on the bowel at the seat of constriction, the bowel and omentum below the constriction become deeply congested and edematous, and, finally, the hernia passes into

Fig. 671.—A strangulated coil of intestine after the strangulation existed for a considerable period of time. The color has become almost black and the peritoneal surface is dull and covered with flakes of fibrin. The constriction rings are deeply sunken, their walls markedly thinned, relaxed, and dirty gray in color. Both constriction rings are gangrenous and hemorrhages are observed in the mesentery. (Sultan).

a state of moist gangrene (Fig. 671). The gangrene may be in spots or the entire mass may be gangrenous. The mucous membrane may be gangrenous when the serous coat looks fairly sound. When gangrene is once established, the bowel is in danger of rupturing. At the point of constriction there may be a line of ulceration or of gangrene. A strangulated femoral hernia becomes gangrenous more rapidly than does a strangulated inguinal hernia.

Symptoms.—This condition is sometimes preceded by diarrhea and uneasiness or pain about the hernial orifice. When strangulation begins, the victim is seized with pain in and about the hernia and with violent colicky pain about the umbilicus, and the paroxysms of colic become more and more frequent, until finally the pain may become continuous. The hernia is found to be irreducible; larger than usual, tender, painful, dull on percussion, without impulse on coughing, and the skin above it may be red-

dened. Eructations of gas are frequent and generally uncontrollable vom and prostration come on. Vomiting, as a rule, is an early symptom, and which increases in severity. Occasionally it only follows the swallowing liquids. Not unusually there is retching rather than vomiting. In rare cases vomiting does not begin for twenty-four to forty-eight hours. During course of a strangulation vomiting may cease for a day or more, and it unusually ceases toward the end, when prostration is profound. The early vomiting is due to reflex causes; the later vomiting is due to waves of peristalsis which produce regurgitation (Macready). The vomiting is first of the alimentary contents of the stomach, next of mucus and bilious material, and finally of the contents of the small bowel (*fecal or stercoraceous vomiting*). Stercoraceous vomiting rarely arises until strangulation has lasted forty-eight hours, and may not appear until much later. "It is seldom met with in the inguinal, more often in femoral, and more often still in obturator hernia (Macready). Prostration is a marked symptom of a strangulated hernia, and it increases hour by hour and goes on to collapse. Early in the case there may be some elevation of temperature, but later it becomes normal or subnormal. The pulse is small, irregular, rapid, and very weak, the extremities cold; the face Hippocratic. Constipation is absolute, no gas even being passed, though in the very beginning there may be some diarrheal passages from below the constriction. The urine is scanty and high-colored, and contains only a small amount of the chlorids; the tongue becomes dry and brown; the thirst is torturing; and the patient often has an imperative desire to go to stool. Pains in the abdomen and in the hernia become more and more violent, and collapse rapidly increases. When gangrene begins the symptoms apparently lessen in violence: there is a "delusive calm." Vomiting usually ceases, though regurgitation may take its place, hunger begins; the pain abates or disappears; the pulse becomes very frequent, feeble, and intermittent, collapse deepens, and delirium is usual. It is a safe clinical rule that in strangulated hernia cessation of pain without the relief of constriction, the disappearance of the lump, or the use of opiates means that gangrene has begun. In some cases of strangulation there are muscular cramps in the legs (Berger). In children convulsions are not unusual. In a pure omental hernia strangulation produces similar but less decided symptoms. It may be that only a portion of the circumference of the bowel is caught and constricted in a hernial orifice (Fig. 678, A). Such a condition is encountered occasionally in the femoral ring, and is called *partial enterocoele* or *Richter's hernia*. The name *Littre's hernia* is often wrongly given to this condition. What Littre described was a hernia of Meckel's diverticulum (Fig. 678, B). In a strangulated Richter's hernia constipation is rarely absolute and a protrusion is often undiscovered.

Treatment. In treating strangulated hernia place the patient upon his back, bend the knees over a pillow, and rigidly interdict the administration of food. An attempt is to be made to effect reduction by gentle manipulation or *taxis*. In applying *taxis* to a femoral or inguinal hernia, flex and adduct the thigh of the affected side. In applying *taxis* to an umbilical hernia, both thighs should be flexed upon the abdomen. Always lower the shoulders and head and raise the pelvis, and accomplish this by lifting the foot of the

bed and placing pillows under the pelvis. In some cases raise the entire body and lower the head. Grasp the neck of the sac with the fingers and thumb of one hand, and employ the other hand to squeeze the hernia and urge it toward the belly. In direct inguinal hernia the pressure should be backward and a little upward; in umbilical hernia it should be backward; in oblique inguinal hernia it should be upward, outward, and backward; in femoral hernia it should be downward until the hernia enters the saphenous opening, and then "backward toward the pubic spine" (MacCormac). If the bowel is reduced, it passes from the hand with a sudden slip and enters the belly with an audible gurgle; omentum, when reduced, slowly glides back without gurgling. Taxis is never to be continued long, and it is not even to be attempted in cases of great acuteness, in cases where strangulation has lasted for several days, in cases known to have been previously irreducible, in cases associated with stercoraceous vomiting, or in inflamed or gangrenous hernia.

If taxis fails, obtain the patient's permission to operate. Anesthetize; try taxis again while ether is being dropped upon the hernia to cause cold; if reduction fails, at once perform herniotomy. Taxis possesses certain dangers: It may rupture the bowel; it may rupture the neck of the sac and force the bowel through the rent into the tissues of the abdominal wall; it may strip the peritoneum from around the hernial orifice and force the bowel between the detached peritoneum and the abdominal wall, it may reduce a hernia into the belly when the bowel is still strangulated by adhesions; it may reduce the hernia *en masse* or *en bloc*. By the term reduction *en masse* we mean that the sac has been separated and dislocated and with the constricted bowel within it has been forced through the internal ring. By reduction *en bissac* is meant the forcing of a congenital hernia into a congenital pouch or diverticulum. Reduction *en masse* is a rare accident. Corner and Howitt collected 137 cases of reduction *en masse* of strangulated hernia ("Annals of Surgery," vol. xlvii). Of these 110 were males; 113 were inguinal, 22 femoral, and 2 obturator. No ventral or umbilical cases are recorded. The accident is a very dangerous one. According to Corner and Howitt (*Ibid*) the mortality after inguinal reductions *en masse* is 48 per cent., and after femoral reductions, 72 per cent. Strange to say, reduction *en masse* can occur spontaneously. The subject most liable to reduction *en masse* is an elderly person with an old hernia. In acute cases the small bowel is the viscus which was reduced. In subacute and chronic reductions *en masse* the omentum, large bowel, or bladder was reduced (Corner and Howitt, *Ibid*). Subacute and chronic cases may happen in non-strangulated hernia. In any of the above accidents obstruction may persist after apparent reduction by taxis. Persisting obstruction means strangulation or peritonitis and calls for instant laparotomy—in most instances through the hernial aperture. If taxis is successful, put the patient to bed, apply a pad and bandage, allow no food until vomiting ceases, merely permit him to take a little hot water for twenty-four hours, and keep him on a liquid diet for several days. At the end of the first week give solid food. Do not disturb the bowels for a few days, but if they have not acted when four or five days have elapsed since the operation, give a saline cathartic and an enema. There is usually a spontaneous movement within twenty-four hours.

Herniotomy.—If there has been stercoraceous

must be washed out before during the administration of should be turned upon its al eral anesthetic can be given cases it is not justifiable to and a local anesthetic must Schleich's fluid). formance of a radical cure in a non-strangulated sues are divided, the aponeurosis is opened as in Bassini's operation and the sac is reached. In most cases the constriction is relieved as soon as the external ring is nicked, and in many cases fibrous adhesions will be found in that region, gluing the sac to the ring. The sac must be identified and it is known by the fat which usually covers it, by the arborescent arrangement of its vessels, by the fact that it can be pinched up between the finger and thumb, and the layers rolled over each other, and by the fluid within the sac. Should the sac be opened? It may not be actually needed but if there is any doubt as to the condition of the

Fig. 673 The dissection

to be attempted, open the sac and be certain as to the condition of its contents. As there is always some doubt as to the condition of the contents, and as a radical cure is to be made, make it a rule to always open the sac. The sac is opened and the contents examined for fecal odor (which is not unusual) and for gangrenous smell; the thickness of the bowel is estimated and the color and lustre are determined. If a constriction exists at the neck the constriction is nicked with a hernia knife. In oblique inguinal hernia nick the constriction upward and outward or directly upward, as shown in Fig. 673. In direct inguinal hernia the cut is made upward and inward. Always pull the bowel down and examine the seat of constriction to see what damage has been inflicted at that point. If the bowel glistens; if the proper color comes back after irrigation with very hot water; and if there are no spots of gangrene, restore the bowel to the abdomen and do a radical cure. If the bowel is in a doubtful condition, fasten it to the incision, apply a dressing, and watch the development of events. If the bowel is gangrenous, our action depends upon the condition of the patient. If the patient is in good condition, resect the gangrenous portion, and perform end-to-end approximation. If the patient's condition is bad, draw the gangrenous portion well out, anchor it to prevent leakage and retraction, make an artificial anus, and at a later period perform anastomosis. An artificial anus can be made by the method of Bodine (page 1112). Unfortunately in these cases the artificial anus must usually be made in the small intestine. In many cases in which there is some uncertainty as to the need for an artificial anus prepare the bowel for the opening, but do not open at once, because the bowel may recover in a day or two, when it can be restored to the belly; or it may slough and form an artificial anus. In such doubtful cases fasten the bowel to the belly wall with sutures, dust it with iodoform, dress it with hot antiseptic fomentations, and await future developments. Gangrenous omentum requires ligation and resection. If the bowel is fit to reduce, push it just inside the ring, irrigate the parts, suture, and perform a radical cure. In *femoral hernia* we can make the incision one inch internal to, and parallel with, the femoral vessels, and crossing the tumor and ligament (Barker); but it is better to make the incision of Fabricius for radical cure. Divide the constriction by cutting upward and a little inward. If the gut is found gangrenous or in a doubtful condition follow Blake's advice ("Surg., Gynecol., and Obstet.," May, 1906), make an incision at the edge of the rectus, draw the affected portion of gut into the abdomen and out of the incision and either resect, fix it under or out of the incision, or wait for return of circulation, as may be indicated in the case. To draw the gut out of the femoral ring makes so much traction that return of circulation may be prevented and any intestinal operation is difficult in this region without splitting Poupart's ligament. In *umbilical hernia* make a slightly curved incision a little to one side of the middle of the tumor, open the sac, separate adhesions, and divide the constriction by cutting upward or downward, and sometimes also laterally.

After an operation for strangulated hernia put the patient to bed; bend the knees over a pillow; give no food by the mouth for thirty-six hours (McCormac), only allowing hot water, and give an enema of salt solution containing brandy every sixth hour. Abdominal pain and tenderness call for the administration of saline cathartics and enemata containing turpentine or oil

of rue. The enema rutaë is a favorite preparation in London. It is made as follows: Take sixteen ounces of oil, warm it, and pour it upon 5ij of confection of rye; if there are no abdominal pain and tenderness, the bowels will move in a few days; but if at the end of four or five days there is no motion, give a saline cathartic and an enema. At the end of a week get the patient up. If a radical cure has not been attained, apply a spica bandage to the groin, and later a truss. A radical cure has been made.

Mortality.—Cases of strangulated hernia in which the patient dies without operation. The mortality is not due to operation, but is due to the condition of the patient at the time of operation, or to forcible antecedent treatment.

Fig. 674.—Double inguinal hernia.

1429 herniotomies, estimates the mortality at 20 per cent. according to the time of strangulation. The following conclusions: The mortality of cases operated on before strangulation is 8.09 per cent.; during the first day, 15.5 per cent.; during the second day, 35.5 per cent.; during the third day, 45.5 per cent.; during the fourth day, 55.5 per cent. ("Atlas and Epitome of Abdominal Hernias," by J. B. Coley, M.D., translated and edited by Wm. B. Coley, M.D.) The mortality is smaller than in adults. In Coley's 12 cases of childhood hernia there was not a death.

Hernia in Childhood.—Hernia is extremely rare in childhood. It is an interesting fact that if one conducts a careful study of the literature, it will be found that but 5 or 6 per cent. of cases of hernia in childhood are operated on. This fact seems to indicate that the majority of cases of hernia in childhood are cured spontaneously. Ochsner ("Jour. Amer. Med. Assoc.," Dec. 22, 1910).

frequency of hernia in childhood, alludes to Malgaigne's statistics. Malgaigne estimated that during the first year of life one child in every twenty-one has hernia, and that this proportion is maintained until the age of six. Then it diminishes rapidly until the age of thirteen, at which age there is one hernia in every seventy-seven children. It is, therefore, obvious that 75 per cent. of all hernia in children of six years will heal spontaneously before the age of thirteen. Ochsner states that 95 per cent. of hernia in children will be cured without operation. He points out that between the ages of thirteen and twenty hernia is fairly common among boys, but very rare among girls. The reason for this tendency to cure is somewhat uncertain. The view advocated by Thomas C. Martin is that, as the pelvis broadens, the parietal peritoneum enlarges. It does this at the expense of the mesentery, which is shortened, and the internal abdominal ring is displaced. In a very instructive analysis of this condition Ochsner shows that in 25 per cent. of cases of hernia in childhood hereditary weakness exists; that the condition is commoner among the poorer classes than among the richer; that in many cases there is an undescended testicle; and that the chief cause is an excess of intra-abdominal pressure. This excess of intra-abdominal pressure may result from flatulent distention of the stomach and intestines, the product of bad feeding; constipation and straining; straining on urinating, due to the existence of phimosis; vomiting, or cough. He thinks that, as a rule, indigestion causes flatulence and pain; that the child cries; that this increases the pressure; that the mother then feeds it, in order to keep it quiet, and that this makes it worse. Strangulation is rare in childhood.

Treatment.—Strangulated hernia, irreducible hernia, hernia with very large rings, cases in which trusses fail, and cases associated with reducible hydrocele require operation (Ochsner). Most cases are curable without operation, the ring being guarded by a truss of rubber or a pad of lamb's wool. Ochsner believes that many cases can be cured by keeping the child recumbent, with the foot of the bed raised, from four to six weeks. If phimosis exists, it should be operated upon, and any other causative condition should be treated (cough, vomiting, constipation, flatulent indigestion, etc.). An umbilical hernia can usually be cured by the use of a cork. The cork should be one inch in diameter and one and one fourth inches in length, and shaped like a cone. The smaller end is pushed into the ring and the cork is held in place by adhesive plaster. In two weeks a smaller cork must be used, and in six or eight weeks it can usually be dispensed with. Radical cure operations are seldom done before the age of four (page 1127).

Varieties of Hernia.—*Direct inguinal hernia* cent. of cases of inguinal hernia. In direct hernia the bowel enters the inguinal canal low down, and pass outside the force the conjoint tendon before them or split the tendon. They do not enter the scrotum. The neck of the sac is above the inguinal artery. The protrusion is globular in shape, and the edge of the tendon, in which case it is pear

Fig. 675.—a, Scrotal hernia; b, congenital hernia; c, funicular hernia; d, infantile hernia; e, encysted hernia.

Congenital inguinal hernia is a portion of the vaginal process. The bowel in congenital hernia is in front of it. The testicle is posterior and below it. In some cases that bowel may not enter the sac of a congenital hernia for several months after birth. Congenital hernia conceals the testicle if it does not. If a vaginal process, open above the inguinal ring, is present, the condition is called *hernia into the funicular process*.

If the funicular process is closed at the abdominal ring, a hernia in a special sac may descend back of the vaginal ring. This condition is known as *infantile hernia*. In infantile hernia the peritoneum is in front of the bowel—the two layers of peritoneum form the one layer of sac. The testicle is in front (Fig.

If the tunica vaginalis is closed above and not below, and a hernia pushes down the vaginal process and causes it to double on itself, the condition is known as *encysted infantile hernia* (Fig. 675, c).

In *femoral hernia* the contents descend along the femoral canal, and the neck of the sac is at the femoral ring. The neck of a femoral rupture is always external to the pubic spine; the neck of an inguinal rupture is always internal to the pubic spine. Femoral hernia contains omentum, but seldom intestine, except in strangulated cases. It used to be said that femoral hernia is never congenital. Russell and Coley show that it may be (page 1124). The coverings of a femoral hernia are skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous tissue, and peritoneum.

Umbilical hernia may be congenital (the ventral plates having closed incompletely), infantile (the cicatrix of the umbilicus having stretched), or acquired.

Ventral hernia is a protrusion through any part of the anterior abdominal wall except at the umbilical or inguinal regions. A ventral hernia may be median (*hernia of the linea alba*) or lateral. The treatment is radical operation.

Epigastric hernia is a form of ventral hernia. In this condition there is a protrusion of the peritoneum in the space bounded by the ensiform cartilage, the ribs, and the umbilicus. The sac of peritoneum may be empty, may contain omentum, or omentum and bowel. The stomach very rarely passes into the sac. The protrusion is usually, but not invariably, through the linea alba. The condition may be due to a congenital gap in the transversalis fascia or to the growth of a fat hernia.

Cecal hernia is very uncommon in women. It may be either congenital, infantile, or acquired. If a vaginal process is open the cecum may readily enter in, it may be drawn in by the plica vascularis as the testicle descends (Wrisberg), it may be drawn in by a descending testicle the posterior peritoneum over which has formed adhesions to the cecum. Most acquired cecal herniae are preceded and caused by hernia of the small gut, but they may occur alone. In the simple form the cecum is completely covered by a coat of peritoneum and lies within the sac. Usually there is a complete surrounding sac, but sometimes the sac partially covers the cecum lying in front and to the inner side. In these cases the cecum is on the posterior and external aspect of the wall of the sac. The appendix may be in the sac, outside of the sac, or part may be within and part without. If the sac is incomplete, it means that we have one of the 18 per cent. of cases in which the cecum is not completely covered with peritoneum. A cecal hernia may be and usually is right inguinal, but may be right femoral, left inguinal, or left femoral. It is most common in advanced life and is frequently irreducible.

Hernia of the appendix may occur alone, and Merigot de Trigney collected 22 cases of it ("Thèse de Paris," 1887). In 17 the hernia was inguinal; in 5 it was femoral. I operated upon a case of appendicitis in which the inflamed appendix was the sole occupant of an incomplete right inguinal hernia sac. In some cases the appendix accompanies the cecum into a hernia.

Sliding hernia of the ascending colon is due to the looseness of the peritoneum of the iliac region, which permits a portion of the large bowel to slide into a hernia. In such a case the posterolateral aspect of the sac is absent (Figs. 676 and 677). The descending bowel carries with it into the scrotum

a fold of loosened peritoneum, just as in the descent of the testis (see Weir, in "Med Record," Feb. 24, 1900). Sliding hernia of the ascending colon is wrongly called sliding hernia of the cecum. *Sliding hernia of the descending colon*, wrongly called sliding hernia of the sigmoid, may occur. In most cases the descending colon is dragged into a preexisting hernia-sac containing small bowel, omentum, or both. The large bowel is covered with peritoneum except posteriorly, where the mesocolon is attached. This form is nearly always irreducible and occurs particularly in elderly men. In another group of cases

Fig. 676.—The large intestine behind the peritoneum (Weir).

Fig. 677.—The retroperitoneal large intestine in a cross section of the hernia with its complete sac (Weir).

the large bowel makes a direct inguinal hernia and the sac is limited to the anterior surface of the protruded gut.

In *properitoneal hernia* the sac is between the peritoneum and transversalis fascia. The form of hernia is sometimes produced by making tap on an inguinal hernia, when the internal ring is small or is blocked by an undescended testicle. In properitoneal inguinal hernia, which is the most common form, there are two sacs detectable, one in the scrotum, the other parallel with Poupart's ligament, and as one sac is emptied, the other distends (Breiter, of Zurich).

In *interstitial or interparietal inguinal hernia* the hernia sac is between the transversalis muscle and fascia, or between the external and internal oblique muscles, or between the fibers of the internal oblique muscle, or between the external oblique muscle and the transversalis fascia, the internal oblique and transversalis muscles being pushed aside (Sultan's "Atlas of Abdominal Hernias").

In *superficial inguinal hernia* the sac is between the aponeurosis of the external oblique muscle and the superficial fascia. This variety of hernia is always congenital and the testicle is invariably misplaced.

Obturator hernia passes through the obturator foramen (or the obturator canal), and is felt below the horizontal ramus of the pubes, internal to the femoral vessels. The obturator nerve is pressed upon and pain arises in its trajectory.

Lumbar hernia is a very rare condition. It may be congenital, traumatic, or spontaneous, and may follow a lumbar abscess. Baracz collected 68 cases. It occurs through the triangle of Petit, or just below the twelfth rib through the superior lumbar triangle, or through a congenital defect in the aponeurosis of the latissimus dorsi muscle, or through a defect near the triangle of Petit (Dowd, in "Annals of Surgery," Feb., 1907). A lumbar hernia may be present at the edge of or through the quadratus lumborum muscles.

The *triangle of Petit* is bounded in front by the external oblique, behind by the latissimus dorsi, below by the iliac crest, and its floor is formed by the internal oblique. The *superior lumbar triangle* (of Grynfelt and Lesshaft) is bounded anteriorly by the external oblique, posteriorly by the iliocostal muscle, above by the serratus posticus inferior and the end of the twelfth rib, and below by the internal oblique. The latissimus dorsi overlies it.

Sciatic or gluteal hernia passes through the great sacrosciatic foramen, above or below the piriformis muscle, or through the lesser sacrosciatic foramen.

Pudendal hernia protrudes into the lower part of the labium, the bowel having descended between the ischial ramus and the vagina.

Perineal hernia presents in the perineum, between the rectum and the prostate gland or between the rectum and the vagina.

Internal, retroperitoneal, or intra-abdominal hernia include hernia into the foramen of Winslow, hernia into the *retroduodenal fossa*, the *retrocecal fossa*, and the *intersigmoid fossa*.

Vaginal hernia is associated with uterine prolapse or ensues upon destruction of the vaginal wall.

Richter's hernia is the catching of a portion of the circumference of the

Fig. 678.—A Diagrammatic representation of Richter's hernia of the intestinal wall. B Diagrammatic representation of a hernia of Meckel's diverticulum ('Sultan').

the side of the chest is unduly prominent. The upper border of the tympanic area does not move with respiration. There are no breath sounds audible over the tympanic area, but gurgling is heard. In 250 cases of traumatic diaphragmatic hernia collected by Leichtenstern the diagnosis was made before death in but 5 cases. The x-rays are of value in diagnosis, especially if the stomach is in the hernia. Strangulation of a diaphragmatic hernia produces severe pain in the upper abdomen, violent vomiting, constipation, boat-shaped abdomen, great thirst, rapid wasting, and the excretion of a very small amount of urea (Mackenzie and Battle, "Lancet," Dec. 7, 1901). Diaphragmatic hernia may be confused with *eventration of the diaphragm*, an unnaturally high position of the left half of the diaphragm, with ascent of the viscera of the abdomen, especially the stomach. It was first described by Petit in 1790. Sailer and Rhein reported a case and collected 12 others ("Am. Jour. Med. Sciences," April, 1905). The physical signs of eventration are practically identical with those of diaphragmatic hernia, except that in the former the upper border of the tympany moves on respiration.

Treatment.—Open the belly for exploration. If a hernia is found, return it to the abdomen; open the chest and suture the diaphragm from above (transpleural suturing). Mackenzie and Battle, Mikulicz, Humbert, and others have operated for this condition.

Hernia of the Ovary.—The ovary, because of failure of descent, may remain in the lumbar region. It may pass into the inguinal canal or labium majus (inguinal hernia); to the gluteal region (gluteal hernia); to the region of the obturator foramen (obturator hernia); or to the front of the abdomen (ventral hernia). In congenital inguinal hernia there may be ovary alone, or ovary, tube, omentum, and even part of a bicornate uterus (Garrigues). It is impossible to restore a congenital hernia. Acquired hernia may follow a fall and sometimes it can be restored. A femoral or crural ovarian hernia, a condition in which the ovary passes to the front of the thigh below Poupart's ligament, is never congenital. In some cases a herniated ovary can be returned within the abdomen. Any herniated ovary may inflame.

Treatment.—If it can be restored, a truss will probably retain it. If it cannot be restored or if it is painful or undesirable to wear a truss, operate. Expose the ovary, return it to the belly if healthy, and do a radical cure of the hernia. In some conditions of disease remove the ovary.

Hernia of the Uterus.—This condition is a surgical curiosity, but a few cases have been reported (see John Howard Jopson's case in "Annals of Surgery," July, 1904). The hernia may be umbilical, ventral, inguinal, or femoral. Hernia of the unimpregnated womb may be congenital or acquired; impregnation may occur when the uterus is herniated, or an impregnated uterus may pass into a preëxisting hernia sac. If a herniated uterus becomes impregnated or if an impregnated uterus becomes herniated, pregnancy may go on to term. Multiple pregnancies predispose to uterine hernia. Ovarian hernia may precede uterine hernia, or hernia of omentum adherent to the uterus may pull that organ into the sac. In many cases congenital anomalies have been found to exist (bicornate uterus, rudimentary uterus, shortness of the round ligament, imperforate vagina, etc.). A hernia of the uterus enlarges and becomes painful during menstruation, and a vaginal examination shows that the uterus is absent from its normal position and that the direction

Dermoids occasionally grow from the mucous membrane of the rectum and are apt to contain an abundant growth of hair.

Examination of the Anus and Rectum.—There are four positions in which we may place the patient for rectal examination, the one to be selected depending upon the probable local difficulty. These positions are the left lateral prone, the knee-chest, the exaggerated lithotomy, and the squatting position. That most commonly employed is the *left lateral prone position of Sims*, in which the patient lies on the left side, the chest on the table, the left arm behind the back, the knees drawn up, and the pelvis elevated on a hard pillow. This position is used in the majority of cases for ocular, digital, or instrumental examinations.

Very stout people must be placed in the *knee-chest position* or *exaggerated lithotomy position*, as the rectum cannot be seen when they lie on the side.

A *squatting position*, when the patient is placed as though on a commode, is best adapted to cases of prolapse and hemorrhoids. It is also used to bring within the range of the finger strictures or new growths that in the other attitudes would be beyond digital reach.

In some patients one is able to pass a sigmoidoscope upon a patient in the *exaggerated lithotomy position* when it has been found impossible to carry the instrument high enough with the patient in any other position.

While making a rectal examination the patient should have no constriction about the abdomen, such as dress, bandages, or any tight clothing.

It is important that the first examination be made when no cathartics or enemata have been administered, so that the condition of the excretions and secretions may be noted. After these observations have been made an enema should be given and the anus and rectum be well cleansed. By such first examination pus, blood, mucus, or inspissated fecal matter if present may be seen, and from their varying characteristics, quantities and locations, causal inferences may be drawn. When the parts have been cleaned and the bowel washed out the anus is carefully inspected, the anal folds being opened during the process. By inspection the surgeon can notice the external opening of a fistula, external piles, protruding internal piles, mixed piles, pruritus, discharge from the rectum, eczema, fissure, tumor, ulcer, condylomata, abscess, whether or not the anus is retracted and funnel shaped or protruding, or if there be parasites on the anal hairs.

Next the thumbs should be placed on either side of the anus and gently separated; this maneuver aided by a bearing down effort on the part of the patient will often cause piles to protrude, exhibit fissures and polypi, and reveal the condition of the mucocutaneous border.

Next, a digital examination of the rectum is made. The nail of the index-finger is filled with soap and the finger is oiled or, better, is covered with a rubber finger-tip which is oiled. The digit is gently inserted through the sphincter, the patient being asked to strain lightly while it is passing. The finger is inserted with a gentle boring motion and is pointed toward the umbilicus until the sphincter is passed. A digital examination enables the surgeon to detect an ulcer, a polypus, a tumor, a stricture, and to determine certain points regarding the condition of the prostate in the male and the uterus in the female.

Next, in some cases the rectum must be examined with a speculum. It

Fig. 679. Mathew's self-retaining retractor.

Fig. 680.—Brinkerhoff's speculum.

Fig. 681.—Martin's speculum.

It is often necessary to give ether. Mathews' speculum (Fig. 679) is very valuable. Sims' duck-bill speculum is a valuable instrument. The speculum is warmed, oiled, and slowly introduced. It is first directed toward the

Fig. 682.—Cook's operating speculum.

pelvicus, and when it passes the sphincter, its direction is gradually altered so that it is toward the promontory of the sacrum. Illumination is obtained by direct sunlight, or by a forehead mirror and an electric light. This examination will extend, confirm, or disprove the findings of the digital ex-

Fig. 683.—Kelly's rectal specula.

amination; ulcers, hemorrhoids, and malignant growths can be carefully examined, and the condition of the rectal mucous membrane can be thoroughly investigated.

Marion Sims in 1845 demonstrated the ballooning of the vagina by atmos-

685). Dr. Tuttle describes it as follows ("Diseases of the Anus, Rectum, and Colon," by James P. Tuttle): "This instrument is composed of a large cylinder (*f*), into one part of the circumference of which is fitted a small metallic tube closed by a flint-glass bulb at its distal end. The electric lamp (*d*) is fitted upon a long metallic stem, and carried through the small cylinder to the end of the instrument, as shown in the illustration. The proctoscope is introduced through the anus with the obturator (*a*) in position. As soon as the internal sphincter is passed, this obturator is withdrawn and the bayonet-fitting plug (*b*), which contains either a plain glass window or a lens focused to the length of the instrument to be used, is inserted in the proximal end of the

Fig. 685.—Tuttle's pneumatic proctoscope. *a*, Obturator; *b*, plug with glass window closing end of tube; *c*, hand; *d*, cords connecting instrument with battery; *e*, inflating apparatus; *f*, main tube of proctoscope.

instrument. This plug is ground to fit air-tight and thus closes the instrument perfectly. The plug being inserted in the tube, a very slight pressure upon the hand-bulb will cause inflation of the rectal ampulla to such an extent that the whole rectum can be observed and the instrument can be carried up to the promontory of the sacrum without coming in contact with the rectal wall. Further dilatation will show the direction of the canal leading into the sigmoid, and, by a little care in manipulating the instrument and keeping the gut well dilated in advance, it can be carried up into this portion of the intestine without the least traumatism of the parts. If any fecal matter obscures the light by being massed or smeared over the glass bulb, the plug can be removed, and a pledget of cotton, introduced with a long dressing forceps, will wipe this off so that the plug can be reintroduced and the examination continued with very slight delay or inconvenience. The adjustable handle (*c*) fits on the rim of the instrument and thus converts it into a Kelly tube. This instrument is operated with an ordinary dry battery of four cells. It is better, however, to have a battery with six cells, as it will not require being recharged so frequently." All the air must be allowed to escape before the instrument is withdrawn, otherwise colic may develop.

If an anesthetized patient is placed in the knee-chest position, the sphincter can be stretched by the fingers, and the rectum will distend with air and can be easily examined. The fingers are introduced as suggested by Martin (Fig. 686) and the rectum becomes visible when they are separated (Fig. 687).

lifted out. If the body is of wood, screw in a gimlet; if of metal, cut with strong forceps; if of glass, break into small pieces. If the article is rough or has sharp edges, pack gauze all around it as a first step to protect the rectal walls. In a case in which a boar's tail had been introduced, large end first, the holding back of the bristles was overcome by sliding over it a large-sized rubber catheter.

Foreign bodies may escape into the sigmoid and necessitate a laparotomy. They may also cause periproctitic inflammation.

A remarkable series of cases of foreign bodies in the rectum may be found in "Anomalies and Curiosities of Medicine," by George M. Gould and Walter L. Pyle.

Wounds and Injuries of the Rectum.—These accidents may result from fractures of the pelvis, most often from fractures of the sacrum, from the improper use of enema syringe nozzles or tips, from gunshot-wounds, stab wounds, from foreign bodies introduced by the patient, and, rarely, from digital examinations. The important points to consider in these wounds are whether or not there is penetration of the entire rectal wall, involvement of the perirectal tissues, or peritoneum. Slight wounds involving only the mucous membrane are frequently very grave from the fact that the hemorrhage is constant into the rectum, filling back into the sigmoid, often followed by collapse when the blood is voided. The investigations in these cases should always be thorough and by both digital and visual examination, for exact diagnosis is of the utmost importance.

If the peritoneum has been lacerated, laparotomy should be performed at once, the wound in the bowel repaired, the peritoneal cavity cleansed, and the Murphy treatment for general peritonitis instituted. If the laceration involves the perirectal tissues but not the peritoneum, cut down on the side of the bowel that is injured and make free drainage. In the event of very extensive injuries to the perirectal tissues the question of inguinal colostomy should be considered. If the wound involves only the mucous or submucous coats, dilate the sphincter, arrest hemorrhage by suture or ligature, and follow by irrigation.

Inflammation of the Rectum and Sigmoid (Proctitis and Sigmoiditis).—These conditions may be acute or chronic, simple or specific. The simple forms are acute catarrhal, atrophic catarrhal, and hypertrophic catarrhal. The specific forms are gonorrheal catarrhal, diphtheritic catarrhal, erysipelalous catarrhal, dysenteric catarrhal, and syphilitic catarrhal (Tuttle).

Acute Inflammation.—Acute catarrhal inflammation may be caused by that class of incidents followed by ordinary catarrh of the respiratory passages and, in addition, errors of diet or sudden change of temperature, as sitting on a cold seat when overheated. The onset is sudden, with chill, general malaise, pain and discomfort locally, and slight fever. There is a sense of fulness and weight, with often a burning sensation referred to the rectum, and at times tenesmus with frequent desire to go to stool. Pain radiates to adjacent parts and there is bladder irritability. Patients usually prefer to be in the recumbent posture.

There will be at first a thin fecal discharge followed by mucus tinged with blood. Ulceration soon supervenes. The parts are hot, dry, and swollen in the first stages and digital examination is very painful. Later the parts are slimy and the mucous membrane is covered with tenacious mucus and pus.

Treatment.—First remove irritating intestinal contents and reduce en-

gorgement by lavage and saline cathartics, followed, if early in the case, by irrigations of cold water, if later, by hot water. A useful medicated irrigation is a 5 to 10 per cent. solution of the aqueous extract of krameria.

Chronic Inflammation.—In chronic proctitis and sigmoiditis the symptoms are similar to those present in the acute forms of the inflammation, but less severe in character. In addition there is increased secretion of mucus, flatulence, and marked general intestinal disturbance.

The mucous membrane is soft, doughy, and thickened, which condition palpably reduces the caliber of the gut. Through the speculum the membrane is seen to be edematous, pale, and covered with secretion. It bulges into the aperture of the speculum and does not bleed easily.

Treatment is hygienic and dietetic, with antiseptic and astringent irrigations.

Atrophic Inflammation.—The atrophic variety of these inflammations is characterized by long-continued constipation, dry stools covered with blood and mucus. There is such pain on expulsion of feces as to simulate in many cases fissure of the anus. The mucous membrane of the anus ruptures easily when stretched during examination. It is bright red and shiny, does not fill the aperture of the speculum, and bleeds readily. Ulceration is common and hemorrhoids are a frequent complication. *Treatment* is local and general. Locally use nitrate of silver, hydrastis, or ichthyol, applied after the rectum is emptied. General treatment is hygienic and dietetic.

Peri-anal and Perirectal Inflammations. These are of two classes—circumscribed inflammations or abscesses and diffuse inflammations that always develop pus. The circumscribed variety may be either superficial or deep. The superficial variety again may be terminal, subterminal, or isomorectal. The deep variety may be of two forms—retrorectal or superior pelvirectal. It is important to note that right sided superior pelvirectal abscess may be confounded with appendicitis.

The diffuse perirectal inflammations are variously classified, but the particular names refer only to the degree of the inflammatory process, which may vary from ordinary suppuration to gangrene.

These inflammations travel in the line of least resistance, which is upward and more often burst into the bowel than externally. They may follow closing of the region or external traumatism, may be caused by perforations of the rectum by hard fecal masses, or by the direct passage of bacteria into the feces through a fissure, an ulcer, or an ulcerated pile. They may be either acute or tuberculous. In many cases the process is at first tuberculous, and secondary infection with pyogenic bacteria takes place.

The **symptoms** are the same as those of abscess anywhere, the swelling, however, being brawny, and it being difficult or impossible to detect fluctuation. Pain in the groin is often complained of, and there may be enlarged glands in these regions. Abscesses commonly result in fistula, and a patient should be warned of this tendency before operation is performed. Superior pelvirectal abscesses generally follow inflammation of some pelvic organ, viz. tubes, urethra, prostate, and the symptoms are mainly those of such an inflammatory condition. The usual tendency of the pus is to burrow upward. The presence of pus is indicated by the symptoms of suppurative toxæmia, which sometimes simulate typhoid fever.

The **treatment** is instant incision. The patient is placed in the lithotomy

position after having been anesthetized. The cut should be parallel to the fibers of the external sphincter and well outside of the muscle and longer than the inflamed area. When this incision is made the finger should be introduced to break down the necrotic septa of cellular tissue. Then an incision should be made from the middle of the first cut radiating outward and opening any pockets external to the original focus. Then the free edges of the cuts are pared away, sacrificing all involved tissue. The wound is irrigated, the sphincter dilated, and the cavity packed with iodoform gauze. If a fistula is found opening into the rectum, it is not to be operated on until after the wound is nearly healed, only a small fistulous tract remaining.

In cases of superior pelvirectal abscess the incision should be made at right angles to the fibers of the levator ani muscle to facilitate drainage. In these cases tubal drainage is used.

Imperforate Anus.—There are two forms of this condition. In one form the rectum empties into the bladder, vagina, or urethra. In the other form there is no rectal opening either upon the surface of the body or in the urinary organs. The diagnosis is usually at once apparent, except in cases where the anus looks normal, when the diagnosis will often not be made until symptoms of obstruction arise.

Treatment.—If the rectum bulges when the child cries, open into it with a knife and keep the opening patent by inserting a plug of iodoform gauze. In cases in which the rectum is more deeply seated, a catheter is introduced into the bladder, an incision is made from the anus to the coccyx, the rectum is sought for, and when found, is sewed to the anus and is incised. In some

Fig. 688.—Fistula in ano. A, Blind external; B, blind internal; C, complete (Fsmarch and Kowalzig).

cases Keen and others have performed Kraske's sacral resection, pulling down the rectum to the anal margin, sewing it there, and incising the occluded anus. If the rectum cannot be found or cannot be pulled down, an artificial anus must be made.

Fistula in ano is the track of an unhealed abscess. An abscess in the anal region is apt to refuse to heal because of the constant movement of the parts (produced by respiration, coughing, the passage of gas, defecation, etc.). The passage of feces will keep a fistula open. If a tuberculous ulcer perforates, a tuberculous sinus forms, and a tuberculous sinus is also apt to follow a cold abscess of the ischiorectal fossa. Fistula is often associated with phthisis pulmonalis, and is not unusually linked with piles, cancer, or stricture.

There are three varieties of fistula—the blind external (Fig. 688, A), the blind internal (Fig. 688, B), and the complete (Fig. 688, C). The external opening is usually near the anus, but may be far away, and there may be only one pathway or there may be several sinuses and openings. In a healthy individual the external orifice is small and a mass of granulations sprouts from it. In a tuberculous fistula the external orifice is large and irregular,

with thin and undermined edges, shows no granulations, extrudes small quantities of sanious pus, and the skin about it is purple and congested. In a fistula following an anal abscess the *internal* opening is just above the anus, between the two sphincters. In fistula following an ischio-rectal abscess the internal opening is usually near the anus, but may in rare cases be above the internal sphincter. A sinus may run up under the mucous membrane from the internal opening. In a *horseshoe fistula* the internal opening is usually upon the posterior wall of the bowel, "and from this a tract leads into the ischio-rectal fossa, not on one side only, but upon both. Therefore we have one opening into the bowel and one through the skin on either side."* In some cases of horseshoe fistula there is no internal opening; in other cases there are two openings. In an old fistula the track becomes fibrous and cannot collapse. Two or more

Fig. 689.—Operation for fistula in ano (Esmarch and Kowalzig).

fistulae may exist in the same patient. In dealing with a fistula always determine if the condition is stationary or progressive. The **symptoms** of a complete fistula are the passage of feces and gas through the opening and the flow of a discharge which stains the clothing. In a complete fistula a probe can be carried from the external opening into the bowel. After a time incontinence of feces is apt to come on, repeated attacks of inflammation thickening the rectum and destroying its sensibility. From time to time the opening will block, and new abscesses form. In examining a fistula use Brodie's probe, as its flat handle enables one to locate the direction the bent instrument has taken, and its slender shaft will find its way through a very small channel.

Treatment.—In treating a fistula cleanse the parts, as cleanly work, though it will not prevent pus, will limit suppuration. The external parts are washed with soap and water. The rectum, which must be empty, is irrigated with hot saline solution. Corrosive sublimate should not be used in the rectum, because it is irritant, causes a flow of serum, and hence lessens tissue resistance, and is rendered inert as an antiseptic by being converted into sulphid of mercury. Anesthetize the patient with ether unless the fistula is tuberculous, in which case use local anesthesia, spinal anesthesia, or nitrous oxid. Ether is avoided for fear of the existence of a pulmonary focus. A tuberculous focus in the lung may disseminate after inhalation anesthesia (page 1141). Place the patient in the lithotomy position. If operating upon a complete fistula, pass a grooved director into the external opening, carry it through the sinus, make it enter the bowel, bring its point out externally, and lift the tissue between the sinus and the surface. Incise the bridge of anal (Fig. 689). If the director ascends above the internal opening, the incision must be made into the bowel from the summit of the sinus. Cut the sphincter at a right angle to its fibers, and do not cut it more than once at one attempt. If a fistula is non-tuberculous, cut with a knife. If it is tuberculous, do not cut the tissues with a Paquelin cautery in order to lessen the danger of dissemination of the infection. Push the finger to the depth of the wound, to determine if the sinus does not ascend above the internal opening. Search with a mil probe for branching sinuses, and if any are found, slit them open. (Page 1141)

* "Diseases of the Rectum, Anus, and Sigmoid Flexure," by Joseph M. Mayhew.

carefully to see if there is a sinus beneath the mucous membrane of the bowel, and if such a sinus is found, slit it up. Curet all sinuses, and if they are very fibrous, clip them away with scissors. Cut away diseased skin; irrigate with salt solution, pack firmly with iodoform gauze to prevent oozing; and dress with gauze and a T bandage. The packing is removed in twenty four hours unless it is soiled earlier, in which case it is promptly removed. After twenty-four hours the wound is irrigated and packed lightly with gauze to its full depth. This dressing should be repeated every day and any bridging of the tissues should be broken down with a probe. If the wound becomes sluggish it is stimulated with nitrate of silver and sodium iodid is given in small doses three times daily.

The bowels should be moved after forty-eight hours by enema. The diet should be light and fluid for the first few days after operation and the bowels should not be restrained by drugs. Get a tuberculous patient out of bed as soon as possible. If there are two fistulae, cut one through, and when one wound has healed, cut the other. In some straight sinuses the tract can be extirpated and the parts sutured, primary union occasionally resulting.

If a blind external fistula does not heal, every sinus must be incised, and thickened walls must be cut away or scraped away.

In a blind internal fistula an external incision is made to convert the case into a complete fistula, which is then treated as is directed above.

In horseshoe fistula, more than one operation may be necessary in order to avoid cutting the sphincter muscle twice in one operation, a proceeding which would probably lead to fecal incontinence. One side alone is operated on at one séance. Sinuses are opened and scraped, the sphincter is divided, the angles and edges of skin are trimmed away, and the wound is packed. When the wound is healed, or nearly healed, the other side should be operated upon.

If fecal incontinence results from an operation for fistula, remove the scar tissue and endeavor to suture the separated muscular fibers. A modern scientific operation for incontinence is that of A. Mayo Robson ("The Practitioner," Feb., 1903). A crescentic incision, from $\frac{1}{2}$ to $\frac{3}{4}$ inch in depth and taking in about one half of the circumference of the bowel, is made at the anterior border of the anus. The middle borders of the incision are then pulled apart until the ends of the cut approximate in the middle line, when they are stitched with deep catgut sutures and the skin is sewed with silk-worm gut, the immediate result being an incision apparently radiating from the anus. Should an operation be undertaken for fistula if phthisis exists? Many of the old masters said *no*. Mathews sums up the modern view: In incipient phthisis operate; in rapidly progressive fistula operate whether cough exists or not, if much cough exists, do not operate unless the fistula is rapidly progressive; in the last stages of phthisis do not operate.

Pruritus of the anus is a symptom, and not a disease. It may be due to piles, fissure, seat-worms, eczema, nerve disturbance, kidney disease, gout, jaundice, constipation, inebriety, the opium-habit, torpid liver, dyspepsia, alcohol, tea-drinking, vesical calculus, tobacco smoking, urethral stricture, uterine disease, diabetes, ovarian trouble, and mental disorder. In some cases it seems to be a pure neurosis and no special causative factor can be recognized. It is vastly more frequent in males than in females, and is espe-

cially common in fat men who sweat profusely. It is seldom seen before the age of thirty, except in children suffering from threadworms. The itching comes on gradually and usually intermittently, but grows progressively worse and worse until it becomes torturing. In many cases it is at first noticed only when warm in bed; in other cases it exists day and night. A violent exacerbation may be excited by worry, anxiety, overwork, dietary indiscretion, a sudden change of temperature, and many other things. The itching finally becomes an unbearable agony, sleep, except in snatches, is impossible, the appetite disappears, the strength fails, and the sufferer may become a nervous wreck. In some cases of pruritus the anal folds are edematous, there are abrasions here and there from scratching, the area is white and moist and gives origin to a fine secretion; in other cases the mucous membrane is dry and fissured.

Treatment. In every case first of all make a careful examination to find a probable or a possible cause, local, reflex, or constitutional, and endeavor to remove this supposed cause. Then undertake treatment for the pruritus. It is very important to prevent constipation. Kelsey directs that the parts be cleansed twice a day, and after each cleansing that the following ointment be applied: menthol, $\mathfrak{z}\text{j}$; cerat. simp., $\mathfrak{z}\text{ij}$; oil of sweet almonds, $\text{f}\mathfrak{z}\text{j}$; acid. carbolic, $\mathfrak{z}\text{j}$; pulvis zinc. oxid., $\mathfrak{z}\text{ij}$. Mathews commends the following mixture: chloral, $\mathfrak{z}\text{j}$; gum-camphor, $\mathfrak{z}\text{ss}$; glycerin and water, each, $\mathfrak{z}\text{j}$.* In this disease a "scarf skin" forms, which must be made to peel off by the application of icolin, pure carbolic acid, corrosive sublimate (gr. iv to $\mathfrak{z}\text{j}$ of cosmolin), calomel ($\mathfrak{z}\text{ij}$ to $\mathfrak{z}\text{j}$ of cosmolin), or camphophenique. In obstinate cases paint the parts, night and morning, with a mixture of 60 gr. of alum, 30 gr. of calomel, and 300 gr. of glycerin; or smear with an ointment composed of $\frac{1}{4}$ part of oleate of cocain, 3 parts of lanolin, 2 parts of vaselin, and 2 parts of olive oil (Morain). In very severe cases in which the skin is dry and cracked, apply a 5 per cent. solution of eucain to the abraded portions and paint the entire surface with a concentrated solution of silver nitrate. It may be necessary to repeat this treatment several times at intervals of four or five days. Adler advised us to apply to the parts the day after the silver has been used unguentum hydrargyri nitratis in full strength, only discontinuing on the day a fresh application of silver is made and the next day resuming the applications of ointment. If during treatment the skin becomes sore, use calomel ointment until soreness disappears. Violent attacks of itching are met by applying hot water and black wash or calomel ointment. This plan of treatment must be pursued for some months (Lewis H. Adler, Jr., "New York and Phil. Med. Jour.," July 20, 1905). I have used this plan with some satisfaction. In severe and protracted cases we may employ the x-rays twice a week (J. R. Pennington). I have seen their application productive of great benefit. In some cases we employ the Paquelin cautery, in others we resect the mucous membrane, as in Whitehead's operation for hemorrhoids. Ball divides the sensory nerves going to the implicated skin and has obtained excellent results.

Fissure of the anus is an irritable ulcer at the anal orifice producing spasm of the sphincter. Pain exists because twigs of nerves are exposed upon the floor of the ulcer. Fissure is caused by constipation or traumatism. The

* "Diseases of the Rectum"

symptom is violent, burning pain, sometimes beginning during defecation, but usually at the end of the act, and lasting for some hours. Constipation exists, and often pruritus. Examination discloses a fissure, usually at the posterior margin, running up the bowel one-quarter to one-half an inch. Piles often exist with fissure.

Treatment.—The *palliative treatment* is to prevent constipation, to wash out the rectum with cold water, and apply an ointment made by evaporating ℥ij of the juice of conium down to ℥ij, and adding it to ℥j of lanolin and gr. xij of persulphate of iron. Pure ichthyol frequently promotes healing unless the edges are thick or the base indurated, when operation must be done.

Operative Treatment.—Anesthetize the patient. Thoroughly cleanse the parts. Some surgeons advocate operation without stretching the sphincter. The fissure is incised through its base $\frac{1}{4}$ inch deeper than the deepest part of the ulcer, extending $\frac{1}{2}$ inch above and below the diseased tissues, so that the healthy muscular fibers at either end are divided. In cases in which the ulcer is at either the anterior or posterior commissure a V-shaped incision is made, the apex of which should begin $\frac{1}{4}$ inch above the highest point of the ulcer and the diverging line running close to the sides of the fissure, but in healthy tissue.

If there are redundant edges, exuberant granulations, a sentinel pile, or a polypus, they should be curetted or excised. The wound is then packed lightly with gauze and the patient kept in bed for twenty-four hours. A large percentage of these operations may be done under local anesthesia.

Many cases are so sensitive and painful to the touch that medication and examination are almost impossible. These may be made bearable by insufflations of orthoform. It has always been my custom to stretch the sphincter for fissure. Stretching gives us room in which to work, and, by thus paralyzing the muscular fibers, the raw surface is put at rest and paroxysms of pain cease to occur. In order to stretch the sphincter the patient is anesthetized, the surgeon's thumbs are inserted into the rectum, and the parts are stretched until the thumbs touch the ischia. After stretching the sphincter incise the floor of the fissure, scrape it with a curet, search carefully with a probe to be sure no pockets exist, and touch it with nitrate of silver stick.

Hemorrhoids, or Piles.—There are three varieties of varicose tumors of the rectum, namely: *internal*, which take origin within the external sphincter; *external*, which take origin without the external sphincter, and *mixed* hemorrhoids, which are a combination of the two.

External hemorrhoids are covered with skin. Internal hemorrhoids are covered with mucous membrane. The term external hemorrhoids is not strictly accurate, as hemorrhage does not occur in external piles, and all external piles are not related to the external hemorrhoidal veins. An external pile may involve the veins or the skin.

External Hemorrhoids. External hemorrhoids are classified as thrombotic, varicose, inflammatory, and connective-tissue external hemorrhoids (Tuttle).

Thrombotic External Hemorrhoids.—These are external hemorrhoidal veins filled with clot. When an external hemorrhoidal vein inflames, the parts become itchy, painful, and swollen, and defecation increases the pain. The blood clots in the inflamed vein and sometimes the vessel ruptures.

Symptoms and Treatment.—External piles of this variety are usually but not always, multiple. Small oval tumors appear beneath the skin or the junction of the skin and mucous membrane. They appear suddenly. The parts itch and pain, defecation increases the pain, and each pile increases rapidly in size. When the vein ruptures, a livid, soft enlargement rapidly forms. External piles of this variety may be absorbed, may become organized into a scar, or may suppurate. These piles do not bleed. In treating external hemorrhoids some surgeons merely use remedies to combat the inflammation. An old plan of treatment is to incise the blood-tumor, turn out the clot, and pack with a bit of iodoform gauze. Mathews freezes the part or injects cocaine, catches up the blood-tumor with a volsellum, excises the tumor and the tabs of inflamed skin, dusts the part with iodoform, and dresses it with antiseptic gauze. The bowels should not be allowed to move for two days. Never inject external piles with carbolic acid; it causes great inflammation, violent pain, and is not free from danger. If the patient declines operation, order rest, a non-stimulating diet, avoidance of tobacco (Mathews), the use of saline purgatives, injections into the rectum of cold water several times a day, sponging of the anus frequently with hot water, and the application of hot poultices. As the acute symptoms begin to disappear use lead-water and laudanum; when they have nearly subsided, apply zinc ointment. Extract of hamamelis is a valuable application to external piles.

Varicose External Hemorrhoids.—These are varicose external hemorrhoidal veins and are visible at the anal margin when the patient strains. They rarely produce pain or discomfort, and it is seldom that operation is necessary. The bowels should be moved daily, but not with violent purgatives, and after each movement cold should be applied to the anus, while the patient is recumbent. Tuttle advocates the use at night of an ointment containing ʒij of suprarenal extract and ʒvj of lanolin. The ointment is spread on cotton-wool, which is applied to the anus and held in place by a T-bandage.

Inflammatory Piles.—By this term we mean edematous inflammation of the anal folds. The inflammation may be due to a traumatism, the presence of an ulcer or fissure, etc. There are burning, itching, and swelling of the anus, which are all greatly increased by defecation. One or more pear-shaped swellings can be seen at the anal margin.

In some cases medical treatment produces cure. This treatment consists, during the first twenty-four hours, in the use of cold and of rest in bed. After this period heat should be employed. Tuttle applies gauze soaked in a 25 per cent. solution of boroglycerid and places a hot-water bag over this. He also recommends the following ointment to be applied two or three times a day:

R.	Morphine sulph.,	gr. v-x
	Ichthyol,	ʒ iv
	Ung. belladonnae, ʒ i	
	Ung. stramonii, ʒ i	ʒ ʒj

Sig.—Apply two or three times a day.

If these means fail, ether is given, the sphincter is stretched, and the tumors are cut away.

Connective-tissue External Hemorrhoids (Skin Tabs).—They are due to hypertrophy of mucocutaneous tissue at the anal margin. Usually

they result from acute inflammatory external piles; sometimes they arise gradually as a result of chronic anal or rectal inflammation or irritation, and they may be due to varicose or thrombotic external piles (Tuttle). They produce no trouble when not inflamed. The treatment, if they cause serious annoyance, is extirpation.

Internal hemorrhoids are varicose tumors of the internal hemorrhoidal plexus, and are found internal to the external sphincter, just within the anus, and they prolapse easily. They are not simply varicosities, but new tissue has been formed, and they are in reality vascular tumors. They are covered with mucous membrane. *Capillary* piles are small, sessile, with a surface like a mulberry, and bleed freely. Children are not very liable to develop piles, excepting the capillary form. *Venous* piles are the most common variety. They extend from just above the anal margin of the rectum for an inch or more. They are purple in color, soft, irregular in outline, and are usually multiple. They bleed when irritated by hard fecal masses, but not so easily as the capillary piles. Each pile is composed of a varicose vein, some fibrous tissue, and a few arterial twigs. *Arterial* piles are very unusual. They are large, smooth, pedunculated, bleed easily and freely, and contain, besides a distended vein, arteries of some size.

Anything producing venous congestion in the rectum—constipation, diseases of the rectum, enlargement of the prostate, pregnancy, tumors of the womb, congestion of the liver, cirrhosis of the liver, certain diseases of the heart and lungs, sedentary occupations, relaxing climate, and stricture of the urethra—will cause hemorrhoids.

Symptoms and Treatment.—If there is neither bleeding nor protrusion, the piles give no trouble. The first symptom is usually hemorrhage, and rectal examination by the speculum will make clear the condition. After a time, during defecation, the piles protrude; they may reduce themselves when the patient stands up, or it may be necessary to push them in. Pain does not exist in uncomplicated cases, and pain during or after protrusion means "abrasion, fissure, or ulceration" (Mathews).

Palliative Treatment.—This will not cure, but it will give great comfort. Some people only suffer at rare times when the liver is congested, and such subjects will not submit to operation. Remove, if possible, the cause (alcohol, irritating foods, want of exercise, etc.); restrict the diet; insist on regular exercise; give a course of Carlsbad salt, and follow this by the administration of bichlorid of mercury (gr. $\frac{1}{4}$ after each meal). Prevent constipation by a nightly dose of extract of cascara. After each bowel movement wash the parts with a soft sponge soaked in cold water and syringe out the rectum with cold water, and dry outwardly with a soft rag. If the hemorrhoids prolapse, after restoring them and injecting cold water, insert a suppository containing gr. v of the extract of hamamelis, and use another suppository at bedtime. A useful suppository for prolapse is that employed by Tuttle: it contains gr. v of ichthyol, gr. v of tannic acid, gr. $\frac{1}{2}$ of ext. of stramonium, gr. $\frac{1}{2}$ of ext. of belladonna, and gr. x of ext. of hamamelis. Bleeding may be arrested by suppositories, each containing gr. v of suprarenal extract. When the piles prolapse and inflame, rub Allingham's ointment on the parts (3i each of ext. of conium and ext. of hyoscyamus, 3j of ext. of belladonna, and 3j of cosmolin). Mathews uses gr. xij of cocain, 3j of iodoform, 3ss of ext.

of opium, and \mathfrak{z} j of cosmolin. Grant uses an ointment containing gr. viij of morphin, gr. xij of calomel, and \mathfrak{z} j of vaselin. This is applied after bathing the part with hot water. If the piles are protruding and reduction cannot be effected, put the patient to bed, give a hypodermatic injection of morphin, and apply hot poultices. If reduction cannot soon be effected, divulsion of the sphincter must be practised or radical operation must be resorted to.

Operative Treatment.—Give a saline the morning before, and an enema the evening before, the operation, and wash out the rectum well the morning of the operation. In treating by *injection of carbolic acid* the sphincter should be divulsed while the patient is under the influence of nitrous oxid gas unless the pile is thrombotic. "Under gas muscular relaxation does not obtain as in the use of ether. Hence dilatation under gas can be more rapidly induced, as we have the sphincteric rigidity as a guide in knowing exactly how much force may be employed in the individual case" (Lewis H. Adler, Jr., in "Jour. Am. Med. Assoc.," Jan. 21, 1905). The surgeon must be careful not to tear the parts. The tumors are drawn out or, if gas was not given, the patient strains them out.

Fig. 690.—Brick's pile clamp.

an injection is given by a hypodermatic syringe into the center of the pile, and as each pile is injected it is pushed into the rectum. But one or two piles are injected at each séance, and the operation is not repeated for one week (Geo. W. Gay, in "Boston Med. and Surg. Jour.," Dec. 5, 1901). The dose for each pile is m̄j or m̄ij of a 10 per cent. solution of pure carbolic acid. The injections relieve the condition, but are rarely absolutely curative, and are not without danger, and may produce, it has been said, hemorrhage, phlebitis, pyemia, stricture, and even death (W. T. Bull). Dr. Collier F. Martin ("American Medicine," August 27, 1904) maintains that the method is safe and satisfactory. He injects equal parts of phenol boboeuf and distilled water, freshly mixed and filtered. From 7 to 15 minims are injected into a pile, and only one pile is injected at a séance. In from five days to one week another injection may be given. Before beginning a course of injections the sphincter is stretched while the patient is under nitrous oxid and oxygen. It is not necessary to repeat this for future injections. During injection a special speculum is used. The pile protrudes into the speculum, is cleansed with a 1 per cent. solution of creolin and the injection is thrown into the most prominent part of the pile. The speculum is withdrawn before pulling out the needle. This maneuver prevents escape of injection and bleeding. The clamp and cautery is, in the great majority of cases, the operation of choice. It requires but a few minutes to do it, after it is done there is little or no postoperative pain, in

very many cases retention of urine does not occur, and the patient usually is about again within ten days. The patient is anesthetized and the sphincter is carefully and thoroughly stretched. The stretching of the sphincter is very important. It gives free access to the parts, prevents subsequent spasm and pain, and lessens the likelihood of venous bleeding after operation. The pile is caught with forceps and drawn outside of the sphincter. Many use Smith's clamp. It is applied with the ivory surface against the mucous membrane of the bowel. I use the clamp devised by Dr. J. Coles Brick (Fig. 690). From the bite of Brick's clamp the pile cannot slip as the blades come evenly and firmly

Fig. 691.—Extripation of hemorrhoids (Esmarch and Kowalsig)

together. The pile is cut off, and the stump is seared with the Paquelin cautery at a dull-red heat. Pile after pile may be thus treated, care being taken to leave some mucous membrane at each side of every pile. If this precaution is not taken, healing will be slow and stricture will result. After cauterization is complete a speculum is inserted and the blades are widely opened. Any bleeding point is at once ligated. Packing is never inserted. I formerly used it but have given it up. It is of no service and produces severe pain and edema. The treatment from this point is identical with that advised below after the use of the ligature. *Excision* is preferred by Allingham. He stretches the sphincter, holds it open with a retractor, catches up the pile, cuts it off, and twists the bleeding vessels. Some prefer to pass a silk or catgut suture, cut off the tumor, and tie the thread (Fig. 691). *Whitehead's operation* (Fig. 692) is only to be performed in severe cases, when the piles are extremely large and form a protruding circular mass. Primary union is rarely secured. When first introduced, the operation was viewed with favor, but experience shows it is sometimes followed by disastrous consequences.* Stricture not infrequently arises after its performance; fecal incontinence occasionally results, and anal anesthesia with inability to restrain the passage of gas is common. After this operation the anus is permanently more or less moist. The entire pile-bearing area of mucous membrane is dissected out, and the cut margin of mucous membrane is pulled down and stitched to the surface. The sphincter may be dilated as a preliminary measure.

The application of the ligature is an easy and useful method. It is not so rapid as the cautery, is followed by more pain, healing requires a longer time, and stricture is more common. In this operation, after anesthetizing, stretch the sphincter and treat each hemorrhoid separately. Catch a pile

Fig. 692.—S, S, The lower circular incision along Hilton's white line; M, Tube of mucous membrane dissected from the sphincter; B, B, dotted line showing the place for the upper circular incision (Edmund Andrews).

* Andrews, in Mathews' Medical Quarterly, Oct., 1895.

with a pair of forceps or a volsellum, pull it down, and cut a gutter through the skin-margin if the pile is of the mixed variety; tie the small piles without transfixing, but transfix the large piles; tie with silk (coarse silk for the large piles, finer silk for the small piles); cut off each tumor beyond the thread, and cut the ligatures short. Treat the other piles in the same manner. Irrigate with hot normal salt solution. Do not insert packing. Apply a gauze pad and a T-bandage. Give some morphin to lock up the bowels, and keep the patient on a light diet for three days, at the end of which time a saline may be given. Just before the bowels act remove the dressings and give an enema of warm water or of glycerin. After the movement wash out the rectum first with dilute peroxid of hydrogen and next with hot salt solution, dust with iodoform, and apply a gauze pad over the anus. Irrigate daily

Fig. 693.—Rectal prolapse.

until healing is complete. After the tenth day examine with a speculum to see that the ligatures have come away; if any are found in place, remove them.

Prolapse of Anus and Rectum.—If the mucous membrane is prolapsed, the condition is called "*prolapsus ani*"; if the entire thickness of the rectal wall is prolapsed, it is called "*prolapsus recti*" (Fig. 693). The commonest form is due to relaxation of the submucous connective tissue permitting the protrusion of a ring of mucous membrane. Prolapse is apt to occur from excessive straining at stool and is commonest in feeble, ill-nourished children. A polypus may be causative. Piles and worms may lead to prolapse. Straining from phimosis, stone in the bladder, or urethral stricture may be causative. Its development is favored by the use of articles of food which cause frequent movements of the bowels. If an individual sits a long time on the seat of the closet or on the chamber the development of prolapse

is favored. Prolapse may be either large or small, but tends to recur again and again, and eventually the mucous membrane inflames, ulcerates, or sloughs. Strangulation of the prolapsed part may occur. The condition is sometimes confused with hemorrhoids, but in prolapse the protruding mass is circular and has a depression in the center (Fig. 693), whereas hemorrhoids are distinct masses. Further, hemorrhoids are very rare in children.

Treatment.—*Palliative* treatment forbids straining at stool and amends an improper diet. Phimosis must be corrected, stone in the bladder must

Fig. 694.—Joseph D. Bryant's method of coloproxy. *A, A*, Longitudinal band with sutures passed behind it, including peritoneal and muscular coats of the intestines drawn forward; *B, B*, parietal peritoneum quilted to sides of the intestine, showing stitches; *C*, old fecal fistula.

be crushed or removed. If prolapse occurs, the protrusion must be bathed with cold water and restored. Constipation must be prevented (enemata of water or glycerin may be used), and after each movement several ounces of a solution of white oak bark should be injected. If a prolapse is caught firmly, place the patient in the knee-chest position, wash the mass with cold water, grease it with cosmolin, insert a finger into the rectum, and apply taxis around the finger (Mathews). If this fails, cover a finger with a handkerchief and insert the wrapped digit into the rectum; if this proves futile, invert the patient. Severe cases require ether before reduction is attempted. After reduction apply a compress, direct it to be worn except when at stool, and before each act of defecation give an injection of cold water containing an astringent (tannin or fluid ext. hydrastis). A useful treatment in many cases is to paint the prolapse with fuming nitric acid, grease it with olive oil, and restore it. Some cases require excision of the mucous membrane, the divided edge of this membrane being stitched to the skin. In other cases the

protrusion is stroked with a cautery and restored. If it operate for recurring prolapse, it will often be drawn and he may be obliged to stretch the sphincter. In persistent cases of rectal prolapse open the rectum to the belly-wall (*colopexy* or *sigmoidopexy*, Fig. 100) to the mass (Cunningham, in "Annals of Surgery," May 1880).

Ulcer of the Rectum.—Ulcers of the rectum are traumatic, the syphilitic, the tuberculous, the gummy, and the malignant. *Simple* ulceration is due to trauma or a foreign body, the abraded area ulcerating, as in the case for piles and also protracted labor (Allingham). The base and edges of a simple ulcer are neither protracted nor rarely forms. *Syphilitic* ulceration is a tertiary form. There are numerous small ulcers of the mucosa, but little indurated, with sharp-cut edges which later ulcers fuse and constitute one large irregular ulcer of the wall of the bowel, induration becomes noticeable. There is profuse discharge, and fistulae are apt to be surrounded by nodules of a bluish color. The condition is stricture due to the formation of indurated rectal walls, and ulceration occurs secondarily (Cunningham) may be a breaking down of a huge gummy mass. It has been proved by the microscope that tubercles are in the rectum. *Tuberculous* ulceration presents hanging edges and a pale-red base. There is tenesmus, and a little pain, but a stricture rarely occurs. diabetes, Bright's disease, neoplasms, and foreign bodies of the rectum.

Symptoms.—There may be merely uneasiness, sometimes there is severe burning pain on defecation time after the act. There may be constipation or diarrhoea at stool, and the stools may contain blood, mucus, or diarrhoea on rising in the morning, the first movement being mucus, and the next movement being fecal. The condition should be inquired into; tuberculosis should be sought for, and should be investigated. A digital examination of the rectum should be investigated. A digital examination of the rectum, and an examination with an ordinary speculum brings it into view.

Treatment.—In *simple* ulcer empty the bowels with a saline cathartic, wash out the rectum with hot water, acted, introduce a speculum, touch the ulcer with silver nitrate (gr. xl to ʒj), place the patient in bed, and every day inject iodoform and olive oil or cod liver oil into the rectum. If this fails, give ether, stretch the sphincter to its entire thickness, and cauterize with fuming nitric acid. In case subsequently as we would a patient who has a *tuberculous* ulcer improve the general health, change the climate, or at least into the sunlight and fresh air, give nutritious food, especially fats, wash out

hot water, and insufflate iodoform or inject iodoform emulsion. Touch the ulcer once a week with silver nitrate (gr. x to $\bar{3}$ j). In *syphilitic* ulcer give antisyphilitic treatment and treat the ulcer locally as is done in tuberculous ulcer. *Dysenteric* ulcer requires injections of hot water, the touching of the ulcer with pure carbolic acid, insufflations of iodoform, and special treatment of the dysentery.

Benign Tumors of the Rectum and Anus.—These tumors may be of the connective, epithelial, or muscular tissue type. Of the first there are fibroma, enchondroma, lymphadenoma, lipoma, and myxoma, of the second, adenoma and papilloma; of the third, myoma and fibromyoma. These tumors usually appear in polypoid form. A polypus is a tumor with a pedicle. The most common forms of tumor are the myxoma, hypertrophied solitary follicles, adenoma, fibroma, and lipoma. Myxoma is most common in children. Fibroma originates in the connective tissue or the submucosa and is very rare.

Symptoms of tumor are dull aching pain, tenesmus, frequent defecation, and sometimes ulceration of the mucous membrane. The absence of hemorrhages and mucous discharges distinguish fibroma from polypus.

Treatment.—Remove the tumor after dilating the sphincter. In tying or snaring off polypi it should be borne in mind that the peritoneum may be invaginated in the pedicle and, therefore, no traction on it should be made when operating. Sessile growths are dissected out. The postoperative treatment is practically the same as for hemorrhoids.

Cryptitis (*Inflammation of the Crypts of Morgagni*).—These crypts, five to ten in number, are situated in the mucous membrane of the rectum about 3 centimeters from the anus. They occasionally become packed with mucus or feces. There is quite severe pain referred to the site, especially after defecation. In this condition the examination of the anus by the finger is extremely painful. The inflamed crypts may be detected by examination with the speculum.

Treatment.—Divide the affected crypts, curet away any granulations, and allow the parts to heal.

Non-cancerous stricture of the rectum may be congenital or acquired. There are two forms of acquired stricture: first, stricture due to external pressure; second, stricture due to primary narrowing of the rectal wall.* Stricture due to external pressure is very rarely complete, and may be caused by bands of adhesions or a cancerous growth. The second form may be produced by syphilitic tissue, ordinary inflammatory tissue, cicatrices after operations, sloughing, tuberculous, syphilitic, or dysenteric ulceration, rectal gonorrhea, and traumatism. The usual seat of simple stricture is from one inch to one and a half inches above the anus. The deposit may be limited to the submucous coat or all the coats may be involved. It is very seldom that stricture arises as a result of abrasion from fecal masses or foreign bodies. It may follow an operation for piles if considerable tissue is removed, and is an occasional sequence of Whitehead's operation. Stricture due to dysentery is extremely rare, and no case has ever been reported to the United States Pension Office (Peterson). The existence of stricture as a result of rectal gonorrhea has not been positively proved. A majority of sufferers from rectal stricture have labored under syphilis, but it is not

* Reuben Peterson, in Jour. Amer. Med. Assoc., Feb. 3, 1900.

probable that the lesion is syphilitic in all or a part of the cases. A rectal stricture may be due to the formation of fibrous tissue or may not occur. It may be caused by the formation of a large ulcer. Some maintain that tuberculous strictures dissent from this view and points out that the matter is to break down, and before the rectum is destroyed by tuberculosis it breaks down from ulceration. Petersen of the victims of rectal stricture die of phthisis. So-called syphilitic cases are tuberculous. It is an infiltration of submucous tissue. Although a tuberculous lesion may cause rectal stricture, in many cases it exposes the tissues to infection, and a benign rectal infection. Hence tuberculosis causes stricture, not directly.

The **symptoms** of rectal stricture are constipation at stool, the presence of blood and mucus in the stool, and the passage of stools flattened out into ribbons. In some cases there is fluid diarrhea, soft stools, and the stricture is found by the passage of a bougie, used with the utmost gentleness and care. Rough use of any instrument would be dangerous. In syphilitic cases, in tuberculous cases, and in cancerous cases, the lesion is usually in the submucous coat, and in syphilitic cases the mucous membrane is apt to ulcerate. It is a common mistake to suppose that a stricture may arise. I have seen obstructive symptoms, but no stricture, in rectal stricture. Distention of the abdomen is a common symptom.

The **treatment** of non-cancerous stricture is by warm-water injections, mild laxatives, and hot sitz-baths. Any existing disease is to be treated. Every other day. Use a soft-rubber bougie, warm it gently. If only the method of gradual dilatation must for the remainder of his life pass a bougie. In fibrous strictures forcible dilatation (*dilatation*) is employed or incision is practised. Incision may be external or internal. In internal proctotomy one makes an incision from the rectum through the stricture down to the perineum in the middle line posteriorly. External proctotomy is apt to leave incontinence as a legacy. Electrolysis, but on what grounds it is difficult to see. In some cases the stricture is removed. In incurable cases perform inguinal amputation.

Cancer of the rectum is the cancer of the rectum. It may be primarily malignant or may arise from benign growths. The most common growths are composed of cylindrical cells. In cases secondary to epithelioma of the anus or rectum the growth is usually of the squamous type.

In most rectal carcinomata the cells present a rounded or polygonal shape, surrounded by a more or less plentiful stroma of connective tissue. In some tumors the connective tissue is scanty; in hard tumors it is abundant.

Cancer is most common after the age of forty, but it is sometimes seen even in childhood.

* Reuben Peterson, in Jour. Amer. Med. Assoc.

year. Extensive ulceration occurs. If a hard ring encircles the rectum, the lumen of the tube is greatly and progressively diminished. In cases of diffuse infiltration the lumen is not greatly lessened. In growths of the anus the inguinal glands are involved and also the glands in the hollow of the sacrum. In growths of the rectum proper the glands back of the peritoneum in the sacral hollow are involved, and the inguinal glands are involved late or not at all.

Symptoms.—The symptoms of rectal cancer are like those of non-malignant stricture, except that the pain is usually greater, the hemorrhage more severe, and constipation is apt to alternate with diarrhea. The diarrhea is usually in the morning. Unfortunately, in many cases symptoms are long trivial; in fact, pain may be absent until the disease is far advanced. Mucopurulent or bloody stools are often thought to result from dysentery or hemorrhoids, which latter condition, however, may be only an accompanying condition of rectal cancer. Or the above symptoms may, on the patient's say-so, have been accepted by the physician as caused by hemorrhoids, without any local examination. The patient again may have only imagined the presence of hemorrhoids, since, according to his notion, the above symptoms must result from hemorrhoids, with which condition so many of his friends with like complaints are afflicted. Loss of strength, emaciation, and cachexia are generally noticeable only in the late stages of rectal cancer. Only in the very latest stages the characteristic odor is perceptible, the patient becomes septic, and abscesses attended by gangrene may form (Ernest Jonas, in "Interstate Med. Jour.," No. 4, 1906). The finger and the speculum make the diagnosis. In rectal cancer metastasis occurs late. The most favorable cases for operation are those in which the growth is small and movable. Accurately define the extent of the growth, and endeavor to make out if it has invaded the cellular tissue outside of the rectum, the prostate, the bladder, the sacrum, the uterus, etc.

Treatment.—In every case of cancer of the rectum the following question must be considered: Shall we perform a radical operation in hope of producing cure or at least greatly prolonging life? In what cases should a radical operation be attempted? It is the proper procedure if there are no metastatic deposits, if the patient is in fair general condition and free from serious organic disease, and if the cancerous bowel is movable and not fixed by dissemination to adjacent structures. As W. Watson Cheyne says ("Brit. Med. Jour.," June 13, 1903), a slight adhesion to the vagina is not a contraindication because this portion of the vagina can be readily removed with the diseased rectum. Some surgeons will not attempt radical operation if they cannot pass a finger through the growth. I do not regard high position as forbidding operation, although, of course, it makes it more dangerous to life and less promising as to cure. Cheyne is of the same opinion. When the surgeon is first called to a case of cancer of the rectum it is usually found to be so far advanced as to be inoperable. In at least 75 per cent. of my cases radical extirpation was impossible when I first saw the case.

If a radical operation is determined on, the next question to answer is, Shall we, or shall we not, do a *preliminary colostomy*? If the cancer is very low down and is to be removed from the perineum, preliminary colostomy should not be done. If the cancer is high up and we propose to attack it by Weir's method, or the Quenu-Mayo method, preliminary colostomy should not be done. If Kraske's operation is to be performed, I believe preliminary colostomy is indicated. It enables us to cleanse the area upon

which operation is to be performed, and to keep the wound clean, and gives us a much better chance of obtaining primary union. In cases in which the sphincter is retained and it is possible to anastomose the divided ends of the rectum together, colostomy is not necessary; and if an artificial anus has been made in such a case, another operation will be required to close it. As a matter of fact, I have found it always difficult and usually impossible to suture the divided ends of the gut together after Kraske's operation, and I now follow the advice of Keen, and always precede it by a colostomy. If radical operation is rejected (and about three-fourths of the cases, when first seen by the surgeon, are beyond

Fig. 695.—Tying off the tumor through an abdominal incision after separating peritoneum from sacrum and bladder (Weir).

Fig. 696.—Lower end of rectum everted through the anus and the upper end of bowel drawn out of the abdominal cavity (Weir).

Fig. 697.—*a*, The upper bowel drawn out through the everted lower end of rectum, *b*, the ends of the two portions of the rectum sewn together (Weir).

such aid), palliative treatment is desirable. One plan is to introduce a tube through the stricture daily, wash out the rectum with warm water, and after washing inject emulsion of iodoform (gr. x to $\bar{3}$ j) of sweet oil. Injections of chlorid of zinc (gr. j to $\bar{3}$ j of water) lessen the foulness of the discharge. The bowels are opened regularly by laxatives, and if the growth causes obstructive symptoms, it is scraped away with a sharp spoon. Opium is given to relieve pain. The advantage of this plan is that the patient does not suffer from the unpleasantness of an artificial anus. Sooner or later, how-

ever, the growth gets outside of the bowel, and terrible pain will arise from involvement of the sacral plexus. W. Watson-Cheyne ("Brit. Med. Jour.," June 13, 1903) would restrict palliative treatment of this character to cases in which fungating masses grow from one side of the bowel.

If a growth encircles the bowel and produces symptoms of obstruction, *palliative colostomy* should be performed. This operation gives great comfort to the patient, and allays pain by intercepting the feces before they reach the cancer. I am not convinced that it distinctly retards the growth of the cancer or notably prolongs life. Unfortunately, colostomy does not do away with pain if the sacral plexus is involved. I have had no experience with radium in inoperable cancer of the rectum and have never seen the x-rays produce any marked or lasting improvement. *Operative treatment* includes one of several procedures. Excision of the rectum from below (*Cripps's operation*) is practised if not more than three inches require removal, if the peritoneum is not invaded, and if the adjacent organs are free from disease. The peritoneum must not be opened in Cripps's operation. After the growth is removed the divided rectum is pulled down and sutured to the skin. Excision of the rectum after excising the coccyx and a portion of the sacrum (*Kraske's operation*, Fig. 699) is a procedure which permits removal of the entire tube, portions of the colon, and even of adjacent parts. The peritoneum is opened deliberately in this operation, and is subsequently closed with sutures before the gut is opened. The glands from the mesocolon are always removed. The lower end of the upper segment of bowel is fastened in the wound, or, if colostomy has been previously performed, may be closed. In some few cases in which it is not necessary to remove the lower end of the rectum, the two portions may be anastomosed after resection of a part of the tube. Kraske's operation may be done by an osteoplastic method, the bone not being removed. It is well to precede a Kraske operation two weeks by an inguinal colostomy, which permits of cleansing the lower bowel of feces and lessens the chance of severe wound-infection and delayed healing after the removal of the rectum. A preliminary colostomy may make the operation of extirpation more difficult by fixing the intestine, and thus interfering with the necessary drawing down of the gut (E. H. Taylor). If the growth is extensive and the mesocolon short, it may be best to perform

a right inguinal colostomy; but in most cases left inguinal colostomy is preferred (Gerster). The colostomy remains open during the patient's life,

Fig. 699.—Different levels of resection of the sacrum: K, O, Kocher's line; B, O, Kraske's; B, H, Hochberg's; B, D, Bardenheuer's; R, S, Rose's (Mass.)

except in those rare cases of Kraske's operation if the rectum can be reestablished after excision of the artificial anus may be closed some time after the operation.

Robt. F. Weir ("Med. News," July 27, 1901) with the difficulties and dangers of Kraske's operation for carcinoma that he now employs it solely in cases from disease for two inches immediately above the cancer does not extend more than five inches. In these cases he does the following operation: Open the abdomen, separate the peritoneum so that the bowel and bladder are liberated behind nearly "to the tip of the coccyx of the prostate." The tumor is then tied off. The portion of the rectum bearing the tumor is removed. The bowel is everted through the anus, and the upper end is brought out through an abdominal incision, Fig. 696). The upper end is then drawn through the everted lower end of the rectum, and the ends of the two everted portions (Fig. 697, b) are sutured together. The bowel is replaced, the divided peritoneum is sutured, and posterior drainage is inserted (Fig. 698). In this operation the object is to remove all of the diseased tissue. (W. J. Mayo in "St. Paul Med. Jour.," April, 1906; of American Proctologic Soc., June, 1906.) The patient is placed in the Trendelenburg position and the belly is opened. The growth is studied to see if it is removable, and the glands which might cause us, and for secondary growths to abandon the operation. If we conclude to attempt the operation, we catch the intestine except the sigmoid, catch two clamps on the level of the sacral promontory. Free the mesosigmoid by lateral cuts and bring it out of the belly, ligate it, and apply a purse-string suture to it. Then made on the left side and the proximal stump is sutured there. Incisions are now made in the side of the rectum, the inferior mesenteric artery is tied above the promontory, the fat and glands are thoroughly removed, the vessels being tied as cut, except the middle sacral vessels, which are tied before division. The abdomen is closed and the patient is put in the lithotomy position. The rectum is packed with gauze, the anus is sutured, and the rectum is closed. The urethra or from the vagina from below upward is closed. An assistant presses the fragment of the rectum into the abdomen and the surgeon removes it from the perineum. The perineal wound is closed. The wound in the belly is closed. In twenty-four hours the sigmoid is opened and an artificial anus is thus made.

The mortality of Kraske's operation is from eight per cent. of Kocher's cases of extirpation of the rectum well from three to sixteen years after operation ("St. Paul Med. Jour.," June 13, 1903).

XXIX. ANESTHESIA AND ANESTHETICS.

Anesthesia is a condition of insensibility or loss of feeling artificially produced. An **anesthetic** is an agent which produces insensibility or loss of feeling. Anesthetics are divided into—(1) *general anesthetics*, as amylene, chloroform, chlorid of ethyl, ether, bromid of ethyl, nitrous oxid, and bichlorid of methylene; (2) *local anesthetics*, as alcohol, bisulphid of carbon, carbolic acid, ether spray, cocain, eucain, stovain, ice and salt, rhigolene spray, and ethyl chlorid spray.

Anesthesia may be induced by a general anesthetic to abolish the usual pain of labor and of surgical procedures; to produce muscular relaxation in tetanus, hernie, dislocations, and fractures; and to aid in diagnosing abdominal tumors, joint-diseases, fractures, and malingering.

Death-rate from Anesthetic Agents.—Hewitt combines the statistics of Julliard and Ormsby, with the following result ("Anesthetics and Their Administration"):

ANESTHETIC.	TOTAL NUMBER OF ADMINISTRATIONS.	TOTAL NUMBER OF DEATHS.	DEATH-RATE.
Chloroform	676,767	214	1 in 3162
Ether	407,553	25	1 in 16,302

Hewitt finds that during the last forty years only thirty fatalities are recorded as produced by nitrous oxid, and he thinks several of these should be excluded. It is practically certain, however, that many deaths, or at least some deaths, have not been recorded.

Seitz collected 16,000 instances of anesthesia by chlorid of ethyl, with one death. I have seen anesthetics (particularly ether) given many thousand times. For five years I gave ether and chloroform for Prof. Keen. I have witnessed three deaths that at the time were thought to be directly due to anesthetics, and two of them were so caused. One death resulted from pouring a quantity of chloroform upon an Allis inhaler, the bandage of which was saturated with ether. At the time the chloroform was poured in the inhaler the patient had just been struggling and consequently was breathing deeply. One death resulted from giving ether on a thick cone made of several towels with paper between the folds. The towels were saturated with ether, the patient got no air at all, and was asphyxiated, as she might have been had the cone only been wet with water. The third case was a man who had an impacted hip fracture. He became cyanotic under ether and died. The death was supposed to be due to ether, but necropsy discovered fat emboli in the brain and lungs.

Preparation of the Patient.—Whenever possible, prepare a patient before administering a general anesthetic and prepare him, if the case admits of it, during two or more days. Heart disease is not a positive contraindication to surgical anesthesia. It is quite true that anesthetics are dangerous to people with fatty hearts, but shock is also dangerous, and the surgeon stands between the Scylla of anesthesia and the Charybdis of shock. Gallant truly says that not enough attention is paid to the "character of the pulse

and action of the heart before operation, by which anesthesia, and after the operation is over, and the necessary stimulation and overdriving a heart which has been depressed. Always examine the urine if the nature of the case is found, operation is not contraindicated; but if albumin is found, and certain dangers are to be watched. If much albumin is present, postpone operation. If sugar is found, the danger is considerable, as it develops. The percentage of sugar does not determine. Coma may arise when only a little sugar is present if there is a considerable amount. The presence of albumin is more ominous than is the presence of sugar. Empty the stomach by purgation a number of hours before anesthetization, six to twelve hours' rest before operation. The use of a cathartic the evening before operation and an enema the morning before operation. Frequently the nature of the case does not permit of preliminary emptying of the intestines by cathartics. During the twenty-four hours preceding operation food should be taken in small amounts and in forms easily digested, or so before operation there is usually impaired digestion. Food should be put upon the stomach. In the morning before operation is to be performed at an early hour, but not later than 10 o'clock. Give a little brandy and beef tea. If the operation is to be performed give a breakfast of beef tea and toast or a little food within three hours of the operation, but brandy is not required. If the stomach is not empty at the time of operation, it is most inevitable, and portions of food may enter the stomach. If the stomach contains no food, vomiting is far less likely to happen. If vomited matter should enter the windpipe, it may cause asphyxia chiefly of liquid mucus. In cases of intestinal obstruction, if there has been stercoraceous vomiting there is much danger during anesthetization. In some cases of intestinal obstruction, after administration of the anesthetic, and during the anesthetization, brown fluid may flow without effort from the mouth. If the expectoration of stercoraceous material is profuse, sudden death may follow. It may flood the bronchial tubes during inspiration and expiration. In a case in which stercoraceous vomiting has occurred before administering the anesthetic. If a patient is too weak to permit lavage, a local anesthetic may be used instead of a general anesthetic. Vomiting while the patient is under an anesthetic is dangerous in any case, because of the asphyxia which precedes and follows it. If a patient survives an operation, he will probably take the anesthetic poorly. Effort should be made to obtain a reflex vomit. An expedient is a hot ammonia bath, followed by a reflex vomit. It may be necessary to administer trional or bromal before giving the anesthetic let the patient drink

* Medical Record, February 2, 1899.

† A. Ernest Gallant, Med. Record, Dec.

material protects the stomach from the irritant effects of any anesthetic which may be swallowed. Before giving the anesthetic see that artificial teeth are removed and that the patient does not have a piece of candy or a chew of tobacco in the mouth. Always have a third party present as a witness, because in an anesthetic sleep vivid dreams often occur, and erotic dreams in women may lead to damaging accusations against the surgeon. Place the patient recumbent. The effort should be to place him in as comfortable a position as possible if this position is consistent with operative necessities. Put a small pillow under him, so as to support the normal lumbar curve and prevent postoperative backache (page 1201). See that the clothing is loose, particularly that there is no constriction about the neck and abdomen. Do not have the head high unless this position is demanded by the exigencies of the operation. The anesthetist must have a mouth-gag and a pair of tongue forceps. It is very wrong to say that a mouth-gag and tongue forceps are never necessary. It is quite true they are often used when not needed, but this does not justify us in being without them when they are needed, and they may be needed very badly. The anesthetist should also have a pair of artery forceps and some small gauze sponges to swab out the mouth and throat. A hypodermatic needle in working order, and solutions of strychnin, atropin, and brandy are to be in a readily accessible place, oxygen must be ready for administration, and it is well to have an electric battery at hand. Accidents, it is true, are rare, but they may happen at any time, and hence the surgeon should always be prepared for them. Any danger which arises must be met with promptness and decision, or action will be of no avail. Many surgeons give a hypodermatic injection of morphin a short time before operation, to steady the heart, to prevent vomiting during anesthetization, to shorten the stage of excitement, to prevent rigidity, and to aid the bringing about of insensibility with very little of the anesthetic. This method has been tried by many during the last forty odd years. It is used in drunkards (as their muscles tend to remain rigid), in those whom it is difficult to make completely unconscious, in neurotic individuals, and in badly frightened subjects. Its greatest use is in operations about the mouth and face, for in these procedures an anesthetic is usually given intermittently and a preliminary dose of morphin keeps the patients from rousing during the intervals. There are, however, objections to morphin before anesthesia, and its use should be the exception and not the rule. It should not be used in children, in cases of stupor, or in cases in which the respiratory center is disordered. It depresses the respiration, lowers temperature, and thus perhaps increases operative shock, interferes with the pupillary phenomena of anesthesia, delays awakening from the anesthetic sleep, adds to subsequent abdominal distention and headache, and actually favors post-anesthetic vomiting. Hewitt ("Anesthetics and Their Administration") says that several recorded fatalities were due to the combination. If the surgeon determines to give morphin, he gives gr. $\frac{1}{2}$ to $\frac{1}{4}$ twenty minutes before the anesthetist begins to give the anesthetic. Hewitt (Ibid.) says: "The anesthetic should be given until the usual signs of anesthesia commence to appear. It should then be discontinued for a few moments and only reapplied as occasion may require. As little as possible of the ether or chloroform should be subsequently administered; the conjunctival reflex should be retained." In the clinic of the Jefferson Hospital the elder Gross long used as a routine the preliminary

embarrassment to an experienced surgeon. In goiter operations ether will decidedly enlarge the veins. In fact, most goiters should be removed with the aid of local anesthesia only. Chloroform is particularly dangerous when there is myocardial disease, and is apt to produce cyanosis and embarrassed respiration. In valvular heart disease chloroform is more dangerous than ether, and even in functional heart trouble it is an undesirable anesthetic. It should not be used in those who smoke or chew tobacco to excess, or who overindulge in coffee or alcohol. Chloroform is more dangerous in shock than ether. A patient in dangerous shock requiring operation should, if possible, have the nerves coming from the part injected with cocaine so as to prevent further shock by introducing a "physiological block"—Crile (page 262). Chloroform is preferred for patients with difficult respiration from any cause other than heart disease (emphysema, bronchitis, or pulmonary tuberculosis), and for patients with kidney disease. I am convinced that etherization is sometimes responsible for a latent area of pulmonary tuberculosis becoming active. Some surgeons do not use ether in abdominal operations because they believe it may cause persistent nozing of blood, but this view is not in accord with the author's experience. Ether is the best and safest anesthetic for general use. It is much safer than chloroform in valvular disease and functional heart trouble. It is dangerous in myocardial disease, but not nearly so dangerous as chloroform. In valvular disease without heightened arterial tension it is reasonably safe, but in valvular disease with heightened arterial tension it is dangerous. Ether is dangerous when atheroma exists. Both ether and chloroform may induce changes in the blood.* In practically all cases they produce a diminution of hemoglobin and leukocytosis. In some cases they produce alteration in the shape of the corpuscles. These changes are especially marked in anemic blood. Ether produces distinct leukocytosis, probably toxic in origin. These blood-changes indicate that prolonged anesthesia may militate against recovery from a severe operation. If a patient's hemoglobin is below 30 per cent., a general anesthetic should not be given. During the state of anesthesia the temperature drops from one to three degrees or more, hence the patient should be carefully covered during the operation. The question as to the effect of ether on the kidneys is much disputed. Most surgeons believe that it tends to cause albuminuria or increase existing albuminuria. Nitrous oxid is very dangerous when there is vascular degeneration, and it may induce apoplexy. It is also dangerous if the air-passages are narrowed as by a goiter. In giving ether or chloroform the administrator must devote his undivided attention to the task. He must note every symptom, must order or carry out proper treatment for complications, and must keep the operator informed as to the necessity for haste. The anesthetist must be a man who has a wholesome respect for ether and chloroform, although not afraid of them.

Can an anesthetic be administered to a sleeping person without waking him? I know that chloroform can be so given, for I have succeeded in giving it to a child without breaking the slumber. Probably, in most cases, an attempt will fail, but in some it will succeed. Stone ("Cleveland Med. Jour.," Jan., 1902) reports successful administration to sleeping children

* See the author on the "Blood-alterations of Ether-anesthesia," *Medical News*, March 2, 1895, and also the author and Kalltayer in *The Proceedings of the American Surgical Assoc.* for 1901.

and also the chloroforming of a resident physician while asleep. Paugh ("Jour. Amer. Med. Assoc.," May 18, 1901) reports three successes with children. Ether, because of the irritant nature of its vapor, would be more apt to arouse a sleeper than would chloroform.

Administration of Chloroform.—Chloroform should be given only by a trained man. In fact, safety in giving chloroform is dependent upon skill and experience more than in giving ether. The most dangerous period is when the patient is incompletely anesthetized, but is going under. Most deaths happen at this time. In administering chloroform have at hand a mouth-gag, tongue forceps, artery forceps, small gauze sponges, a clean towel, a hypodermatic syringe, solutions of strychnin, atropin, and brandy, an electric battery, and a can of oxygen. Use only *pure* chloroform. The patient must be recumbent. No special inhaler is required, but the mask of Skinner is very useful (Fig. 701). Junker's inhaler is used by many anesthetists (Fig. 700). In operations about the face Souchon's instrument is serviceable. Souchon's apparatus is so arranged that chloroform may

Fig. 700.—Junker's inhaler.

Fig. 701.—Skinner's mask.

be given through a tube which is introduced through the nose, the instrument being well out of the way of the operator. Some surgeons cocaineize the nostrils before giving chloroform, so as to prevent the supposedly dangerous nasal reflex (Rosenberg). It is a good plan to smear the lips and face with vasoline to prevent blistering. The chloroform-vapor must be well mixed with air. The chloroform is sprinkled on the fabric with a drop-bottle. Raise the napkin well above the mouth, add five drops of chloroform, and tell the patient to take deep and regular breaths, but do not tell him to breathe forcibly. Forcible respiration may lead to cessation of respiration. Add a few more drops of chloroform, and when the patient grows so accustomed to it that it does not choke, turn the wet part of the fabric toward the face; place it near the mouth; do not touch the mouth with the wet lint, because it will blister. If the drug is given *gradually*, struggling is not usually violent or prolonged. Never pour on a large amount at one time. Keep the head pushed forward during the time the chloroform is being given. Coughing and vomiting at this time mean that the vapor is too strong. During this stage of excitement do not suspend the administration of chloroform until respiration becomes difficult, in which case suspend it until the patient is

one or two respirations. If the patient struggles, do not hold him and push the administration of the drug. He holds his breath while struggling, and as struggling ceases takes full, deep breaths. If the inhaler is saturated with chloroform, he may inhale a dangerous amount during the deep respiration after struggling. Chloroform given in considerable amount when the patient is breathing deeply from the effects of ether is unsafe. If chloroform is given subsequent to anesthetization by ether, it should be given gradually and well mixed with air. When the patient becomes anesthetized, give just enough of the drug to keep him so. After the patient has been anesthetized, hiccough usually means that vomiting is going to occur. If vomiting occurs at this time, more chloroform must be given to abolish the reflexes. Deep and sighing respiration and repeated swallowing indicate that more of the anesthetic is required. Stop the administration or give very little when shock becomes evident or when there is profuse hemorrhage. Chloroform-vapor is not inflammable, hence it is safer than ether when a hot iron is to be used about the face and when there is a lighted lamp or a stove in a small room; but the presence of a naked gas-flame decomposes chloroform into irritant products of chlorin, which sometimes cause the patient and the surgeon to cough (COCl_2).

Chloroform and Oxygen.—The use of this mixture was suggested by Neudorfer. Some anesthetists advocate the use of chloroform and oxygen, asserting that it does not produce spasm of the glottis or muscles of respiration, that it does not produce cyanosis or weakness of circulation, that it does not irritate the kidneys, is safer to life than pure chloroform, and is less often productive of severe and prolonged vomiting. These alleged advantages are probably stated with rather undue emphasis, although I do believe the mixture has less tendency to produce cyanosis than has the pure drug, does not so often induce vomiting, and is somewhat safer. Hewitt does not think that the method offers any "special advantages" ("Anesthetics and their Administration," by Fred. W. Hewitt). If this method is used, a bag containing oxygen is attached to the hand bellows attachment of a Junker inhaler, and oxygen is forced through the chloroform and flows to the face-piece.

Administration of Ether.—The administration should not be intrusted to a novice. The anesthetist should be one of your best men. Ether is best given by a partially open inhaler. The most satisfactory appliance is Allis's inhaler (Fig. 702). This inhaler secures a plentiful supply of air. Before being used, the metal frame is scalded, dried, and threaded with a clean gauze bandage. The end of the frame which is to be toward the mouth is covered with one layer of gauze. The frame is then inserted in a clean metal case and the case is wrapped in a clean towel. Probably the safest way to administer ether and the most comfortable for the patient, is to take a piece of gauze or an Esmarch inhaler and give the drug drop by drop, the drops following each other in regular sequence. This is

Fig 702.—Allis's ether-inhaler.

known as the *drop method*. Many surgeons prefer this inhaler is popular in England (Fig. 703). *F* is the ether through which the air-current passes; *B* is an In apparatus there is no provision for the entrance of fresh air. *C* on the tube *I* the amount of current passing is regulated. When this apparatus is used, the ether vapor expired into the bag and is rebreathed. This inhaler is very useful; but any lack of watchfulness or skill and the very young, the senile, the anemic, and the feeble by the Allis inhaler.

An admirable detailed account of anesthetics will be found in Mr. Frederic W. Hewitt's treatise "Administration" (page 272), and in Mr. Dudley "Anesthetics, their Uses and Administration" (page 10). Have at hand the same drugs and appliances as for ether and keep the lower jaw pushed forward during

Fig. 703. Clover's portable regulating ether

anesthetizing by Allis's inhaler, take every care to keep the patient's head back and the mouth open. If the ether vapor irritates the eyes and boracic acid solution should be used during the administration to flush out the conjunctiva. To grease the face and lips with cosmolin. Place the patient's mouth and nose, let the patient take several breaths, then pour a few drops of ether into the inhaler, let the patient take several breaths, and so on, gradually increasing the amount of ether. When the patient struggles, diminish the amount of ether for a time, but tell him to breathe forcibly. Forcible breathing is essential for respiration. Never suddenly add a large amount of ether, which causes coughing and often vomiting. When the patient becomes fully anesthetized, give a very little ether as often as is required to

When bleeding is profuse or shock is marked, suspend the administration of ether or give very little of it. If a hot iron is to be used about the face, remove the inhaler and fan away the ether before bringing the cautery near. Have any light set high up, as ether vapor is heavier than air, and no explosion is possible until it reaches the level of the flame. If the vapor takes fire, cover the patient's mouth and nose with a towel. If he rolls his eyes from side to side, if the respirations are deep and sighing, if there are repeated movements of swallowing, more anesthetic should be given (Tarnowsky). Hiccough is often preliminary to vomiting, and always means that the reflexes are returning.

The patient should be kept in a condition in which he feels no pain, makes no movement, and is not rigid. In this condition the cutaneous reflexes are abolished, the breathing is regular and quiet, the color is good and the pupils react to light, though slowly. Just enough anesthetic must be given to cause the patient to pass into this condition and remain in it. To give any more is to poison him. The amount necessary varies with the individual and the operation, and requires skill, experience, and attention on the part of the anesthetist.

The old idea that we must poison a man into dangerous coma has been abandoned. When the breathing becomes louder, more rapid, or spasmodic, it means that reflexes are returning and a little more anesthetic should be given.

Ether and Oxygen. This mixture is useful in certain cases in which respiratory difficulty exists, particularly in empyema. If during the administration of ether cyanosis tends to occur, it is often advantageous to give oxygen with the ether. The process of anesthetization by ether and oxygen is somewhat slower than by ether vapor mixed with air. It can be given by inserting beneath the Allis inhaler or pushing deep down into it, from above, a tube attached to a reservoir of oxygen and from which a stream of oxygen emerges.

Rectal Etherization. Pirogoff suggested this method in 1847 and Roux employed it the same year. The method is only used in operations about the face, tongue, nasopharynx, larynx, mouth, and larynx; in other words, in cases in which, were the ether given by inhalation, the operator and anesthetist would interfere with each other. The rectum should be emptied by a purgative enema the day before the operation, and again the morning of the operation, and a short time before giving the ether the rectum should be irrigated with warm salt solution. A dose of laudanum is given a few hours before. We should employ an apparatus of the type of Buxton's, which prevents liquid ether from passing into the rectum.

A tube containing ether is set in a vessel containing water at a temperature of 122° F. The ether tube is joined by a glass tube and rubber pipe to a glass globe, and the globe is connected by a rubber pipe to the tip, which is inserted into the rectum. If ether vapor condenses into liquid in the glass globe the globe should be at once emptied. During the administration abdominal distention occurs from unabsorbed ether, and from time to time the administration should be suspended temporarily to permit the gas to escape, otherwise too much will be given and prolonged stupor and postoperative colic may result. It takes much longer to obtain unconsciousness by rectal administration than by inhalation. The method must never be used if the intestines are irritated or inflamed (Dumont, in "Corr-Bl. f. Schweizer Aerzte," Dec. 15,

1908). The method has never come into general use, as it often produces colic, and sometimes is said to produce emphysema of the lungs. ("Anesthetics and Their Administration," by Fred Buxton, however, has employed it in many operations on the trachea and larynx, and in some operations for empyema, and etherization does not produce a sense of suffocation, and struggling is trivial or absent.

Anesthetic State from Ether or Chloroform

When an anesthetic produces irritation of the fauces, often with secretion of mucus, acts of swallowing, dilatation of the throat, and sometimes struggling (especially in children) as the vapor is given at once in concentrated form, coughing and cyanosis. If the anesthetic is given carefully, the respirations become rapid and often convulsive, and the patient passes into a condition of unconsciousness, but with preservation of sight and touch, loss of hearing, loss of pain and sensibility, and often with illusions of sight. In the early stage the patient may struggle, and while efforts are made to restrain him, cyanosis may occur. From the stage of unconsciousness many subjects (strong men and drunkards) pass into a stage in which the muscles become firmly fixed, the breathing is stertorous, and the face bluish and congested. If the anesthetic tends to cause rigidity, and a skilled operator to avoid its production, because it is dangerous to produce a state of insensibility; the pupils are contracted, but react to light. If the anesthesia is deep, the contracted pupils will not react to light. If the anesthesia is found, the pupils dilate, but will not react to light. If the anesthesia is gone; the lids are closed; if the arm is lifted and held up as a dead weight; the skin is cool and moist, and the respirations are easy and shallow, the pulse is slow and weak. Unconsciousness to pain. The loss of conjunctival reflex is an accepted sign that the patient is unconscious. If the patient is soon exhausted by touching the eye, and the sign is to be anesthetized, the administrator places his finger on the eye. The child grasps the finger, and relaxes its grasp when the finger is removed.

Always bear in mind that dilated pupils reacting to light with preserved conjunctival reflex mean that an anesthetic is not given; that contracted pupils reacting to light and without conjunctival reflex mean moderate anesthesia; that contracted pupils not reacting to light and without conjunctival reflex mean deep anesthesia; that dilated pupils reacting to light and associated with lost conjunctival reflex mean found anesthesia. The pupillary phenomena are valuable, but unfortunately they are absent at some stage of the anesthesia. Inequality of the pupils is not unusual and fixation of the pupils may occur. A preliminary dose of morphia interferes with the pupillary phenomena. Sudden dilatation with fixation is always valuable, and pallor may be due to nausea, but always requires attention. It may be due to forcing strong vapor upon the patient, or due to his partially emerging from a state of insensibility.

Watch the pulse carefully to see if it becomes very weak, irregular, abnormally slow, or abnormally fast. Syncope may be due to nausea, shock, hemorrhage, or the giving of too much of the drug. Watch the respiration, and do not forget that the chest-walls and belly may move when no air is entering the lungs, hence always *listen* to the breathing. Cyanosis is a dusky or bluish discoloration of the skin. This condition indicates want of oxygen in the blood. The individual may have been cyanotic or predisposed to cyanosis to start with; cyanosis may be due to pressure; to cough early in the administration; to struggling during the stage of excitement; to gathering of mucus in the respiratory tract; or to rigid fixation of the respiratory muscles. It may also be due to obstruction of the air-passages by some foreign matter, as blood or vomit, lodging in the bronchial tubes, windpipe, larynx, or pharynx; falling back of the tongue (*swallowing of the tongue*); closure of the epiglottis; or to the glottis being pushed against the pharyngeal wall by bending the head forward. Some patients with occluded nostrils may fail to get enough air because of closure of the lips. A patient may, while taking an anesthetic, lie perfectly quiet and appear to "forget to breathe." Ether and chloroform can certainly cause shock. Neither drug keeps nerves from conveying stimuli and each produces a fall of blood-pressure, chloroform directly by its action on the vasomotor center, ether by overstimulation of the vasomotor center (Buxton, in "Proceedings of the Royal Soc. of Med.," April, 1909). Each produces a fall of temperature. Buxton heartily condemns the once common belief "that evidences of shock during a surgical operation are a proof that an insufficient quantity of the anesthetic has been given and that the symptoms of shock can be abrogated by increasing the depth of the narcosis" (*Ibid.*). Shock is manifested by deathly pallor, weak, rapid, and irregular pulse, slow respiration, cold extremities, and a drenching sweat. Edema of the lungs occasionally arises during or after anesthesia.

Treatment of Complications.—*Vomiting* due to too much anesthetic is corrected by giving a few breaths of air; vomiting due to incomplete anesthesia is amended by giving more of the vapor. When the patient vomits, hold the head over the edge of the bed, separate the jaws with the gag, and wipe out the vomited matter, mucus, and saliva. *Shock* is treated by diminishing the amount of the anesthetic given, by the hypodermatic injection of atropin (atropin is very useful when there is a profuse sweat), by the administration of hot saline fluid by the rectum, by surrounding the patient with hot-water bottles, or by wrapping him in hot blankets, and by lowering the head of the bed. Syncope is sudden cerebral anemia usually due to a reflex cause. A tendency to *syncope* requires lowering of the head of the bed, suspension of the anesthetic, and hypodermatic injection of strychnin. In *extreme syncope*, which is most apt to occur from chloroform, do not wait for breathing to cease, but suspend the anesthetic, lower the head of the bed, open the mouth with the gag, catch the tongue, and make rhythmic traction while an assistant is making *slow* artificial respiration. If the patient does not *at once* improve, invert him completely, holding him by the legs and continuing artificial respiration by compressing the sternum (Nélaton). By continuing artificial respiration the blood is urged on through the heart. Give hypodermatic injections of atropin, ether, or even of ammonia. Put mustard over the heart and spine. Employ faradism to

the phrenic nerve (one pole to the epigastric region, the other to the right side of the root of the neck). Let fresh air into the room, put hot water bottles around the legs, apply friction to the extremities, wrap the patient in hot blankets, give an enema of hot salt solution, and hold ammonia to the nose. In some cases of chloroform poisoning *direct heart massage* has been successfully employed. In Sencert's successful case an operation was being done for gall-stones when collapse occurred, and the surgeon stroked and kneaded the heart through the diaphragm. In a case recorded in the "Brit. Med. Jour.," Nov. 18, 1905, respiration and pulse had ceased three minutes when the abdomen was opened and the heart was kneaded. Recovery ensued. Muller, of Hamburg, advocates exposing and opening the pericardium to perform massage, introducing oxygenated salt solution into a vein, opening the trachea, and performing artificial respiration. Leonard Hill holds that in the failure which arises soon after administration of chloroform is begun the trouble is due to vasomotor paralysis with starvation of the nerve-centers. In such a case he applies abdominal compression and inverts the patient, making artificial respiration at the same time. In the failure which occurs after *considerable chloroform has been taken* there are paralytic distention of the heart, fulness of the venous system, and loss of the compensations for the hydrostatic effects of gravity. In such a condition empty the distended heart of venous blood by raising the patient into an erect position; and after a moment place him recumbent and make artificial respiration.

"*Forgetting to breathe*" is met by removing the inhaler and waiting a moment; a breath will usually be taken soon; but if it is not taken, somewhat forcibly knead the structures in the arm pit. If this fails, open the mouth and pull forward the tongue; this causes a reflex inspiration. Cyanosis is practically not encountered when oxygen is given with ether or chloroform. Cyanosis, if slight, and due to cough or struggling, is met by removing the inhaler while the patient takes a breath or two of air. If position is responsible for cyanosis, correct it. In emphysema, lying upon the sound side may produce it, and obstruction to breathing may be due to bending down the head. If due to stenosis of the nares in a person without teeth, hold the lips apart with a finger. If due to collection of mucus, wipe the mucus out of the mouth by means of bits of gauze firmly clamped in forceps; raise the shoulders, extend the head and place it on its side in order that mucus may run out of the angle of the mouth; and give a dose of atropin. If the amount is large and the secretion persistent, it may be necessary, especially in children, to empty the respiratory passages by inverting the patient. In cases of excessive bronchial secretion we fear the development of pulmonary edema or postoperative bronchopneumonia.

Dudley W. Buxton points out that duskiness will often pass away if ether is removed, one or two inhalations of chloroform given, and ether then continued. If in any case cyanosis is severe or grows worse, suspend the drug, dash cold water in the face, force open the jaws, pull forward the tongue, make artificial respiration until a breath is taken, and then give oxygen for a time. If these means fail, stretch the sphincter ani and bleed from the external jugular vein. If a breath is not now taken, do tracheotomy. In respiratory or heart failure forced artificial respiration by Fell's

method is of great value (page 894). In Fell's method a tracheal tube is inserted, and by means of a foot-bellows air is forced into the lungs, after first passing through a warming chamber. Instead of a tracheal tube, we may use a face-mask and an intubation-tube. "*Swallowing the tongue*" is corrected by pulling the tongue forward. If it tends to recur, lay the head upon its side or keep the tongue anchored with forceps. *Closure of the epiglottis* is corrected by pulling the patient's head over the edge of the table and pushing strongly back upon his forehead. This maneuver lifts the hyoid bone, and with it the epiglottis. The epiglottis can be lifted by passing a spoon-handle or the index-finger over the dorsum to the base of the tongue and press-

Fig 704.—Artificial respiration, first movement.

ing forward. If, in obstruction to respiration, the above means fail, make artificial respiration at once; if obstruction continues, perform tracheotomy.

Edema of the lungs is treated by instant venesection, the inhalation of nitrite of amyl, and the administration of stimulants and nitroglycerin hypodermatically. Sometimes, during the anesthetic state, the muscles of the belly become very rigid, a condition which greatly interferes with an abdominal operation. It may arise during cyanosis, and if so caused, is amended, as cyanosis abates, under proper treatment. In some cases it is due to the fact that sufficient anesthetic has not been given. If the air-passages are

Fig 705.—Artificial respiration, second movement

obstructed, abdominal rigidity is apt to arise. In some cases it seems impossible to overcome it with ether. In such a case, if the anesthetist is a trusted man, anesthetize the patient with gas and ether and then give chloroform (Blumfield, in "*Lancet*," May 31, 1902).

Artificial Respiration.—Laborde's Method.—Place the patient on his back with the head lower than the body, all the clothing loosened, and the jaws wedged apart, and wipe the mucus from the throat and mouth. Grasp the tongue with forceps, and once in every four seconds pull it quickly

and strongly forward and then permit it to go back. It may be necessary to keep up this proceeding for thirty minutes or even more.

Laborde's method should be associated with "concentric thoracic and upward abdominal pressure applied in a rhythmic manner by two assistants at the time of relaxation of the tongue."* Laborde believes that tongue traction causes contractions of the diaphragm.

Sylvester's Method (Figs. 704, 705).—The patient is placed recumbent with the foot of the bed raised. The surgeon grasps the arms just above the elbows, and draws them outward and upward until they are nearly perpendicular (Fig. 704); they are held perpendicular for two seconds, while air is entering the lungs; the arms are then lowered and pressed against the sides of the chest (Fig. 705) for two seconds, during which time the chest is emptied as in expiration. These movements of elevation and depression are made twelve or fifteen times a minute.

The Reaction from Anesthesia.—When ether or chloroform is given, a considerable quantity is swallowed and either drug irritates the stomach and creates nausea and often vomiting. The longer the operation, the more of the anesthetic enters the stomach, and the greater the liability to subsequent vomiting. At the termination of a prolonged operation upon an adult, if the patient's condition admits of it, and if the nature of the operation does not forbid it, I like to have a stomach-tube passed and the stomach well washed out with warm water. The washings smell strongly of the anesthetic, and the procedure greatly lessens the severity and frequency of post-operative vomiting (Geo. S. Brown, in "Surgery, Gynecology, and Obstetrics," August, 1905). After the administration of the anesthetic has been suspended and the operation has been completed, the temperature is usually subnormal. The patient must be watched until consciousness returns. If he is left alone, a change of posture may lead to arrest of feeble respiration; the assumption of the erect position may cause fatal syncope, or mucus vomited matter may block the air-passages and cause suffocation. The best position to place him in is the recumbent, the head being level with the body or somewhat lower, and the side of the face resting on the pillow. Shock is treated by ordinary methods. The inhalation of oxygen is of great value in rousing a patient from the state of anesthesia, and will often prevent vomiting. If vomiting occurs, the head should be upon its side or should be held over the edge of the bed, and after the spell of vomiting the mouth must be kept clean. The face should be washed with cold water and be fanned rapidly and actively. It is the routine practice of some surgeons to administer vinegar by inhalation during the reaction from an anesthetic. This proceeding some times seems to prevent vomiting. Some patients awake from anesthesia from a quiet sleep; others are noisy, turbulent, and violent. The duration of the period of reaction varies with the anesthetic used, the amount given, and the personal tendencies of the patient. The patient must not be allowed to eat for several hours at least. No food is to be allowed for at least six hours. Unless the operation was upon the stomach, I do not forbid water, but allow the patient to drink freely of hot water. This dilutes any irritant material in the stomach and dissolves mucus, and if vomiting does occur it serves to wash the stomach out. All fat patients, all patients with respiratory difficulties,

* Joseph D. Bryant's "Operative Surgery."

whom we apprehend respiratory complications, should be placed in a sitting or, at least, a semi-erect posture as soon as reaction from anesthesia is obtained. If this plan is followed, ether-pneumonia and other respiratory troubles will very seldom develop.

After-effects of Anesthetics.—Vomiting.—Vomiting may occur in spite of all we can do, and may persist for hours, greatly exhausting the patient and doing infinite harm, it may be, if the operation were upon the brain or an intra-abdominal structure. If vomiting continues, forbid food. Very hot water in doses of a teaspoonful should be given at frequent intervals. A draught of hot water may relieve the condition by washing out the mucus from the stomach. Other remedies which may succeed are: inhalations of vinegar, hot black coffee by the mouth, a mustard plaster over the stomach, fresh air in the room, small pieces of ice placed in the mouth and sucked, small doses of iced champagne, and drop doses of a 3 per cent. solution of cocaine or 3-drop doses of a 5 per cent. solution of eucain. The best remedy for persistent vomiting is lavage of the stomach. Some persons, as Dudley W. Buxton points out, suffer greatly from nausea, although there is little or no vomiting. In such cases Buxton uses $\text{m}j$ of tincture of *nux vomica* in a teaspoonful of hot water every ten minutes until six doses are taken. If this plan fails, he gives drop doses of wine of ipecac or minim doses of dilute hydrocyanic acid.*

Vomiting from chloroform is usually more difficult to check than vomiting from ether.

Backache.—This is a very common and often a very distressing consequence of anesthesia. It is often complained of soon after consciousness is regained, it may persist for several days, and it is a not uncommon cause of wakefulness. It is usually greatly aggravated by turning and twisting, and by attempting to rise up. The pain is located in the lumbar and sacral regions and is often accompanied by rigidity of the lumbar muscles. Various explanations have been given of it. One view is that it is due to renal congestion. Another, that it results from congestion of the spinal cord. I believe that the real explanation is that of John Dunlop ("N. Y. Med. Jour.," July 10, 1909), viz.: "The patient during the operation lay upon a flat table without support of the lumbar curve, consequently the sacro-iliac synchondroses were strained. The backache may be largely prevented by placing a small pillow so that it will support the lumbar curve during anesthesia."

Respiratory disorders are more often noted after ether than after chloroform. Bronchitis may follow or bronchopneumonia (*ether-pneumonia*). Respiratory difficulties may be due to chilling the patient by bringing him from a warm operating room through a cold hall and into a cool bedroom. Bronchopneumonia is especially common in septic patients, and may be due in some cases to septic emboli and in others to aspiration of septic material from the bronchi (cases of cancer of tongue and pharynx, and cases with stereotyped vomiting). They are treated by ordinary methods. If chloroform is given when a gas light is in the room, the vapor is decomposed and certain highly irritant products are formed, which, when inhaled, cause laryngeal spasm and possibly bronchitis. The irritant material is probably COCl_2 . The treatment is freely to admit fresh air into the room and to have the patient inhale oxygen or vinegar. Ether-pneumonia

* "Anesthetics," by Dudley W. Buxton.

must not be confounded with postoperative pneumonia, described by Wm. H. Bennett*. This latter condition may arise from seven to fourteen days after operation in robust, gouty people, and is usually unilateral. If the patient is placed in a sitting position, or at least, semi-erect in bed, as soon as he reacts from the anesthetic the danger of serious respiratory disorder will be at a minimum.

Renal Complications.—After the administration of an anesthetic, blood, albumin, or sugar may appear in the urine, and the secretion may become scanty or even be suppressed. It is usually maintained that chloroform is less apt to irritate the kidney epithelium than is ether, but there has been much dispute on this point. If casts and albumin are present before anesthetization, the condition may be rendered worse when ether or chloroform is given. If neither casts nor albumin are present, they will not be so apt to appear after taking chloroform as after taking ether, but if they do appear after chloroform, they remain longer than after ether (Legram). The truth of the matter probably is that if the kidneys are healthy, a small or moderate amount of either drug is not particularly irritant; but if the kidneys are diseased, a small amount, and even if they are healthy, a large amount, of either drug produces decided renal irritation. Chloroform is less irritant because less chloroform than ether is given to secure and maintain anesthesia. Scantiness or suppression of urine may be due to operative shock rather than to ether or chloroform. If the urine becomes somewhat scanty or if albumin appears in it, give non-irritant diuretics, diaphoretics, and cathartics, and employ enteroclysis. If the urine becomes very scanty, use hypodermoclysis. If post-operative suppression arises, it is the usual custom to give intravenous infusion of hot saline fluid, but I am doubtful of its value. Exposure of each kidney in the loin and incision of its capsule to relieve tension is justifiable and may do good.

Acid Intoxication.—This condition has been called "*delayed poisoning*," *acetonuria*, and *acidosis*. It is known that even in healthy urine there may be a trace, but a bare trace, of acetone. In certain cases in which dangerous symptoms arise after anesthesia, the urine contains albumin, casts, and either diacetic acid or acetone or both of these substances. Acid intoxication is very much commoner after the administration of chloroform than of ether, but may follow the giving of any general anesthetic. It may occur in individuals whose tissues contain areas of fatty degeneration, but it also occurs in those entirely free from degeneration; in fact, children particularly suffer in this way after the use of chloroform. The actual operation has nothing to do with the trouble, and sepsis is not causative. The drug used as an anesthetic causes acute fatty degeneration of the liver, quantities of toxins are formed and these toxins cause the symptoms. Acetone, diacetic acid, and beta-oxylutonic acid are by-products of the process and are antecedents or precursors of acetone. The symptoms arise after the patient has emerged from anesthesia and reacted from shock. There is persistent vomiting of thin and foul fluid, the patient is extremely restless and much excited, there may be delirium, but dullness and heaviness may take the place of restlessness and excitement and coma may arise (J. A. Kelly, in "*Annals of Surg.*," Feb., 1905). Usually the temperature is subnormal, but sometimes there is elevated temperature. In many cases jaundice arises. There is an odor of acetone on the breath. The urine con-

tains albumin and casts, and either diacetic acid or acetone or both. Some cases recover, but most of them die in from one to five days. A knowledge of this condition explains some otherwise inexplicable deaths, and also some cases of retarded convalescence. In acid intoxication there is fatty degeneration of the kidneys, of the liver, of the suprarenal glands, and of the gastric mucosa. The occurrence of such a condition is an impressive admonition that a surgeon should operate quickly, that as little of the anesthetic should be given as possible, that the urine should be carefully examined each day after operation for certainly several days, and that chloroform should not be used for prolonged administration. Severe acid intoxication is treated as follows: Encourage skin activity by wrapping the patient in blankets and surrounding him with hot-water bags. Give salt solution with bicarbonate of sodium by hypodermoclysis and by the rectum. In mild cases of acetonuria simply give sodium bicarbonate by the stomach. Bevan and Farill ("Jour. Am. Med. Assoc.," Sept. 20, 1905) reported one case and collected 27 from literature. In this series there were 2 recoveries. (On this subject see Lewis Beesly, in "Brit. Med. Jour.," May 19, 1906; J. A. Kelly, in "Annals of Surgery," Feb., 1905; A. D. Bevan and H. B. Farill, in "Jour. Am. Med. Assoc.," Sept. 20, 1905; Geo. E. Brewer, in "Transactions Am. Surg. Assoc.," vol. xx, 1902.)

Postanesthetic Paralysis or Narcosis Palsy.—Paralysis may arise during anesthesia as a result of cerebral hemorrhage or embolism.

It sometimes happens that when a person has come out of anesthesia a palsy of some part is found to exist, the condition being peripheral and not central in origin. Peripheral narcosis palsies are pressure palsies, although it is held by some that the anesthetic has a toxic influence which distinctly lowers the capacity of the nerves to sustain pressure. Certain it is that palsy sometimes follows what seems a degree of pressure inadequate to cause such a result. Narcosis palsies may be due to pressure of an extremity upon a table-edge or to pressure upon nerves by placing the patient in certain positions.* When the Trendelenburg position has been employed, the flexures of the knees are in contact with the edge of the table, and paralysis of one or both external popliteal nerves may be induced. When the patient lies upon the side any nerve of the arm or forearm may suffer, but the circumflex and radial are most liable. When the arm is elevated to the side of the head or when it is drawn out strongly from the body the brachial plexus may be compressed by the head of the humerus (Braun, in "Deutsche Med. Woch.," 1894). When the arm is in external rotation and is drawn backward and outward, the median nerve is stretched, and when the forearm is flexed and supinated, the ulnar nerve is stretched (Braun, *Ibid.*). In most cases the paralysis involves muscles supplied by the brachial plexuses and is due to drawing the arm upward and backward over the head, a position which may squeeze the cords of the plexus between the collar-bone and the first rib. Garrigues shows that the plexus is particularly apt to be squeezed when it is stretched by the head being drawn to the opposite side or being allowed to fall back † According to Budinger the mounting up of the clavicle squeezes the plexus as its cords cross the first rib. This surgeon thinks that extreme abduction of the arm may squeeze the cords.

* H. J. Garrigues, in *Amer. Jour. Med. Sciences*, Jan., 1897.

† *Amer. Jour. Med. Sciences*, Jan., 1897.

Postanesthetic paralysis is most common in the arm, but may occur in the leg or face. The prognosis is good as a rule. Slight cases are recovered from; more serious cases, in which degeneration occurs, may not be recovered from for months. The treatment is that of any pressure palsy.

Primary Anesthesia.—Instruct the patient to count aloud and hold one arm above his head. Give the ether rapidly. In a short time he becomes mixed in his count and his arm sways or drops to the side. There is now a period of insensibility to pain lasting only about half a minute, and during this period a minor operation can be performed. The patient quickly reacts from primary anesthesia without vomiting (Packard).

Mixtures.—Mixture of Ether and Chloroform.—This may be used in varying proportions. Hewitt employs 2 parts of chloroform to 3 parts of ether.

Mixture of Alcohol and Chloroform.—All the chloroform mixtures produce the effects of chloroform, but we are giving the drug in an unknown amount. It was believed by Sansom, who devised this mixture, that the alcohol prevents concentration of chloroform-vapor by retarding evaporation. When used, 1 part of alcohol is added to 4 parts of chloroform.

Nitrous Oxid and Oxygen.—(See page 1206.)

A. C. E. Mixture.—This mixture is often valuable in cases in which ether cannot be given. It is composed of 1 part of alcohol, 2 parts of chloroform, and 3 parts of ether. Its action is supposed to be between that of chloroform and ether. The objection to the A. C. E. mixture, as to a mixture, is that the materials do not evaporate in the ratio in which they are mixed, hence an uncertain amount of chloroform-vapor is being inhaled (Buxton). This mixture is given by some in a Junker and by others in an open inhaler. Plenty of air should be given with it. The anesthetic acts similarly to chloroform.

Schleich's Mixture for General Anesthesia.—Schleich has recently introduced a new anesthetic agent which he claims is safer than chloroform. This surgeon maintains that a material is safe as an anesthetic only when almost all of the amount taken in at an inspiration is expelled on expiration. The anesthetic is unsafe in direct proportion to the amount absorbed, and the lower the boiling-point of an anesthetic, the less is absorbed, hence an anesthetic agent, to be safe, should have a low boiling-point. Schleich makes three solutions. The first contains (by volume) $1\frac{1}{2}$ oz. of chloroform, $\frac{1}{2}$ oz. of petroleum ether, and 6 oz. of sulphuric ether. The second contains $1\frac{1}{2}$ oz. of chloroform, $\frac{1}{2}$ oz. of petroleum ether, and 5 oz. of sulphuric ether. The third contains 1 oz. of chloroform, $\frac{1}{2}$ oz. of petroleum ether, and 2 oz. of sulphuric ether. The anesthetic can be given on an open inhaler or a towel. The anesthetic state is quiet, reaction is rapid, and vomiting occurs in but half the cases. The superiority of this new anesthetic has not been proved. It sometimes causes dangerous symptoms, and has produced death. Some surgeons who formerly approved of it, have abandoned it. It will certainly not displace ether or chloroform. Petroleum ether has no anesthetic power and Meltzer shows that it is dangerous and tends to paralyze the respiratory muscles. Willy Meyer ("Med. Record," August 15, 1908) believes in the Schleich principle, but substitutes ethyl chlorid with a boiling point of 59° F for the petroleum ether. He uses 17 per cent volume of ethyl chlorid with 83 per cent. volume of the molecular mixture of ether and chloroform.

Ethyl bromid is sometimes used for short operations. It is given while the patient is recumbent. The unconsciousness is obtained in from one to three minutes and is rapidly recovered from, and there is no after sickness. The unconsciousness lasts about three minutes. Three drams are given to a child, and six drams to an adult. A towel is put over the face, and the entire amount to be given is poured on at once, and as soon as the patient is unconscious the towel is taken away and no more of the drug is given (Cumston). Even if consciousness is regained too quickly to suit the purposes of the surgeon, it is not safe to give more of the drug, a notable objection which chlorid of ethyl does not possess. Cases have been reported in which sudden death has followed the administration of this drug, and it should not be given if there is disease of the heart, lungs, or kidneys.* Twenty-four deaths from bromid of ethyl are on record (Gaudiana). If it kills, it acts like chloroform. It may be given *before* ether to prevent unpleasant effects, but it is usually not considered proper to give it before chloroform. Zematski, however, has used it before chloroform in 2000 cases ("Vratch," August 25, 1901). There were recently two deaths from it in Philadelphia, neither of which was published. I never use it and regard it as unsafe.

Chlorid of ethyl is a rapid anesthetic and statistics imply that it is a safe one. My faith in it has been greatly shaken by knowledge of three unpublished deaths in Philadelphia. It was first used by Heyfelder in 1848. A committee of the British Medical Association condemned it in 1880. Carlson and Thiesing reintroduced it in 1895 (McCardie, in "Lancet," April 4, 1903). It may be sprayed upon a mask covered by six to eight layers of gauze, so that the drug does not evaporate too quickly in the air. Many anesthetists give it in a closed apparatus, the patient respiring into and from a rubber bag. The odor of the drug is agreeable. From 5 to 10 gm. of ethyl chlorid are given for a short operation if the mask is used. The patient must always be recumbent when taking it. The anesthetic state is induced, when the mask is used, in from two to three minutes, and as soon as it is obtained the patient is allowed to get air. If the closed inhaler is used unconsciousness is obtained more rapidly. The anesthetic condition lasts from one to three minutes, and it is recovered from rapidly, usually without vomiting or unpleasant after-effects. If the patient recovers too rapidly for the surgeon's purpose, more ethyl chlorid can be given. It is to be noted that complete muscular relaxation does not occur, in many cases the conjunctival reflex is not completely abolished, and often the pupils do not dilate. It has no superiority over nitrous oxid, except as to cost and portability, and sometimes it fails to produce complete unconsciousness. A large dose rapidly given is dangerous, as it may cause cessation of respiration and spasm of the diaphragm. A contraindication to its use is any respiratory obstruction. In many cases there is spasm of the masseters. Concentrated vapor administered for a considerable time lowers the blood pressure, induces cyanosis and asphyxia, and would eventually cause death by respiratory failure (McCardie, in "Lancet," April 4, 1903). Lotheisser, in a study of 2500 cases of anesthesia by this agent, reports 1 death. Ware collected 12,436 cases with 1 death ("Jour. Am. Med. Assoc.," Nov. 8, 1902). Seitz, of Konstanz, collected 16,000 cases with 1 death. It is perhaps safer than chloroform, not nearly so safe as nitrous oxid, and not so safe as

* See Cumston, in Boston Med. and Surg. Jour., Dec. 20, 1894.

ether. The drug is used only for a brief operation or examination. It can be given to infants a few days old with reasonable safety and it has been administered many times to the aged. When it kills, it acts in a similar manner to chloroform. I have often given it *before* ether to prevent unpleasant symptoms and to hasten the advent of anesthesia, but it must *never* be given before chloroform. Of late I have practically ceased to use it.

Nitrous oxid gas may be used to obtain anesthesia for brief operations. It is contraindicated when vascular degeneration exists, because apoplexy may follow its administration. It should never be given when the air channel is narrowed, as in Ludwig's angina, abscess in or below the tongue, and thyroid enlargement (F. W. Hewitt, in "Lancet," July 26, 27, and

August 10, 1907). This gas is stored in steel cylinders, in which it is liquefied. The gas is passed into a rubber bag (Fig. 706), and is given to the patient by means of a tube and a mouth-mask, a wedge being placed between the patient's molar teeth, and the nostrils being closed by the anesthetist's fingers. The wedge must be held by a string, so that it cannot be swallowed. The patient becomes unconscious in about one minute, and we know the patient is anesthetized by the stertor and cyanosis and the insensitiveness of the conjunctiva. Watch the pulse, and if it flags, at once suspend the administration. The phenomena are asphyxial, stertorous respiration, cyanosis, and even convulsions, dilatation of the pupils, rapidity of the heart, and swelling of the tongue.* It is sometimes useful to give nitrous oxid and follow this with ether (page 1208). By this method the patient is anesthetized rapidly and pleasantly with the nitrous oxid, and the anesthesia is maintained by the ether.

It was formerly taught that nitrous oxid necessarily produces cyanosis because the gas can only cause anesthesia by partially asphyxiating the patient. We know this is *not* true

Fig. 706.—Hewitt's nitrous oxid apparatus.

because if nitrous oxid is mixed with oxygen or atmospheric air anesthesia is obtained without cyanosis. Nitrous oxid is a genuine anesthetic agent. In prolonged administration of nitrous oxid is desired, pure nitrous oxid is not

* See Hewitt, Brit. Med. Jour., Feb. 18, 1899.

given, a breath of fresh air being allowed from time to time. By this method Preston has anesthetized many patients, the duration of the anesthesia being from ten to fifty minutes. A better plan is to give nitrous oxid and oxygen. I am satisfied that this combination does not occupy the place in surgery its merits entitle it to. One reason is the absolute necessity of having a specially skilled administrator. A trouble frequently encountered is persistent rigidity. This can often be prevented by a preliminary dose of morphin. Postanes-

Fig. 707. Hewitt's nitrous oxid and oxygen apparatus.

thetic vomiting is rare (Teter, in *Thirteen Thousand Administrations of Nitrous Oxid with Oxygen*, "Jour. Am. Med. Assoc.," August 7, 1909). Hewitt formulates the following views as to the use of oxygen and nitrous oxid.*

"In order to obtain the best form of anesthesia oxygen should be administered with nitrous oxid by means of a regulating apparatus (Fig. 707), the percentage of the former gas being progressively increased from 2 to 3 per cent. at the commencement of the administration to 7, 8, 9, or 10 per

* Brit. Med. Jour., Feb. 18, 1899.

cent., according to the circumstances of the case. The longer the administration lasts, the greater may be the percentage of oxygen admitted.

"The next best results to those obtainable by means of a regulating apparatus for nitrous oxid and oxygen are to be secured by administering certain constant mixtures of these two gases. Mixtures containing 5, 6, or 7 per cent. of oxygen are best for adult males; and mixtures containing 7, 8, or 9 per cent. are best for females and children. The next best results to those last mentioned are to be obtained by means of mixtures of nitrous oxid and air, from 14 to 18 per cent. of the latter being advisable in anesthetizing men, and from 18 to 22 per cent. in anesthetizing women and children."

Bichlorid of Methylene.—The composition of the so-called bichlorid of methylene is a matter of dispute. Some high authorities believe it to be a mixture of methyl alcohol and chloroform. It rapidly produces unconsciousness, and the patient returns quickly to consciousness when the administration is suspended. Some surgeons have thought highly of it, and claim that it is pleasant, safe, and is not followed by vomiting as often as is chloroform. The weight of opinion is that it is dangerous, death being similar to death from chloroform. It is given by means of a Junker apparatus.

Anesthetic Successions.—**Bromid of Ethyl Followed by Chloroform or Ether.**—(See page 1205.)

Chlorid of Ethyl Followed by Ether.—(See page 1205.)

Chloroform Followed by Ether.—Chloroform is sometimes given until the sensation becomes more or less obtunded, when ether is substituted. This is done to save the patient from the unpleasant sensations of etherization. It is a practice not to be commended, because it is precisely in the beginning that chloroformization is most dangerous.

Ether Followed by Chloroform.—When the patient cannot be relaxed or rendered unconscious by ether, or when some other complication develops, it is common practice to suspend ether and substitute chloroform. If the change is made, chloroform should be given cautiously. A large quantity should never be poured upon the inhaler at one time. The change should never be made when the patient is struggling, because the deep respirations which attend or follow struggling may lead to the rapid inhalation of a dangerous dose of chloroform-vapor. Further, as Hewitt points out, when the patient is deeply under the influence of ether, the change should not be made unless it is imperatively necessary.

Nitrous Oxid Gas Followed by Ether (Gas and Ether).—This very valuable method was suggested by Clover. I have used it repeatedly with great satisfaction. The patient is made unconscious by nitrous oxid and is kept unconscious by ether. Thus are avoided excitement, struggling, choking, and the very unpleasant sensations induced by ether. It lessens the amount of time requisite to obtain anesthesia and lessens the amount of ether used. More important even than this, the method is safe. It is more satisfactory in women and children than in men. In very muscular men and in very stout elderly men it should not be used. In many cases nitrous oxid causes a flow of mucus from the respiratory tract. Because of the frequency of this happening it is wise to precede gas and ether anesthesia twenty minutes by a

natic injection of morphin and atropin (Van Kaathoven, in "Annals ry," Sept., 1908), or, as I usually prefer, of atropin alone. Many first anesthetize with nitrous oxid, using an ordinary dental apparatus, then give ether on an ordinary inhaler. The anesthetist must bear that ether must be given gradually, not suddenly poured on in large

Others prefer to use a combined gas-and-ether inhaler. Hewitt tribes the administration by means of Clover's portable ether-inhaler th a stop-cock and a detachable gas-bag ("Anesthetics and their ration"):

he patient be lying upon his back, his head should be turned to

The face-piece with the charged ether chamber is then applied n expiration. Air will be breathed backward and forward. When ration is seen to be proceeding freely, and the face-piece fits well, ged gas-bag is attached to the ether chamber. Air will still be but not through the valves of the special stop-cock. When the e heard to be working properly, 'gas' is turned on, and is likewise through the valves. Three or four respirations (or about one-half ntents of the bag) are allowed to escape. The valve action is now y turning the tap at the upper part of the stop-cock. At the same at which the patient begins to breathe 'gas' backward and for- : rotation of the ether chambers, for the addition of ether-vapor e commenced. The administrator will, in fact, find that he can, seconds from the commencement of the administration, rotate the mber as far as '1' or '1½.' Should swallowing or coughing

must rotate more slowly. Respiration mes deep and regular, and more and more y be admitted. At about this juncture, if atus has been fitting the face well, signs of rid narcosis may appear, especially in those quickly affected by this gas. Should jerky ; or 'jactitation' arise, one full inspiration y be admitted at the air-tap. It should be red, however, that in giving 'gas and ether' ethod, the object is to just steer clear of the id 'stertor' of nitrous oxid narcosis, and to but increasingly mix ether with the gas.

muscular and vigorous subjects, the quantity ove mentioned will be found to be, as a ale, insufficient to lead to the usual signs of ous oxid anesthesia. The rotation of the mber should be continued till the indicator '2,' '3,' or 'F.'

mistake that is most commonly made is mitting air too soon. Should air be given e first half or three-quarters of a minute, the ill partially come round, hold his breath, set and give a good deal of trouble. Duskiness atures must be expected. Speaking generally, air should not be until the patient is stertorous, when one breath may be given. In

Fig. 708.—Gebauer's ethyl-chlorid tube

this manner the patient will continue breathing a mixture of nitrous oxid, ether, and air, till the usual signs of deep ether anesthesia appear, when the gas-bag may be detached, and the little bag ordinarily used with Clover's inhaler substituted."

Hewitt prefers to use a modified Clover's inhaler, which permits the introduction of ether after the inhalation of nitrous oxid has begun.

Scopolamin-morphin Anesthesia.—This method has been enthusiastically praised and I used it with satisfaction in a number of cases, but I have grown afraid of it. In a patient in the Jefferson Hospital dangerous symptoms arose after a dose of gr. $\frac{1}{64}$ of scopolamin. Ely records a death from respiratory failure two hours after the administration of gr. $\frac{1}{8}$ of morphin and gr. $\frac{1}{16}$ of scopolamin ("New York Med. Jour.," Oct. 20, 1906). Fifteen deaths have been reported as following its use and there are beyond doubt unreported cases. Four deaths in 2400 cases were certainly directly due to it (H. J. Whitaker, in "New York Med. Jour.," March 31, 1906). It has even been stated that the death-rate is 1 in 100 ("Semaine Medicale," Jan. 11, 1905). Scopolamin is chemically identical with hyoscin and must never be used unless freshly, as it decomposes in air and light. If given without morphin, it is ineffective. Large doses are certainly dangerous, and the combination should never be given in sufficient amount to induce anesthesia unaided. If used at all, it should only be as an aid to local anesthesia or to general anesthesia by ether or chloroform. I have used it as an aid to local anesthesia in 6 goiter operations, and in 2 cases of removal of the Gasserian ganglion. It should not be used in heart disease (Hayem); in persons under sixteen or over sixty (Kochmann), in any one with a tendency to pulmonary edema or with any acute condition of the throat which interferes with respiration (A. C. Wood, in "American Medicine," Nov. 11, 1905).

It produces a drowsy, heavy state or actual sleep, and the patient can be kept unconscious with an extremely small quantity of ether or chloroform. For five or six hours after the operation the sleep continues, and in most cases there is not post-operative vomiting.

If it is used, a mixture is freshly made containing gr. $\frac{1}{64}$ of scopolamin and gr. $\frac{1}{8}$ of morphin, and this is given hypodermatically one-half an hour before the operation. During the operation the sleep may be maintained by ether or chloroform. If symptoms of poisoning occur, artificial respiration and oxygen inhalations may be required, external heat is needed, and emetics, glycerin, strychnin, or caffein are given.

I agree with Kochmann that we are not as yet justified in recommending this method of anesthesia ("Munchener medizinische Wochenschrift," 1905, No. 17).

Local Anesthesia. In every case requiring operation we should inquire whether local anesthesia can be used instead of general anesthesia. Many really extensive operations can be done under it and its field has been greatly broadened by the knowledge that viscera innervated by purely visceral nerves are insensitive and sensation exists only in those which receive branches from the somatic nerves (K. G. Lennander, in "Mittheilungen aus dem Grenzgebiet der Medizin und Chirurgie," Bd. x, Heft 1 and 2, 1902). Lennander shows that the parietal peritoneum is sensitive to pain, but not to touch—that the intestine, stomach, edge of liver, mesentery, gall-bladder,

urinary bladder, kidney parenchyma, lung, anterior wall of the trachea, testicle, and epididymis are insensitive, though the coverings of the testicle and epididymis are sensitive. My experience is that the viscera may be cut, sutured, and handled without any severe pain if they are not pulled upon. In removing an appendix the only pain felt will be when the meso-appendix is pulled upon or adhesions to the parietal peritoneum are separated. Bakdy recently affirmed Lennander's views ("Surg., Gynecol., and Obstet.," May, 1909). The advantages of operation under local anesthesia are freedom from the danger of anesthetic accidents, blood changes, and postanesthetic discomforts and dangers. The disadvantage is the knowledge of the patient as to what is taking place. He may become alarmed and turbulent and may thus interfere with a necessary procedure at a vital moment. I have operated under local anesthesia with satisfaction in the following cases: Tracheotomy, rib resection, goiter, iliac colostomy, typhoid perforation, abscess of the lung, gangrenous appendicitis, radical cure of hernia, strangulated hernia, suprapubic cystotomy, extirpation of the external carotid artery (Dawbarn's operation), and ligation of the femoral artery. There are many methods of local anesthesia.

Freezing.—*Ice and salt* may be used. Take one-quarter of a pound of ice, wrap it in a towel, and break it into fine bits; add one-eighth of a pound of salt; then place the mixture in a gauze bag and lay it upon the part. The surface becomes pallid and numb, and in about fifteen minutes decidedly analgesic. A *spray of rhigolene* freezes a part in about ten seconds. It is highly inflammable. *Ether-spray* anesthesia was suggested by Benjamin Ward Richardson. *Chlorid of ethyl* comes in glass or metal tubes (Fig. 708). Remove the cap from the tip of the tube and hold the bulb in the palm: the warmth of the hand causes the fluid to spray out. Hold the tube some little distance from the part, and let the fine spray strike the surface. The skin blanches and whitens, and is ready for the operation in about thirty seconds.

Hypodermatic Injection of Cocain Hydrochlorate.—Always bear in mind that cocain is sometimes a decidedly dangerous agent. There are on record fourteen deaths from cocain (Reclus). The urethra is a particularly dangerous region, and so is the face. Never use more than two-thirds of a grain upon a mucous surface, and never inject hypodermatically more than one-third of a grain, and be sure never to inject the drug into a vein. Mild cases of cocain-poisoning are characterized by great tremor, restlessness, pallor, dry mouth, talkativeness, and weak pulse. In severe cases there is syncope or delirium. Death may arise from paralysis or from fixation of the respiratory muscles (Mosso). Cases with a tendency to respiratory failure require the hypodermatic injection of strychnin. In cases with tetanic rigidity of muscles give hypodermatic injections of nitroglycerin, or inhalations of the nitrite of amyl. In cases marked by delirium, if the circulation is good, give hyoscin. In any case give stimulants, employ a catheter, and favor diuresis. Cocain-poisoning is always followed by a wakeful night. Cocain should not be used if the kidneys are inefficient. In using cocain try to prevent poisoning. Because of the dangers inherent in cocain, have the patient recumbent. One minute before giving the cocain administer hypodermatically one drop of a 1 per cent. solution of nitroglycerin and repeat the dose once during the operation. In operating on a finger, after making the part anemic, tie a tube around the root of the

digit before injecting cocain, and after the operation gradually loosen the suture. A hot solution of cocain is more efficient than a cold solution (T. Costello). Hence hot solutions can be used in much less strength and are safer. The method of injection is as follows: A sharp needle is held at an angle of forty five degrees to the surface, and is pushed into the Malpighian layer. One or two minutes after a 2 per cent. solution are forced into the Malpighian layer, and a white wheal of elevation forms. The needle is withdrawn, at the margin of the wheal is reinserted, and more fluid is introduced, and so on until the region to be operated upon has been injected. After waiting five minutes the operation is begun. If, after cutting the skin, it is necessary to cut the subcutaneous tissue, pour a few drops of a 1 per cent. solution into the wound from time to time. After the completion of the operation, if a rubber band was used, it is loosened for a few seconds, tightened for a few minutes, again loosened and readjusted, and so on several times (Wyeth). In this way only a small quantity of cocain is admitted into the circulation at one time, and toxic symptoms are prevented. For operations upon the eye a 1 to 4 per cent. solution is employed; a drop of fluid is instilled every ten minutes until three drops have been given. Rarely use over a 10 per cent. solution on mucous membrane, although in laryngeal operations a 20 per cent. solution may be required. For the nasal mucous membrane a bit of wool soaked in a 5 per cent. solution is inserted or a spray of 4 per cent. solution is thrown from an atomizer into the nostrils. In the rectum, vulva, vagina, and uterus use a 5 per cent. solution; in the urethra, a 4 per cent. solution, and in the bladder, a 2 per cent. solution.

Cocainization of a Nerve-trunk.—Krogius has pointed out that if cocain is injected into the tissue about a nerve-trunk anesthesia will follow in the area supplied by the nerve. The anesthesia will be produced in five minutes, and will last fifteen minutes. If cocain is injected about the root of the finger, all of the tissues of the digit will become insensitive. Injection over both supra-orbital notches renders the middle of the forehead insensitive. Injection over the ulnar nerve causes complete anesthesia of its trajectory. This plan is extensively used in Helsingfors.

It has been demonstrated by Crile ("Jour. Amer. Med. Assoc.," Feb. 22, 1902) that the injection of cocain into a nerve-trunk interposes an absolute block to the transmission of afferent and efferent impulses and greatly lessens operative shock. In 5 cases he employed this method to secure anesthesia for amputation of the leg, and 4 of the patients did not know that any operation was being performed.

Eucaïn hydrochlorate (β -eucain) is far safer than cocain, and in most cases is to be preferred to it. It is injected in the strength of from 2 to 5 per cent. It can be boiled without destroying its properties, and hence can be readily rendered sterile. It occasionally, though rarely, happens that the injection of eucain causes sloughing, especially at the extremities, in fatty tissue, in tendon-sheaths, and in bursae. It can be used on mucous membranes.

Stovain.—This agent is a new local anesthetic introduced by Fournier. It is as powerfully analgesic as cocain, is only one-third as toxic, and is slightly germicidal. It is dissolved in cold water, or salt solution and a solution used of the strength of 0.5 per cent. Adrenalin can be given with it (see Sonnenburg, in "Deutsche medicinische Wochenschrift," March, 1905).

Infiltration-anesthesia was devised by Schleich, of Leipzig, who was dissatisfied with cocain, because it is not safe and sometimes fails to produce complete local anesthesia, owing to want of thorough diffusion. He found that salt solution (0.2 per cent.), if injected into uninfamed parts, produced anesthesia. To obtain this anesthesia the part must be distended by wide infiltration. If minute quantities of cocain, morphin, and carbolic acid are added to the solution, the anesthesia becomes more thorough and more prolonged, and can be obtained even in inflamed areas.

Schleich uses three solutions:

No. 1, a strong solution, which is used in inflamed areas: cocain hydrochlorate, gr. iij; morphin hydrochlorate, gr. $\frac{2}{3}$; sodium chlorid, gr. iij; distilled sterile water, $\text{3ij}\frac{1}{2}$; phenol (5 per cent.), 2 drops.

No. 2, medium solution, which is employed in most cases: cocain hydrochlorate, gr. iss; morphin hydrochlorate, gr. $\frac{2}{3}$; sodium chlorid, gr. iij; distilled sterile water, $\text{3ij}\frac{1}{2}$; phenol (5 per cent.), 2 drops.

No. 3 is the weak solution used to infiltrate extensive areas: cocain hydrochlorate, gr. $\frac{1}{3}$; morphin hydrochlorate, gr. $\frac{2}{3}$; sodium chlorid, gr. iij; distilled sterile water, $\text{3ij}\frac{1}{2}$; phenol (5 per cent.), 2 drops.

The injections are begun *in* the skin, not *under* it (Fig. 709), and are made one after another until the area to be operated upon is surrounded above, below, and on all sides with Schleich's solution. At each infiltrated area a wheal forms in the skin. This infiltration can be made painlessly by touching with pure carbolic acid the point where the needle is to be inserted, or by freezing this spot with ethyl chlorid. After infiltration of the skin the surgeon waits ten or fifteen minutes and then operates, incision is made, and when deeper tissues are reached, they are infiltrated before incising them. If a nerve comes in sight, touch it with a drop of pure carbolic acid. Van Hook says that the anesthesia obtained by this method is due to artificial ischemia, pressure upon the tissues, the direct action of the drugs, and the lowered temperature.* The method is very efficient, and can be used for operations of considerable magnitude. Matas uses a special apparatus to infiltrate the tissues. The fluid is driven by compressed air, and wide-spread or "massive" infiltration is produced. The addition of adrenalin chlorid to the cocain solution is an advantage, as it retards the circulation and hence favors analgesia and lessens bleeding during the operation. I do not believe that adrenalin in any way modifies the toxic action of cocain—in fact, Berry ("Am. Jour. Med. Sciences," Nov., 1905) seems to prove that it actually increases it. A satisfactory fluid for infiltration is 1 part of a 1:1000 solution of adrenalin chlorid and 9 parts of a 0.5 per cent. solution of cocain (Gangitans, in "Riforma Medica," Sept. 9, 1903). Eucain and adrenalin are preferred by some. Barker uses distilled water, 100 gm.; pure sodium chlorid, 0.8 gm.; β -eucain, 0.2 gm.; chlorid of adrenalin, 0.001 gm. After injecting this fluid the surgeon waits for twenty minutes before operating.

Bier's Intravenous Method of Local Anesthesia.—This plan was described by Bier at the German Surgical Congress of 1908. It permits of serious operations upon the limbs, operations for which ordinary methods of local anesthesia would prove quite inefficient. Suppose the surgeon intended

* Med. News, Nov. 16, 1895.

to resect an elbow-joint. The Esmarch bandage is used to make the limb bloodless. A thin soft-rubber band is applied many times around the arm or the elbow, and a like band is applied below the elbow. The anesthetic is injected into a superficial vein (basilic or the cephalic). The vein is exposed, the syringe of the canula is introduced, and ligatures are used as though we were going to give an ordinary intravenous injection of salt solution, except that the canula is pointed to the periphery. The fluid used is a .12 or .2 per cent. solution of novocain. The syringe, containing 50 cc. of fluid, force the solution downward into the veins and the limb swells.

If the stronger solution is used, 50 cc. are enough; if the weaker solution is used, 100 cc. will be required. If resecting the knee the injection should be made into the internal saphenous vein and twice the amount would be necessary as advised for the elbow.

After injecting the strong solution operation may be begun at once. After injecting the weak solution we should wait ten minutes. The anesthesia is entirely satisfactory and passes away as soon as the band is removed. Sometimes motor palsy occurs as well as sensory paralysis. When the operation has been completed, wash out the vein with salt solution in order to prevent toxic effects.

Anesthesia by Infiltration with Sterile Water.—When the tissues are well infiltrated with warm or cold sterile water, anesthesia ensues promptly. I have not found it as complete as when cocain or eucain is employed, even when a considerable amount of fluid is introduced. Giant uses it a great number of operations and commends it strongly ("New York and Phila. Med. Jour." Jan. 28, 1904).

Spinal Analgesia.—J. Leonard Corning in 1885 discovered that cocain injected between the spines of the eleventh and twelfth dorsal vertebrae produces analgesia of the lower limbs ("N. Y. Med. Jour.," Oct. 11, 1885). From this observation spinal anesthesia springs. Bier produced complete anesthesia of the entire body except the head by the injection of a small amount of cocain into the subarachnoid space of the spinal cord. A solution of cocain of a strength of from 0.5 per cent. to 1 per cent. is used by some but cocain cannot be boiled without impairment of its anesthetic power and carbolic acid must be added to it in small amount. Hence cocain as prepared is not certainly sterile, and the carbolic acid added may induce harmful symptoms. (See Neugebauer, in "Wien. klin. Woch.," 1901, No. 25, p. 52.) Some surgeons use a solution of eucain which can be boiled, but it is not so rapid and certain as cocain. Some use tropacocain (Hillier). A solution of this drug can be boiled, is less poisonous than cocain, and somewhat slower in action. Experimenters tell us that gr. ss to gr. iss may be given, but it is not wise to give over 0.5 grain. I have used stovain in a number of cases. It may be combined with adrenalin if this is desired. The dose is 5 to 10 gm. The analgesia lasts from one half an hour to an hour or more, and was followed in my cases by retention of urine. Some have used novocain, alone or combined with adrenalin.

The best plan is that of A. W. Morton. He takes chemically pure crystalline hydrochlorate of cocain, places it for fifteen minutes in a dry temperature of 300° F., and puts it in sterile tubes until wanted. The dose depends upon the locality in which we wish to induce analgesia, and varies between 0.3

and 0.5 gr. The required dose is placed in the barrel of the sterile syringe and is dissolved in cerebrospinal fluid drawn into the syringe for that purpose. The syringe should be of glass, so that it can be boiled. The concave portion of the needle should be dull, so that a plug of skin will not be cut out and obstruct the needle (A. W. Morton, in "Jour. Amer. Med. Assoc.," Nov. 8, 1902). The patient lies upon his side with the back curved. The back has been previously sterilized. The dressings are removed and the region to be punctured is resterilized. The spines of the third and fourth lumbar vertebrae are located, and the needle is entered in the mid-line beneath the spine of the third or fourth lumbar vertebra and is pointed upward and forward. The surgeon determines that he has punctured the subarachnoid space by lessened resistance and the appearance of fluid at the needle-opening. The syringe, with a closed piston, contains 0.3 gr. of sterile cocain. It is attached to the needle; the piston is withdrawn until the syringe is half full of cerebrospinal fluid. When the cocain is dissolved, the solution is slowly injected, the needle is withdrawn, and the puncture is sealed with collodion.

The anal region becomes anesthetic in from one to two minutes, the lower extremities in from three to six minutes, and the upper extremities in from fifteen to thirty minutes. The anesthetic condition lasts from one to three hours, or even longer, and is due to the contact of cocain with the nerve-roots (A. W. Morton, "Jour. Amer. Med. Assoc.," Nov. 8, 1902).

In performing the operation care must be taken to prevent the escape of cerebrospinal fluid.

Fig. 700.—The syringe-point stops at the papillary layer, and the fluid lodges in the skin itself (Van Hook).

After cocainization of the spinal cord surgical operations can be performed on many regions without causing pain. Among the operations which have been performed are resection of the knee, resection of the ankle, osteotomy (Bier), amputation of the leg (Lower), and hysterectomy (Tuffier).

Spinal analgesia is not growing in popularity. It is regarded by most surgeons as a method to be used in exceptional cases. It should never be used as a routine procedure, and it will not displace ether or chloroform. By it analgesia can usually be secured. A. W. Morton ("Jour. Amer. Med. Assoc.," Nov. 8, 1902) has used it 673 times without a failure, and 60 of these operations were above the diaphragm. If we desire to obtain analgesia of the upper portion of the body the patient must be placed in the Trendelenburg position after the fluid has been injected. Most operators have had failures, especially above the diaphragm. In Sonnenburg's 1117 cases there were 78

utter failures ("Jour. de Chir.," Oct., 1908). Bier says that failures occur in 4 per cent. of cases; Moynihan says in 14 per cent.; Leguen says in the seventh of the cases. In Barker's last 100 cases it failed 2 times. No one should attempt it who is not well trained in aseptic methods, because infection of the cord or its membranes will prove fatal. Untoward effects are common, and they may arise during or after the operation.

Sonnenburg had them in 193 out of 1117 cases. Among the untoward effects reported are grave collapse, temporary paralysis of the abducens nerve, of the facial nerve, of the hypoglossal nerve, meningitis, retention of urine, chills, elevation of temperature, incontinence of urine, persistent paraplegia pain in the back and legs, perhaps lasting for months, nausea and vomiting during and after the operation, sweating, overaction of the heart, dimness of vision, cramps in the limbs, dyspnea, violent headache, involuntary evacuation of feces, and cardiac overaction. Many of the immediate symptoms are probably due to the absorption of the drug injected. The headache is due to tension and is relieved when some cerebrospinal fluid is withdrawn by lumbar puncture.

Whether or not permanent harm ever comes to the cord is not certain. Bristow ("Brooklyn Med. Jour.," 1902, xvi, page 410) reports the case of a man, fifty-five years of age, on whom he operated for hemorrhoids after spinal cocainization. An examination one month later indicated degeneration of the posterior and lateral columns of the cord (spastic lower extremities, ataxic gait, increased knee-jerks, ankle-clonus, and inability to retain urine). Marx ("New York Med. Record," Dec. 22, 1900) states that one case in his experience, after cocainization of the spinal cord, developed typical locomotor ataxia. Dandois ("Jour. de Chir. Brux.," April-May, 1901) reports a case upon which he had operated for traumatic rupture of the uretra. Spinal cocainization was employed. Paraplegia developed and lasted ten months. Several cases of hemorrhage into the subarachnoid space are on record. Leguen states that persistent paraplegia and persistent incontinence of urine may arise ("Rev. de Chir.," Oct., 1908).

Is there any danger of death from spinal analgesia? If the operation is not performed with scrupulous aseptic care it is very dangerous. Even when performed by the best surgeons death may occur. Taffet gives the mortality at 3 in 2000, but excludes from consideration 3 deaths ("La Presse Medicale," vol. iv, 1901, page 190). Reclus finds 6 deaths in less than 2000 cases (Address before the Paris Academie de Médecine, March 14, 1901). Hahn, in 1708 cases collected from literature, found 8 deaths ("Monat. a. d. Grenzgeb. d. Med. u. Chir.," 1900, iii, 337). The mortality is usually supposed to be about 3 in every 1000 cases. Wm. N. Perkins ("New England Med. Jour.," Jan.-Sept., 1902) collected 2345 cases with 16 deaths or 1 death in 146 administrations. Strauss's table shows 46 deaths in 22,717 cases collected by Hardonin, in "Archiv. Générale de Chir.," August, 1908).

Cocain seems to act like a toxin on the pia and arachnoid. Examination of fluid withdrawn after the performance of cocainization shows that it contains polymorphic leukocytes (Ravant and Aubourg, in "Gaz. Hebdom. de Méd. et de Chir.," June 27, 1901).

In a case in which, because of heart disease, pulmonary disease, kidney disease, or some other condition in which a general anesthetic is inadmissible,

spinal cocainization is justifiable. It should be reserved exclusively for cases in which other forms of anesthesia are positively contraindicated. The method should not be employed on those under fifteen or on the subjects of central nervous disease.

A solution of Epsom salts has been used by Blake, Haubold, and Willy Meyer. It was discovered (Meltzer and Auer, "Am. Med.," Nov. 25, 1905) that subcutaneous injections of salts of magnesium produce local anesthesia. The same investigators later pointed out (S. J. Meltzer, "Med. Record," Dec. 16, 1905) that subarachnoid spinal injections produce widespread and complete anesthesia. A 25 per cent. solution is used and 1 cc. of this is given for every 25 pounds of body weight. After a wait of three or four hours the drug causes paralysis and analgesia of the legs and pelvic region. Sensation and motion do not return for eight to fourteen hours. Retention of urine may last two days. The pulse and blood-pressure are unaffected, but the respiration is slowed. Large doses would endanger life by respiratory arrest. In view of the fact that in some cases the effect of the drug is inordinately prolonged, it is wise, when the operation is completed, to puncture the theca of the cord again and wash it out with salt solution.

XXX. BURNS AND SCALDS.

BURNS and scalds are injuries due to the action of caloric. Scalds are due to heated fluids or vapors. There is no true pathological difference between burns and scalds. Dupuytren classifies burns into six degrees, as follows: (1) Characterized by erythema; (2) characterized by dermatitis with the formation of vesicles; (3) characterized by partial destruction of the skin, which structure is not, however, entirely burned through; (4) characterized by destruction of the skin to the subcutaneous tissue; (5) characterized by destruction of all superficial structures and of part of the muscular layer; (6) characterized by "carbonization" of the whole thickness of the muscles.

The **symptoms** of a severe burn are local and constitutional. *Local symptoms* are pain and inflammation, which vary in nature, in intensity, or in degree according to the extent of tissue damage. *Constitutional symptoms* are very weak pulse, shallow respiration, and subnormal temperature—in other words, the condition of shock exists. The patient may die without reacting from shock, but in most cases there is reaction, followed by a severe reactionary fever, with a strong tendency to congestion of internal parts. During the existence of fever there may be vomiting, diarrhea, hemoglobinuria, albuminuria, and enlargement of the liver, spleen, lymph-glands, and tonsils. Marked blood changes follow burns (see "Clinical Hematology," by J. C. DaCosta, Jr.). There is a marked and rapid increase in red blood-cells (polycythemia). This is due in part to venous stasis and in part to loss of blood plasma. Leukocytosis is rapid and pronounced and there is a notable increase in blood plaques.

The blood has a marked disposition to clot, and clots may damage various structures or organs. Further, the altered blood damages the organs of excretion, and the liver and kidneys may cease to perform their functions properly. After a severe burn there are imperfect oxygenation and a ten-

dency to universal fatty degeneration. The symptoms designated as *prostration*, *reaction*, and *suppuration* eight hours after a burn there are congestion in a severe pain, and possibly internal congestions, possibly toxic delirium or convulsions. From the end of the eighth or ninth day there are severe inflammation of sloughs, and a strong tendency to in head burns, of the lungs in chest burns, of the abdomen, and of duodenal inflammation in any burn. Unusual cases cause *Curling's ulcer* of the duodenum. Curling's ulcer are possibly due, as Wm. Hunter has become irritant by the excretion in it of toxic matter. "Treatment," by W. Watson Cheyne and F. F. Bardeen, or ninth day the sloughs separate from the burn. The raw surface is slow to heal, hemorrhages may apt to be exuberant and edematous, and the scars often produce hideous or disabling deformity. If the surface is badly burned, death will almost certainly follow in two days. The danger of a burn depends upon the situation. Burning of a large area superficially is less dangerous than burning a small area deeply. Burns of the face are as serious as are burns of the head, chest, or abdomen. Death is positively not due to loss of body-heat in the burn, but produced by autointoxication with retained body-heat. The burn produces blood-changes—viz., disintegration of the blood, thrombosis may occur, and irritation of the kidneys and "products of corpuscular degeneration."*

The blood of burned animals contains toxins in the urine (Reis). It seems probable that the causes of death, if it occurs, are due partly to corpuscular changes, to the absorption of toxic matter from the seat of the burn, and partly to the action of heat on the body. Death is not infrequent. Death may be directly due to shock, to embolism or thrombosis, to congestion of the lungs, or to Curling's ulcer of the duodenum.

Treatment.—The local treatment of slight burns is frequently with a saturated solution of zinc chloride in a 1:8 solution of phenol sodique. In burns of the face use of zinc ointment with iodoform, though not a dressing.

If a large surface is burned, remove the clothing, apply antiseptic dressings, give a hypodermatic injection of stimulants, and if the patient has a chill, place him in bed by ordinary means to secure reaction from shock. For a severe burn aseptically, anesthetize the patient, spray the burn with oxid of hydrogen, irrigate it with a solution of salicylic acid, dust with Senn's powder (three parts of boric acid), and dress with salicylated cotton.

* Bardeen, in Johns Hopkins Hospital Bulletin.

than iodoform. Iodoform may allay pain, but is apt to produce dermatitis. Change the dressing no oftener than is required, and at each change proceed as above described, although it will not be necessary to anesthetize. Peroxid of hydrogen softens and loosens the dressings, and they can be readily removed. The custom in the Jefferson Medical College Hospital is to give morphin and stimulants, to cut away the clothing, to wrap the unburned parts with blankets, and place about them cans or bags of hot water. The burned region is sprayed with peroxid of hydrogen contained in an atomizer, and irrigated with salt solution. Portions of epidermis which remain are retained. Any blisters are opened with a sterile needle, and the part is dressed with several layers of sterile lint or tarlatan soaked in normal salt solution, and the dressing is kept moist. During the second or inflammatory stage use stimulants and concentrated food, allay pain by opium or morphin, favor elimination by the skin, bowels, and kidneys, and combat any tendency to internal congestion or inflammation. In very extensive burns complete and continuous immersion of the part in warm salt solution is an excellent treatment.

The *picric acid treatment*, first suggested by Thiery, has many advocates. It greatly mitigates the pain. It is used early only in limited burns of the first and second degrees, but it can be employed in late stages of deep burns to stimulate the formation of epidermis. If used early in a large or a deep burn, it may poison the patient. It may poison a child when used upon a burn of the second degree. A case was reported by Dr. J. Stuart Rose ("Scottish Med. and Surg. Jour.," Dec., 1903), occurring in a boy of nine, who was treated with picric acid for a scald of the first degree, there being only one or two small blisters in addition to the redness. Ointment of picric acid was used (℥ss to an ounce of vaselin). Symptoms were noted three days after beginning the treatment. The symptoms are dark-colored urine (carboluria), albuminuria, marked yellowness of the skin, yellowness perhaps of hair at the scalp margins, diarrhea, and elevated temperature. Rose considers a 1 per cent. solution safe. It is applied as follows: The part should be disinfected, gauze saturated with a 1 per cent. watery solution of picric acid should be laid upon the burned area, and be covered with absorbent cotton and a bandage. This dressing is not changed for three to five days, and the next dressing can be left in place until the burn is healed. D'Arcy Power has carefully studied the real status of picric acid as a remedy for burns, and some of his conclusions have been set forth above.

Périer dresses a burn with a tarlatan compress, folded six times and soaked in the following solution: boric acid, ℥iiss; antipyrin, ℥iiss; sterile water, ℥viiij. The following ointment is used by Reclus: iodoform, gr. xv; antipyrin, gr. lxxv; boric acid, gr. lxxv; vaselin, ℥iiss.

Carron oil consists of equal parts of linseed oil and lime-water. It allays the pain of a burn, but it is a filthy preparation, and its use is followed by much pus-formation. Cosmolin gives comfort as a dressing, but should not be used on the face, lest it cause pigmentation. The elder Gross used lead paint. A solution of nitrate of potassium allays the pain. In every burn of the fingers and toes keep the burnt digits separated by gauze, lint, or rubber tissue during healing, otherwise adjacent fingers will adhere and "webbing" will result. Where extensive destruction of tissue has taken place and

sudden and overwhelming cold is caused by anemia of the brain from weak circulation and capillary embolism. To bring a partly frozen person into a warm room may cause death by embolism.

Treatment.—Frost-bite is treated as outlined on page 192. When a person is nearly frozen to death place him in a *cool* room, but under no circumstance, in a cold bath; make artificial respiration, rub him briskly with flannel soaked in alcohol or in whisky, and follow this by rubbing with dry hands. After a time wrap the patient in warm blankets and give an enema of brandy. Mustard plasters are to be applied over the heart and spine. As soon as swallowing is possible brandy, is administered by the mouth. As the condition improves gradually raise the temperature of the room and give *hot* drinks.

Chilblain or pernio is a secondary effect of cold. It is really an area of local asphyxia (page 188). It usually appears as a local congestion upon the toes, the ears, the fingers, or the nose, and now and then inflames and ulcerates. A chilblain is apt to become congested on approaching a fire or on taking exercise, and when congested, it itches, tingles, and stings. Frequent attacks of congestion produce crops of vesicles; these vesicles rupture and expose an ulcer, which in rare instances sloughs.

Treatment. If chilblain affects the toes, prevent congestion of the legs and feet. Order large shoes and woollen stockings, and forbid tight garters. The patient with pernio must take regular outdoor exercise and must not loiter around a hot fire. Every morning and evening he should take a general cold sponge-bath, following by rubbing with alcohol and frictions with a coarse towel, and in winter he should sleep with warm stockings on or with his feet upon a warm-water bag. When a chilblain is only a congested spot, it should be washed twice a day in cold salt water, rubbed dry with flannel, and subjected to applications of tincture of iodine and soap liniment (1:2), tincture of cantharides and soap liniment (1:6), or equal parts of turpentine and olive oil (W. H. A. Jacobson). Jacobson says itching is relieved by painting belladonna liniment upon the part and allowing it to dry. Tincture of iodine may relieve it, and so may a mustard foot-bath. A valuable preparation for itching is composed of \mathfrak{z} j of powdered camphor and \mathfrak{z} iv of cosmolin. A little of this ointment is rubbed in twice a day. The following prescription, the source of which I do not remember, is very valuable for itching. \mathfrak{z} j of powdered camphor; \mathfrak{z} ss of ichthyol; \mathfrak{z} ss of lanolin, and \mathfrak{z} iv of cosmolin, rubbed into the part and covered with cotton-wool. If vesicles form, paint with contractile collodion; if ulcers form, dress antiseptically. If ulcers are sluggish, use equal parts of resin cerate and spirits of turpentine. A good antiseptic and protective is the following: oxid of zinc, gr. vj; chlorid of zinc, gr. xx; gelatin, \mathfrak{z} ij; distilled water, \mathfrak{z} j.

XXXI. DISEASES OF THE SKIN AND NAILS.

Dermatitis venenata is a dermatitis resulting from irritants. It may be caused by wearing garments containing arsenic, but is generally due to rhus-poisoning. Rhus-poisoning arises from the poison-oak, the poison-ivy, and some species of sumach. Actual touching of the plants is usually, but not always, necessary. Some suffer if they simply come near them. Some people are immune to rhus-poisoning, some are slightly susceptible, some are strongly predisposed. It is believed that toxicodendric acid is the irritant agent. The condition is most apt to arise when the skin is moist from perspiration.

The **symptoms** are burning and itching, redness and edema of the affected parts. The hands and forearms are most apt to suffer, but any part may be attacked. If the penis and scrotum suffer from rhus-poisoning there is great swelling from edema. An eruption on the hands may inoculate the penis when that organ is handled. A vesicular eruption begins between the fingers, and the eruption and the fierce red edematous inflammation spread widely over the body. There may be slight fever. The condition begins to abate in two or three days, as a rule, and desquamation follows.

When one, knowing from experience that he is predisposed, feels the inaugural itching, he should at once apply to the parts a 1 per cent. solution of lactic acid in 95 per cent. alcohol (R. F. Ward, in "N. Y. Med. Jour.," Dec. 26, 1908).

The **treatment**, when a moderate area is involved, comprises the application of cloths wet with black wash or lead-water and laudanum, or a saturated solution of acetate of aluminium (R. F. Ward, *Ibid.*). If an extensive area is involved, apply grindelia robusta (3iv to Oj of water) or moisten the surface frequently with sweet spirits of niter. Oxid of zinc ointment, containing 10 gr. of carbolic acid to 3j, gives great relief. A 1:8 solution of phenol and sodique allays pain and itching.

Furuncle, or boil, is an acute and circumscribed inflammation of the deep layer of the true skin and the subcutaneous cellular tissue following on bacterial infection of a hair-follicle or a sebaceous gland. A boil is caused by infection of a hair follicle through a slight wound (by scratching, shaving, etc.) with the staphylococcus pyogenes aureus. Boils are very common in individuals with Bright's disease, diabetes, gout, lithemia, tuberculosis, and disorders of menstruation and digestion; and crops of boils are apt to appear during convalescence from typhoid fever. Boils are commonest in the spring, and sometimes an epidemic of furunculosis appears in a hospital, a jail, or an asylum.

The **symptoms** of a boil are as follows: a red elevation appears, which stings and itches; this elevation enlarges and becomes dusky in color, a pustule forms, that ruptures and gives exit to a very little discharge which forms a crust. Inflammatory infiltration of adjacent connective tissue advances rapidly, and the boil in about three days consists of a large, red, tender, and painful base capped by a pustule and a little crusted discharge.

In rare instances, at this stage, absorption occurs, but in most cases the swelling increases, the discoloration becomes darker, the skin becomes edematous, the pain becomes severe and pulsatile, and the center of the boil becomes raised. About the seventh day rupture occurs, pus flows out, and a "core" of necrosed tissue is found in the center of a ragged opening. This core consists of the sebaceous gland and hair-follicle, which have undergone coagulation necrosis (Warren). In a day or two more the core will be discharged, and healing by granulation will begin. A *blind boil* lasts only three or four days and has no core. The constitution often shows reaction during the progress of a boil. Boils may be either single or multiple. The development of one boil after another, or the formation of several boils at once, is known as "*furunculosis*." Boils are commonest upon the neck and the back.

The **treatment** consists of crucial incision, removal of necrotic tissue, irrigation with peroxid of hydrogen, touching with pure carbolic acid, and the application of hot antiseptic fomentations.

Aleppo boils (*endemic boils of the tropics*) are papules appearing upon the exposed parts of the body. These papules, which ulcerate and do not cicatrize for at least a year, are due to a pathogenic bacterium and leave ineradicable scars.

Carbuncle (*benign anthrax*) is a circumscribed infectious inflammation of the deeper layer of the true skin and of the subcutaneous tissue, with fibrinous exudation, multiple foci of necrosis arising, and the tissue adjacent to each necrotic plug becoming gangrenous. The infection takes place through a hair-follicle. It is really a boil with extensive infiltration of adjacent tissues. A boil may become a carbuncle, and pus from a carbuncle inoculated into a healthy person may cause either a boil or a carbuncle. The causative organism seems to be the staphylococcus pyogenes aureus. Carbuncle is most common in the upper part of the back and on the back of the neck. In this region the skin is very thick; each hair-follicle holds only a downy hair, is shallow, and projects but a short distance into the cutis vera. Columns of fatty tissue run from the subcutaneous tissue in an oblique direction to join the point and sides of the hair-follicle. These columns are known as *columnæ adiposæ*, and each one contains a sweat-gland (Fig. 710). When pus runs down one of these columns, it seeks an outlet; it cannot spread easily to the sides, so it slowly works its way to deeper tissue and from one to another interspace and finds its way to the surface through other fatty columns (Warren's "Surgical Pathology") (Fig. 711). When pus finds its way to the surface, an opening forms, hence the numerous foci of pointing; finally a large opening forms (Fig. 712). Carbuncles are most common in the spring of the year. In persons with diabetes and Bright's disease carbuncles not unusually occur.

The local **symptoms** in the beginning resemble those of a boil, but the constitution sympathizes from the very start (perhaps a chill and always a septic fever) and the pain is usually severe. The inflammatory area begins as a papule with an indurated base, it enlarges enormously, is boggy to the touch, is dusky in color, is edematous, and the skin is not freely movable over the deeper parts. In a few days many pustules appear, each pustule marking the site of a focus of necrosis. Large vesicles filled with bloody serum very frequently form. In some cases, about the tenth day, the pustules

rupture, the narcotic plugs are discharged, and

Fig 710.—Columna adiposa (Warren).

Fig 711.—Infiltration of columna adiposa and subcutaneous tissue

tality of facial carbuncle is at least 50 per cent. for carbuncle are the neck, the back, and the b

carbuncle is made by noting the multiple foci of necrosis and the profound constitutional involvement. A carbuncle may produce death by causing septicemia, pyemia, or profuse hemorrhage.

Treatment.—Some have suggested the treatment of a carbuncle in an early stage by injecting from five to thirty drops of carbolic acid (80 per cent.) into and around the inflammatory mass. Such a method does not promise success and necessitates dangerous delay. The best treatment if the case is seen sufficiently early is thorough extirpation while the patient is anesthetized. The entire area of the infection is thus removed, and the large wound heals by granulation and is subsequently skin-grafted. When the condition is too far advanced to admit of complete extirpation, the following useful plan should be employed:

Give ether, make free crucial incisions, remove dead and necrotizing tissue and also the points of the skin-flaps with the scissors and forceps, curet pockets, arrest hemorrhage by pressure and hot water, cauterize with *pure* carbolic acid, dust with iodoform, pack with iodoform gauze, and dress with hot antiseptic fomentations. Cover the gauze with a piece of some impermeable material and lay a hot-water bag upon the dressing. Every day, or several times a day, remove the dressings, wash with peroxid of hydrogen, irrigate with corrosive

Fig. 712.—Diagram of a carbuncle (Warren).

sublimate solution, dust with iodoform, and reapply the iodoform gauze and antiseptic fomentation. Keep up this treatment until sloughs are separated, then dress with dry antiseptic gauze. Secure sleep by morphin, give quinin, milk-punch, and nourishing diet, and maintain the action of the bowels and kidneys.

Erysipelas.—(See page 215.)

Clavus or Corn.—A corn is a tender, painful, and circumscribed thickening of the epidermis, and is commonest over one of the joints of the toes. *Hard* corns are situated on exposed parts of the digits; *soft* corns appear between the digits, where the parts are kept constantly moist. Corns are caused by pressure.

Treatment.—The wearing of well fitting boots will usually cause a corn upon the toe to disappear. Soak the feet often in water containing bicarbonate of sodium, dry them, and apply a circular corn plaster to the corn to take off the pressure of the boot. Another method is to touch the corn with iodine every night and pare away the hard tissue every morning. An old and valuable plan is to paint the corn every night and morning for several days with a mixture composed of salicylic acid, gr. xl, extract of cannabis indica, gr. x; and collodion and flexible collodion, of each, 3ij; then soak the parts in hot water and scrape away the mass. *Soft* corns are treated by washing the feet often with ethereal soap, drying, gently removing the sodden

epithelium, dusting the toes and between them with absorbent cotton between the digits. In the removal of the skin from the adjacent sides of the toes, bring them together (thus converting two toes into one), and apply rest and lead-water and laudanum, and remember that in old persons the cutting of a corn is a dangerous operation. In the inflamed and painful feet of a person with hemorrhoids, much relief is afforded by washing the feet with ethereal and wrapping the feet for half an hour in cloths composed of linseed oil and lime-water, each, $\mathfrak{z}\text{ij}$.

Warts.—(See page 375.)

Onychia is inflammation of the matrix of the nail. A severe onychia which requires specific treatment is called paronychia. It is suppuration of the matrix at the free edge of the nail, of traumatic origin. It requires the removal of the nail, and packing with iodoform gauze, and the internal use of stimulants. Onychia is referred to in page 322.

Malignant onychia, which is inflammation of the matrix, occurs only in a person of dilapidated constitution. It requires removal of the entire nail, cauterization with iodoform gauze, and the internal use of stimulants.

Ingrowing toe-nail (page 173) is sometimes due to the edge of the nail, but usually to forcing of the soft tissue under the nail. An irritable ulcer arises. The condition is relieved by removing the ingrown piece, the soft tissue at the free edge of the nail, and dressing antiseptically.

XXXII. DISEASES AND INJURIES OF THE THYROID GLAND

THE thyroid gland possesses important functions. It has been pointed out that its complete removal in a young person causes operative myxedema (*cachexia strumipriva*). The removal of the gland in an elderly person does not cause myxedema. Later knowledge indicates that removal of the gland certainly produces myxedema or tetany, unless adequately compensated. Removal of the thyroid without the use of thyroid extract has a permanent grave consequence, even when there is a compensatory increase in the secretion of the thyroid. The thyroid furnishes an internal secretion which is essential to the metabolism. It is thought that the parathyroid glands furnish poisons formed during digestion.

Wounds cause violent hemorrhage which may be controlled by cutting out and forceps will not hold. The wound may be closed by suture ligatures, purse-string sutures, the actual cautery, or the use of the gland.

The thyroid gland may be absent at birth. Congenital hypertrophy may exist.

Acquired atrophy leads to myxedema, a condition characterized by the presence of a firm subcutaneous swelling in the

speech; mental dulness; and subnormal temperature. The condition is identical with that produced by removal of the entire gland.

Cretinism is a form of infantilism and idiocy due to atrophy of glandular elements in the thyroid, although the size of the gland is often increased. The body is dwarfed; bone development is very defective, the face, neck, and extremities resemble those parts in myxedema, and a low grade of idiocy exists. Myxedema and cretinism are treated by the internal administration of thyroid extract.

Thyroid Grafting.—Many experiments have been made and are being made on thyroid grafting in the treatment of cretinism and myxedema. Grafts have been placed under the skin, in bone at the junction of the epiphysis with the diaphysis, in the spleen, and in other regions. Very encouraging cases have been reported.

Congestion of the thyroid may be caused by violent exertion, prolonged effort, febrile maladies, and venous obstruction. It is treated by removing the cause and applying heat locally. Tracheotomy may be required.

Inflammation of the thyroid (*acute or inflammatory goiter*) may be induced by a septic or febrile malady, rheumatism, muscular strain causing vascular rupture, a wound or contusion of the thyroid. But one lobe is affected. The ordinary symptoms of inflammation are present. In addition there are dysphagia, dyspnea, venous congestion of the face, epistaxis, nausea and vomiting, and possibly delirium. It may terminate in resolution, suppuration, or fibrous induration.

Tuberculosis of the Thyroid.—Is usually a part of general miliary tuberculosis. It is very seldom that a local caseating focus occurs, but such cases have been reported.

Syphilis of the Thyroid.—Early in the secondary stage there is apt to be slight and painless thyroid enlargement. In the tertiary stage gummata may form.

Tumors of the thyroid are of various sorts. Among them are adenomata, cystic adenomata, sarcomata, and carcinomata. Eight cases of teratoma are on record (Isabella C. Herb, "Am. Jour. Med. Sciences," June, 1906). Malignant disease is unusual. I have operated on but two cases: one of cystic carcinoma in which operation was rapidly fatal, and one of round-celled sarcoma, which is living and apparently well four years after partial thyroidectomy. Malignant disease may arise in the normal, but is more apt to arise in a goitrous thyroid. In over 50 per cent. of the reported cases there is a history of antecedent goiter. Malignant disease is more common in women than in men and is very seldom met with before the age of thirty. It is most common between forty and sixty. One should always suspect malignant disease of the thyroid gland when the growth appears rather suddenly in a patient over forty years of age. If the growth is irregular in outline and is accompanied with pain and difficulty in swallowing, the diagnosis becomes reasonably certain. Later in the case there are symptoms due to pressure upon and infiltration of the nerves; the growth becomes firmly anchored and the lymph-glands adjacent to the thyroid become involved; there may be tracheal bleeding, and perhaps fever, and eventually cachexia develops. Sarcoma or carcinoma may occur and it is seldom possible to determine clinically with which we are dealing. The cancer may be a scirrhous or an epithelioma, but is usually an adenocarcinoma.

A sarcoma may be either round cell or spindle cell in type. In malignant

Fig. 713.—Sarcoma of thyroid gland

disease of the thyroid, metastasis occurs early in a great majority of cases, the lungs being first involved, and then the bones and other structures, though it has been stated that in adenocarcinoma the lungs are likely to escape and that solitary bone metastasis is not infrequently noted. Sarcoma (Fig. 713) may involve one lobe, but carcinoma (Fig. 714), even at an early stage is apt to involve both lobes (Berry). Diseases of the Thyroid Gland. These growths soon penetrate the gland capsule, become anchored to surrounding parts, and involve the vocal cords, trachea, and even the great vessels of the neck. It is after the fortieth year that malignant growths may be met with.

are hard and nodular and grow rapidly. At first the gland moves with deglutition, but later becomes anchored to surrounding parts. In malignant disease of the thyroid it is usual to find difficulty of swallowing and paralysis of the vocal cord on the side of the growth. Malignant disease is rapidly fatal. Many die within six months and few survive over eighteen months. Radical operation is proper only before the growth breaks through the capsule, although at any stage it may be necessary to operate in order to prevent suffocation.

Goiter. A goiter is an enlargement of the thyroid gland not due to a malignant tumor or to inflammation. The enlargement may affect a small portion of the gland, one lobe, both lobes, or both lobes and the isthmus, and it may occur either sporadically or endemically.

Fig. 714.—Cystic carcinoma of thyroid gland

here are a number of forms of ordinary goiter. The most common is called *parenchymatous goiter* (Fig. 716). In this condition all portions of the gland enlarge, and the goiter is consequently bilateral. It does appear first in one lobe and at a considerably later period in the other. Each lobe is enlarged equally or nearly equally. Parenchymatous goiter is often spoken of as simple goiter, and is sometimes, though not with entire accuracy, designated hypertrophy of the thyroid gland.

Adenomatous goiter (Fig. 715) is a condition due to the growth of encapsulated adenomata in the thyroid gland. It may be a single adenoma, but usually there are multiple growths. In both lobes may be involved. Adenomatous goiter, however, seems to begin in one lobe; and if both lobes enlarge, one does so at a period distant subsequent to the enlarging of the other. Adenoma may develop in a healthy thyroid gland, but adenomatous growth is usually associated with some parenchymatous growth.

Cystic goiter, or *bronchocoele*, is a condition in which the chief mass of the enlargement is composed of a cyst or of multiple cysts. When cysts form,

the thyroid gland is usually hypertrophied or adenomatous; occasionally, however, cysts form in a non-hypertrophied thyroid. The great majority of cysts are due to cystic degeneration of adenomata; some are formed by the running together of overdistended thyroid vesicles, and some few follow blood-extravasation into the thyroid tissue. The liquefaction is due to mucoid or colloid degeneration, and the fluid of the cyst is sometimes clear and thin, sometimes viscid, and often coffee-ground in appearance.

A *fibrous goiter* is a fibrous induration. It is likely to arise in

bronchocoeles, which may actually pass into a calcareous condition. By *malignant goiter* is meant malignant disease of the thyroid gland, either adenoma or sarcoma. As stated above, such cases are not really goiters.

Fig. 715.—Adenomatous goiter.

Fig. 716.—Parenchymatous goiter.

When hemorrhage takes place into a goiter, the condition is often spoken of as a *hemorrhagic goiter*. A *colloid goiter* is a form of parenchymatous goiter in which there is an extremely large amount of colloid material. *Exophthalmic goiter* is discussed on page 1234. Occasionally an ordinary goiter becomes exophthalmic. This evolution gives rise to what the French call a *Basedowian goiter* (see Morestin, in "Rev. de Chir.," Nov. 10, 1899). A goiter that develops with great rapidity is sometimes called an *acute goiter*, and one that induces marked dyspnea is designated a *suffocating goiter*. Syphilitic, tuberculous, and amyloid enlargements are extremely rare, but occasionally occur. Further, a goiter may be behind the sternum, that is *substernal* or *retrosternal*. A very movable goiter which is now above and now below the sternal notch, is called a *wandering goiter*. A goiter within the thorax is called *intrathoracic*; and such a goiter may be *retrosternal*, *retrotracheal*, or *retro-esophageal*. When a number of persons in the same region are attacked with goiter, the condition is frequently referred to as *epidemic goiter*. When the condition is common in a certain district, it is called *endemic goiter*. When a person living in a district in which the disease is rare develops goiter, we speak of the condition as *sporadic goiter*. It has long been known that *accessory* or *aberrant thyroids* exist. The term *aberrant* is better than *accessory* because in some reported cases the thyroid proper was absent (V. L. Schrager, in "Surgery, Gynecology, and Obstetrics," Oct., 1906). Aberrant thyroids are masses of tissue composed of structure identical with the thyroid gland, and distinct and separate from the thyroid gland proper. Median accessory thyroids are found about the hyoid bone and are formed from remnants of the thyroglossal duct. Lateral accessory thyroids are found and develop from the remains of the lateral anlagen of the thyroid (Schrager). Aberrant thyroids vary in number: there may be none, one, several, or a mass of them. An aberrant thyroid may enlarge with the thyroid, may not enlarge even though the thyroid does, or may enlarge when the thyroid proper remains normal. When cachexia strumipriva does not develop after complete thyroidectomy, including the parathyroids, the patient has been saved by enlargement and functioning of accessory thyroids.

Causes of Goiter.—It is known that goiter is extremely common in the valleys at the foot of certain mountain ranges in Switzerland, southeastern France, northern Italy, the Austrian Tyrol, and in the Himalayas and the Andes. In a portion of England it is so common that it is referred to as the Derbyshire neck. It seems evident that the disease is due to the introduction of some poisonous element into the system; but what this element is, is not positively known. Some writers maintain that individual liability is developed by habits of life; others think that susceptibility depends upon hygienic surroundings; and some attach great importance to hereditary influence. The probability is, however, that the disease is due to the existence of some poisonous substance in the drinking-water. Some observers have blamed snow-water; many have laid the cause of the trouble at the door of water impregnated with salts of lime; but the real cause has not been positively demonstrated.

An ordinary parenchymatous goiter seems to be a species of hypertrophy. A number of years ago I suggested the view that the gland has undergone such an enlargement and has become distended with colloid material because the human body has demanded more of the secretion of the gland than the

normal gland has been able to supply; as a consequence, the normal gland has enlarged its capacity and increased its output.

Symptoms of Goiter.—One may determine that a growth is in the thyroid gland or is connected with it by studying a number of facts. A goiter, as a rule, follows the movements of the larynx and the trachea during deglutition, and this sign may be obtained in the great majority of instances. There are, however, rare conditions, such as hyoid cyst, in which a movement of the mass takes place during the act of swallowing, although the thyroid gland is not involved. Then, again, a malignant or an inflammatory growth of the thyroid usually becomes anchored to the surrounding tissues and does not show this mobility. Certainly, however, in the greater number of the cases the goiter moves with the larynx and the trachea during swallowing.

Goiters vary greatly in size. Cases in which the goiter was as large as an adult's head, and some cases in which the goiter hung in front of the breast-bone and reached to below the level of the ensiform cartilage, have been described. A very large goiter may have a stalk.

When the entire gland, as well as the isthmus, is enlarged, or when the isthmus alone is involved, the swelling may appear to be in the median line of the neck. If the condition begins in one lobe, the growth will, for a time at least, be distinctly one-sided; though when such a growth has attained a large size, it may displace the windpipe and come itself to the middle line of the neck.

A goiter of any considerable size pushes the sternocleidomastoid muscle externally and anteriorly, and the muscles that run from the sternum to the hyoid bone and to the thyroid cartilage overlies the front of the growth. The carotid artery is displaced externally and posteriorly. The relation of the jugular vein to the carotid artery is usually profoundly altered. The artery, as already stated, goes externally and posteriorly, while the vein is actually pulled anteriorly and is flattened out upon the side or the anterior surface of the goiter; hence the vein comes to lie to the inner side of the artery. This curious alteration in relationship is due to the fact that the common carotid artery has no branches, and therefore is pushed externally with ease; but the internal jugular vein receives branches that lie in the tumor, pull upon the vein, and prevent its displacement with the artery (Lücke).

Berry alludes to the fact that the tumor, unless it is very small, usually reaches the upper level of the sternum, and frequently passes below this level; and that only extremely large goiters hang in front of the sternum, but that it is not at all unusual for prolongations from a goiter to extend for quite a distance into the mediastinum. A substernal goiter is productive of very dangerous symptoms and offers many difficulties in diagnosis. A goiter will occasionally wander, now appearing in the neck and again disappearing behind the sternum.

Some goiters are said to pulsate. This takes place in exophthalmic goiter, the vessels of the goiter pulsating as do the other vessels of the body; but in the ordinary simple goiter, what is called pulsation of the goiter is usually the transmitted pulsation from the carotid artery.

Some of the most important symptoms of goiter are due to pressure and to the displacing of anatomical structures. Pressure upon the veins at the root of the neck causes great enlargement of the veins above the goiter and

in it. Pressure upon the recurrent laryngeal nerve may induce characteristic symptoms (spasm of the glottis or paralysis of a vocal cord), but the exposure of goiter is due to pressure upon the trachea and not to interference with the recurrent laryngeal. Paralysis of a vocal cord is rare in non-malignant, common in malignant, goiter. Pressure upon the cervical sympathetic may cause contraction of the pupil and narrowing of the palpebral fissure (Berry). Pressure upon the cervical plexus or the brachial plexus causes paresthesia, anesthesia, or paralysis in the parts supplied by nerves from the compressed plexus. Pressure upon the larynx and the trachea may cause very great displacement, and any such displacement is productive of marked dyspnea. This displacement is usually to the side; and it may cause such a flattening out of the tracheal rings that when the tumor is removed, the trachea collapses and the patient perishes of suffocation.

A parenchymatous goiter usually begins insidiously and grows slowly. It occasionally ceases to grow for a considerable period of time, and may even shrink. It frequently enlarges temporarily during menstruation or pregnancy, and occasionally attains an enormous size by changing into the cystic form. Alterations in its consistency and outline may be due to the developing of adenomatous masses.

In making a diagnosis between the different forms of goiter, one should remember that a fairly symmetrical, bilateral growth is probably parenchymatous; that sudden enlargements are produced by hemorrhage; that excoriation may lead to very great enlargement, and possibly to fluctuation; that if a non-malignant goiter induces dyspnea, it almost invariably does so by pressing upon the larynx and the trachea, whereas a malignant goiter may do so by interfering with the nerves of the part; that a non-malignant goiter very rarely produces difficulty in swallowing, but that a malignant goiter frequently does so; and that cough often exists if there is pressure upon the larynx or the trachea, such a cough being metallic in nature and unassociated with impairment of the voice.

In any goiter there may be cerebral symptoms, such as anemia, convulsions, or even convulsions. Rapidly growing goiters are often fatal, and slowly growing goiters are very rarely so. A malignant goiter grows with great rapidity, becomes adherent, infiltrates, and quickly produces metastases; and both sarcoma and carcinoma produce metastases by way of the venous system.

Metastasis of Non-malignant Goiter.—An ordinary goiter which presents no sign of being malignant may suddenly be disseminated. The deposits are apt to take place in the bones and in the lungs. Tumors have been removed without any thought of thyroid trouble being responsible, and examination has shown thyroid structure. Patel collected 18 cases of thyroid metastasis ("Tumeurs bénignes du corps thyroïde donnant des métastases," "Revue de Chirurgie," 29, 1904). The bones most apt to receive metastases are the bones of the cranium, the lower jaw, the vertebrae, the pelvis, and the long bones. In 4 of these 18 cases the spine was affected. Detering reported a case of thyroid metastasis to the spine ("Journal of Nervous and Mental Diseases," March, 1906). Colloid goiters are particularly prone to metastasis. Some surgeons maintain that if a metastatic deposit grows and destroys bone, the primary tumor should be regarded as malignant no matter what histological studies indicate.

Treatment of Goiter.—Iodid of potassium and arsenic internally have been advised; ointment of red oxid of mercury locally is advocated by some writers. The administration of thyroid extract may do much good in a case of parenchymatous goiter, but it is useless in other forms of the disease. It should be associated with the local use of tincture of iodine or ointment of red iodid of mercury. In times past it was customary to treat cystic goiters by aspiration and injection with a solution of iodine. Electrolysis may benefit a soft goiter, the negative pole being pushed into the growth, the positive pole being applied to its surface. In some cases the x-rays may prove of benefit. In considering the propriety of operation remember that a goiter which begins at puberty may pass away. We should operate on every non-malignant goiter which is increasing in size steadily or rapidly. Operation is justifiable even if there is not pressure because the mortality is very small, and it saves the patient from the possibility of malignant change, of hemorrhage, and of inflammation. If enucleation or extraglandular extirpation is performed, ether is seldom given. General anesthetics increase bleeding and are to that extent dangerous. Do the operation with the aid of local anesthesia (cocain, eucain, or Schleich's fluid). It is a great advantage to have the patient conscious, because by asking him to speak during the operation the surgeon can tell if the recurrent laryngeal nerve is being approached or touched. In many cases intraglandular enucleation is performed, in other cases extirpation. Occasionally these two methods are combined (Bergeat). Some surgeons advise simple division of the isthmus. Ligation of the thyroid arteries has been recommended. *Exothyropexy* is the operation of exposing the thyroid gland, dislocating it through the wound, and leaving it in this situation. Exothyropexy is now almost never performed, on account of the safety of the operation of thyroidectomy. Atrophy of the gland follows the operation. Enucleation, if possible, is the desirable operation. It may easily be employed for the removal of a single adenomatous, colloid, or cystic area. *Thyroidectomy* or extirpation is employed when enucleation is impossible. The entire thyroid is not removed for an innocent growth: a portion of the gland is left behind, otherwise operative myxedema will probably arise. Unilateral extirpation is the method usually chosen. In sarcoma or cancer of the thyroid complete extirpation may be attempted. The operation in malignant disease will occasionally prolong life, but it will rarely effect a cure. In malignant disease tracheotomy may be rendered necessary by urgent dyspnea. The operation is often very difficult because the growth may cover the trachea, the trachea may be deviated a considerable distance from its proper position, and the veins are very large. After the performance of the operation it is usually impossible to use an ordinary tracheotomy tube, and in such a case Koenig's long, flexible tube is employed (Fig. 717).

Fig. 717.—Koenig's tracheotomy tube

Endotracheal Goiter.—Such a goiter may be due to misplaced thyroid tissue, or may be a prolongation from the thyroid gland. Occasionally the

growth is situated in front, but, as a rule, it is on the inner face of the larynx or trachea. The first symptoms are slight and become very severe. An examination of the throat condition is evident. Endotracheal goiter is much more common in the male. It is believed to begin usually in childhood, though it may exist for a long time unnoticed. In some patients were forty years of age before being diagnosed. The first sign of an endotracheal goiter is the performance of the voice, then extirpation.

Exophthalmic Goiter (Graves' Disease) — This condition was first described by Graves. It is vastly more common in women than in men.

Fig. 718 — Exophthalmic goiter and total blindness from protrusion of eyes (Hansell).

troubles, and abdominal and pelvic diseases are responsible in some cases. It is frequently associated with result of excessive vomiting. Many believe that the real cause is hypertrophy of the thyroid gland (*hyperthyroidism*). This view is recalled that a condition known as myxedema is the opposite to those of Graves' disease and that it is due to great diminution or absence of thyroid secretion, or to a lack of adrenal secretion. The administration of iodine to an individual may produce some symptoms observed in Graves' disease. A partial thyroidectomy may improve or cure the disease, but it probably removes the poisonous element.

An apparent objection to this view is that Graves' disease may exist without detectable thyroid enlargement, but this objection loses force when we recall that the thyroid may be somewhat enlarged, though we cannot detect the increase. It is probable in exophthalmic goiter that whether or not there is an excess of thyroid products passing into the circulation, toxic materials of some sort are formed in the gland and are taken into the lymph and blood. The real cause of exophthalmic goiter is not positively proved, but it seems probable that the disease is due to the action on the sympathetic system of large amounts of thyroid material or of some poisonous product of thyroid activity.

In exophthalmic goiter the vessels of the gland are not dilated—in fact they are “usually smaller and less numerous than in a parenchymatous goiter of the corresponding size” (Berry on “Diseases of the Thyroid Gland”). The surface of the gland is smooth. On section, the cut surfaces seem solid and very little colloid is visible. The enlargement is due to growth of the glandular epithelium, and this epithelial proliferation may be induced by the different exciting causes previously mentioned.

In exophthalmic goiter the lymphatics within the lobules are usually obliterated, and the lymphatics around the lobules are present in increased number and are of exaggerated size. Sometimes the thyroid becomes fibrous, and in such cases myxedema is apt to arise. In a typical case there are rapid pulse or *tachycardia*, protrusion of the eyeballs or *exophthalmus* (due to a collection of fat back of each eye), and enlargement of the thyroid gland or *goiter*. Either thyroid enlargement or *exophthalmus* may be absent—in fact, in some rare cases both are absent. The pulse-rate in most cases is from 90 to 140. *Exophthalmus* is present in at least 80 per cent. of cases. The enlargement of the thyroid is bilateral. Supposed unilateral enlargements are instances of Basedowified goiter—that is, are cases in which hyperthyroidism arises in the course of an ordinary goiter. A systolic bruit is usually audible over the thyroid region, and the large vessels at the root of the neck pulsate strongly because of arterial dilatation. The cardiac symptoms are of great importance. Cardiac dilatation occurs during tachycardia, and for a time, at least, disappears as tachycardia abates. Even trivial fatigue brings on temporary dilatation. Dilatation may become permanent, valvular insufficiency may arise, or cardiac hypertrophy may occur (see Grocco, in “Riv. Crit. di Clin. Med.,” Jan. 2, 1904). *Von Graefe's sign* may be present; this is inability of the lids to follow the eyes in looking down. *Stellwag's sign* is retraction of the upper lids. The lids in some cases cannot be completely closed, and when the eyeball is suddenly turned up, the lid and brow may fail to act together. *Moebius's sign* is inability to maintain the eyes in convergence. In some cases ocular palsies exist, in others there is photophobia or nystagmus. Patients may suffer from neuralgia, colic, choreic movements, tremor, flushes of heat, and gastric crises. Tremor is practically always present when the arms and forearms are extended, the palms of the hand are turned down, and the fingers are spread apart. Widespread tremor is apt to arise from any excitement, shock, or surprise. Dyspnea often exists and albuminuria and polyuria are not uncommon. Hemoptysis, hematemesis, or mental disturbance is sometimes noted. The patient is usually greatly depressed mentally, sometimes is excited, and may have outbreaks of violent hysteric excitement or even of mania. The usual expression is one of fright. There may be insomnia, elevated tempera-

ture, excessive sweating, or sudden attacks of increased by fear or fright. Exophthalmic with osteomalacia. This fact is important in observations on the action of the parathyroid bolism. The duration of a case is entirely chronic, with remissions or actual intermissions entirely well, but this result is rare. There is at any time be followed by a renewed outbreak passes away rapidly, but abatement is usually progressively worse and die. Certain cases are fatal. A man in the Jefferson Hospital died symptoms were noted. He was delirious for a

Treatment.—Thyroid extract does harm. Every case should comprise rest in bed, the use of and the administration of adrenalin. When he must avoid alcohol and all forms of excitable, but never violent exercise. Diet is to be plain. Electricity is said to be of benefit. T. Experiments in organotherapy are being tried. Enriquez assumed that the thyroid gland fulfills body poisons, that an excess of thyroid secretion neutralize toxin causes the condition known as symptoms of Graves's disease should disappear. He injected to antidote the excess of thyroid secretion. "Medicine," August, 1906). The two observed blood serum from thyroidectomized dogs and that from Graves's disease and claim that they cured of their patients, however, tetany developed, thyroidectomized goats instead of the serum of serum of thyroidectomized sheep, powder of cretin, and the powdered flesh of thyroidectomized (Hubert Richardson, "Am. Med.," August, 1906). *Thyroidectin* is the dried serum of an animal from which the thyroid has been removed. John W. Rogers and S. P. Bates have made interesting studies on the production and application of two sera, using one or the other, according to the type of case. One serum, called the normal serum, is obtained by injecting them with the combined nucleoprotein of normal thyroids, the other, called the pathological serum, is obtained after injecting them with combined nucleoprotein from the thyroids of Graves's disease. In some cases improvement and apparent cure follow the use of serum treatment is as yet undetermined. It is dangerous and some deaths have followed its use. One case of use of goat serum may be found in the fact that the patient was probably incompletely thyroidectomized. The thyroid glands and these must be removed as well as the sympathetic plexus of the cervical ganglia of the sympathetic system. The ganglia, have been employed, and it is

I have not employed the operation for this disease. Ligation of the thyroid arteries may do good. Partial thyroidectomy is the operation commonly employed in severe cases, it cures within six months 50 per cent. of the cases operated upon. Some cases do not improve; others improve slowly and relief is only partial. It is the operation which I prefer. The Mayos have obtained a splendid series of results from this operation. They have operated on 110 cases with 9 deaths, but in the last 64 cases there were but 2 deaths (C. H. Mayo, "Jour. Am. Med. Assoc.," Jan. 26, 1907); 50 per cent. of the survivors were cured; 25 per cent. showed lasting improvement in the main symptoms; 20 per cent. were greatly improved, but have temporary relapses of tachycardia and tremor. The Mayos had but one case of tetany (and that slight) in 375 operations on the thyroid gland. It is their custom to apply the x-ray daily for several weeks and then to operate. The rays produce decided but temporary improvement. The operation is intracapsular extirpation of one lobe. Ether is given to most cases. In some cases thyroid intoxication follows operation. In other cases very rapid growth follows incomplete removal, and the operation seems actually to have done harm. Sudden death occasionally follows the operation. The removal of an exophthalmic goiter is difficult; the capsule and blood vessels rupture from slight force. All cases should not be operated upon; in fact, only those cases should be operated upon in which medical treatment has proved futile, or in which there is profound toxemia or excessive dyspnea. If extraglandular extirpation is performed, neither ether nor chloroform should be given. Such an operation is to be done under local anesthesia (eucain, cocain, or Schleich's fluid). The younger Kocher reports the experience of the Berne Clinic ("Mittheilungen aus den Grenzgebieten der Medizin und Chirurgie," Bd. ix). He reports 74 cases of true exophthalmic goiter, 59 of which were operated upon. Every operation was done with the aid of local anesthesia (1 per cent. cocain). In some cases partial thyroidectomy was performed; in some the thyroid arteries were ligated; in 3 cases not only were the arteries tied, but the sympathetic ganglia were resected. In these 59 cases were 4 deaths within ten days from tetany, and in 39 of the cases there were marked disturbances (tremor, irregularity and palpitation of the heart, vomiting, sweating, and elevated temperature). These abnormalities were possibly due to forcing diseased thyroid secretion into the circulation; 45 of the 59 cases were cured and 8 were greatly improved. In 3 of the fatal cases autopsy was made, but did not disclose the cause of death. Kocher believes in operation. He thinks, however, it removes but one element of the disease, and that medical treatment

Fig. 719.—Enucleation of cystic goiter; capsule opened (C. H. Mayo).

may remove the others. He advises strongly a exacerbation, unless relief has been sought, but not That Kocher had 4 cases of tetany in 59 operations 110 operations seems a complete confirmation of the posterior portion of the capsule. The x-rays effect upon the symptoms of exophthalmic, destroy some of the secreting glandular epithelium, of the thyroid secretion and alter its character. They will produce a cure. It is my custom to use tion, in order to decrease the vascularity of the p diminish the toxic quality of the thyroid secretion symptoms.

Operations on the Thyroid Gland.—The re operation and one beset with difficulties and danger successful operation. I have operated on 54 cases of sarcoma of the thyroid goiter without a death. I thyroid and a case of adenoma of the inferior right these cases is considered a goiter). In 200 cases of had a mortality of 1 per cent. following extirpa .4 per cent. Certain anatomic points are to be b jugular vein is frequently found internal to the c goiter (because the vein has branches which run vessel against the thyroid). selected cases, and can be performed rapidly, but the arrest of bleeding is often tedious and troublesome.

Extirpation.—This term means removal of the entire gland (*complete thyroidectomy*) or a portion of the gland (*partial thyroidectomy*) with the glandular capsule, the operation being an extracapsular procedure. Usually but one lobe is extirpated. This method enables the operator to tie the chief vessels before he cuts them, and as his vision is not obscured by bleeding,

Fig. 722.—Exposure of veins at lower end before ligation (Kocher).

Fig. 723.—Dislocation of the goiter toward the right (Kocher).

he can avoid cutting the glandular capsule, which would be sure to provoke copious bleeding, and he keeps a safe distance away from the recurrent laryngeal nerve.

If the patient suffers from dyspnea, a general anesthetic is contraindicated. It is best in any case not to use one. Local anesthesia is reasonably satis-

factory and is far safer. The patient is placed a little raised and the neck laid upon a sand-p

back as far as is consistent with comfortable re

with a blunt instrument, the patient's voice becomes metallic. A deliberate attempt is made to locate it and the patient is engaged in a conversation requiring answers while the surgeon is investigating. The lobe is lifted from its bed and dislocated from the wound and the inferior thyroid vessels are tied close to the border of the gland in order to avoid the recurrent laryngeal nerve (Fig. 725). The vessels are tied and cut across as were the superior thyroid vessels. The isthmus is next exposed, clamped, ligated, and cut across, every care being taken to prevent colloid from being squeezed into the wound (Fig. 727). After dividing the isthmus, any bleeding point is ligated and the stump is cauterized. The divided muscles are sutured with catgut, a drainage-tube is inserted, and the superficial wound is closed with sutures of silkworm-gut.

Intracapsular Extirpation.—This operation is warmly advocated by the Mayos. I have employed it in my last 10 cases. The preservation of the posterior portion of the capsule protects the recurrent laryngeal nerve and greatly lessens the risk of injuring the parathyroids. Ether is given unless there is grave respiratory difficulty with myocardial degeneration, and one-half an hour before administering the ether the patient is given a hypodermatic injection of gr. $\frac{1}{4}$ of morphin and gr. $\frac{1}{16}$ of atropin. When anesthetized, the patient is placed in the reversed Trendelenburg position and the shoulders are elevated (C. H. Mayo, in "Surg., Gynecol., and Obstet.," June, 1907). Kocher's transverse collar incision is made. Muscles are separated or divided as in ordinary extraglandular extirpation. If the ribbon muscles are divided the cut is made near their upper insertion to save their nerve supply and prevent the muscle scar from being in line with the skin scar. The gland is elevated. The vessels entering and leaving the raised lobe are double clamped and tied. The capsule is incised along the outer side of the gland, is pushed back with gauze, and the lobe is drawn toward the midline, and vessels are caught by forceps, the tissues being grasped in line with the midline of the body (C. H. Mayo, *Ibid.*).

Every structure bearing any resemblance to a parathyroid is allowed to remain. The isthmus is clamped, divided, and closed by suture. The muscles and skin are sutured. Drainage is required after removal of large growths, a separate incision being made to permit of it.

Dangers in Goiter Operations. During any operation for goiter sudden death may occur. In some cases a general anesthetic is responsible. In others suffocation arises from pressure upon or bending of the trachea or collapse of the trachea as the goiter is lifted from its bed. In rare cases dangerous dyspnea arises from irritation of the laryngeal nerves, and cardiac inhibition may be induced in the same manner. The parathyroids may be injured or removed and myxedema may result. Rough handling and flooding the wound with colloid may be followed by great and even fatal hyperthyroidism. The trachea or esophagus may be opened. The recurrent laryngeal nerve may be injured. Air embolism seldom occurs. Reactionary or secondary hemorrhage is usually due to slipping of the ligature on the superior thyroid artery "caused by including a piece of muscle" (C. H. Mayo, *Ibid.*).

Acute Thyroidism (Hyperthyroidism).—When colloid from the thyroid is squeezed into the wound during the operation or leaks into it later, it is absorbed and may produce serious symptoms or even death. This is most

apt to happen in exophthalmic goiter. The symptoms arise soon within forty-eight hours and usually within twenty-four hours after they arise quickly after operation. In some cases it is so severe that the patient never reacts from the operative shock, but develops a very high fever and intense dyspnea, and dies in a few hours. In some cases there is a period of circulatory excitement, dyspnea, and elevated temperature (hyperpyrexia). The surgeon seeks to prevent acute thyrotoxicosis by thoroughly coagulating the stump, by cauterizing the stump, by washing the stump with alcohol, and by suturing the capsule over the raw stump of the gland and covering it with a dressing.

The Parathyroid Glands.—These glands were discovered by Starling in 1880, and their vital functions were realized only after he showed that removal of the parathyroids causes tetany.

The parathyroids are brownish red and are larger in absolute size than the thyroid. They are constant in man, never being congenitally absent.

They are usually four in number and are usually found external to the thyroid capsule. In some cases, however, one or more of them may be embedded in the thyroid gland, but even when they are said to be within the thyroid they are always separated from it by a capsule of connective tissue.

While there are usually four parathyroids, there may be only three or there may be six, seven, or eight. A lesser parathyroid has been reported over wide areas. One was discovered by Rogers and Ferguson in the wall of the posterior portion of the pharynx, and there was found in the thyroid (Ogle) a gland that was partly parathyroid.

From their situation the parathyroids are divided into superior, common, and inferior, or internal. Walsh describes these glands in adult man as each from 6 to 7 mm. in length, 3 to 4 mm. in breadth and of uniform thickness. Each of these glands is supplied by a terminal artery, and the arterial supply is very largely obtained from the inferior thyroid artery of the trunk branch of anastomosis between the superior and inferior thyroid vessels.

If the parathyroid glands are extirpated from an animal, tetany develops. This is positively the case in dogs. These glands certainly have important functions in the metabolism of the body. MacCallum and Voss (Johns Hosp. Bull., March, 1928) believe that damage or removal of these glands causes great changes in calcium metabolism.

Very little is known of diseases of the parathyroid glands. A few small tumors have been reported, each being an example of a hyperplastic adenoma. One of these cases was reported by the author in "Surgery, Gynecology, and Obstetrics," Jan., 1909. In this case the tumor was removed under the impression that it was an adenoma of the right lobe of the thyroid gland. The pathologic report, however, showed it to be a parathyroid. A tumor of any kind followed the operation, though at a later period enlargement of the opposite side of the neck occurred. This has been let alone through fear that it may be a left parathyroid.

Some persons have maintained that deficiency of parathyroid secretion is the cause of paralysis agitans, but this idea has been warmly contested. It lacks evidence. Several observers believe that there is a deficiency of parathyroid secretion in exophthalmic goiter.

In view of the well-known fact that removal or damage of the parathyroids will result in tetany, provided that several of these glands or all of them are

damaged or removed, it becomes the duty of the surgeon, when operating for goiter, to exercise the utmost care that he does not remove any of these bodies. The safest way to avoid them is to retain the posterior portion of the capsule of the thyroid gland. If, during an operation, any small body that resembles a parathyroid is detected, it should be let alone; or if such a body has been accidentally removed, it should immediately be implanted into the capsule of the lobe of the thyroid gland that has been left undisturbed. It is highly improbable that the removal of even both parathyroids on one side will cause tetany if there are two normal parathyroids on the opposite side.

On account of the possibility of the development of tetany, the question of the transplantation of parathyroids from animals becomes extremely important. Halsted has made some very valuable experiments upon the auto- and iso-transplantation of the parathyroid glands in dogs ("Annals of Surgery," Oct., 1907; "Jour. of Experimental Med.," vol. xi, No. 1, 1909). He has shown that if the parathyroid be transplanted into an animal with normal parathyroids failure will follow, and the transplanted glandule will disappear. If, however, there is parathyroid deficiency in the animal into which the transplantation is made, the glandule will attach itself and grow. He obtained the best results by placing the parathyroid beneath the posterior sheath of the rectus muscle of the abdomen. Some observers have placed it in the spleen; others, within the peritoneum and in various other regions.

If tetany follows an operation, it may be treated by the intravenous, rectal, or stomach administration of a 5 per cent. solution of lactate of calcium (MacCullum and Voegtlin, *Ibid.*). Beebe and Berkeley have prepared a parathyroid serum that they claim to be efficient. Charles H. Mayo maintains that in tetany either the serum or the calcium lactate should be used, in the hope of tiding the patient over until parathyroid glands can be secured and implanted ("Annals of Surgery," July, 1909). Joseph H. Branham ("Annals of Surgery," August, 1908) has reported tetany following thyroidectomy cured by the subcutaneous injection of parathyroid emulsion. The emulsion was made by grinding up fresh glands of heeves in a mortar, and then pouring 400 cc. of sterile salt solution into the mortar. The preparation was filtered through sterile gauze and was administered beneath the patient's breast.

When tetany begins to develop in a patient there are usually headache, dizziness, and pain in the extremities. The muscles in one or both forearms and hands are liable to be affected. The hand flexes at the wrist, while the fingers are extended, and in some cases the forearm flexes at the elbow. Now and then the fingers will flex at the metacarpophalangeal joints, but the distal phalanges will remain extended. These spasms are painful. Similar spasms may occur in the feet and toes. In the most severe cases the trunk muscles and those of the chest, throat, and eye may be involved.

Trousseau, years ago, showed that a spasm may be brought on in the affected limb by pressing upon the nerve-trunks and blood-vessels; this is called the *Trousseau sign*. Pressure upon the facial nerve may induce the spasms, and it is called *Chrostek's sign*. *Erb's sign* is a great increase in the galvanic irritability at the motor nerves. *Hoffmann's sign* is excessive sensitiveness of the sensory nerves.

Tetany due to absence of the parathyroids will inevitably prove fatal without active treatment.

XXXIII. DISEASES AND INJURIES C

Wounds, Ruptures, and Occlusions of

--It was long believed that wounds of any almost certainly fatal. It is now known the root of the neck are rarely very dangerous to the vein. A wound of the duct is rarely so because the adjacent vital structures are apt and death rapidly ensues. Wounds of the occasionally, but very rarely, are inflicted during surgery. In 18 cases thus inflicted; in 8 cases of the glands, in 3 for malignant glands, and in 1 for the clavian artery. One alleged danger of wound is the adjacent vein. This is said to have happened when the short end of the cut duct does not bleed, the hemorrhage. In Fullerton's case, when a groove appeared in the stump of the duct and by way of a term appeared. In most cases the injury is not repaired when white fluid escapes from the wound. It may or may not cease spontaneously. If it continues, the strength is lost. I assisted Dr. Keen in the case in which it was inflicted. A thin fluid was found to come from a tear in the duct. It is to be remembered that the part of the duct is very variable and sometimes the clavicle. There was 1 death in 17 recorded cases. C. E. Briggs, in "Amer. Med.," Sept. 21, 1901.

The discharge from a cut duct may continue for more than twenty-four hours. In some cases the local effects will sooner or later become evident. In a case reported by Klin, Woch., Nov. 28, 1901, it was not known until the stitches were removed from the wound that the duct was found distended with chyle and Scholl packed it. Five days later the patient died from chylothorax and chylous diarrhea.

Rupture of the thoracic duct or of the cervical duct may be a primary traumatism or be a secondary consequence. Rupture leads to death by starvation, or to fatal chylous diarrhea. Rupture of the main duct may be followed by rupture of the branches. Gradual occlusion by a tuberculous or inflammatory process may cause any serious symptoms. Cushing assumes that the current is reversed and is taken up by the right lymphatic system. In cases of obstruction masses of dilated lymph vessels are found in the thorax and abdomen. If lymph vessels are occluded, according to the situation, there arises "chylous diarrhea" or "chylous sweat" (Harvey W. Cushing, "Ann. Surg.," 1901).

Treatment of Wounds.—If the wound is deep, it should divide the duct, and if the duct wound is discovered

suture the duct. Allen sutured the duct and had no further leakage. Keen sutured the duct and recovery followed. If the duct is completely divided, follow Cushing's advice: "It would seem advisable to place a provisional ligature about the duct on the proximal side of the wound, and to control the leakage, if possible, by a gauze tampon. This would act as a safety-valve, and allow chyle to escape, if the pressure in the duct became too great and there was difficulty in establishing a collateral lymphatic circulation. The patient meanwhile should be given a meager diet. If the leakage should become uncontrollable and threaten starvation, the provisional ligature should be tied, with the hope of a final readjustment of collateral circulation or trusting in the presence of some anomalous anastomotic branch which might suffice to carry the lymph into the venous circulation" ("Annals of Surgery," June, 1898). Fullerton tied both ends of a divided duct and the patient recovered ("Brit. Med. Jour.," June 16, 1906). Deanesley ("Lancet," Dec. 26, 1903) inserted the divided duct into the internal jugular vein and sutured it in place. There was some leakage, but recovery ensued. After ligation the duct on the proximal side of the ligature may distend greatly and may actually rupture. When a wounded duct is leaking, the patient should be fed exclusively on proteids. The diet should be scanty and the patient must be kept absolutely quiet in order to keep pressure in the duct at as low a level as possible during the establishment of a collateral lymphatic circulation (Fullerton).

Lymphangitis is inflammation of lymphatic vessels. *Reticular or capillary lymphangitis*, which is inflammation of lymphatic radicles, is seen in some circumscribed inflammation of the skin. It is apt to attack the hands, causing redness and swelling, fading at the point of initial trouble while it spreads at the periphery; it is caused by micro-organisms derived from decomposing animal matter (Rosenbach). Erysipelas also causes it (see Erysipelas). *Tubular lymphangitis*, which is due to the entry into the lymphatic ducts of virulent micro-organisms or toxic materials, is seen after the infliction of dissecting-wounds, septic wounds, snake-bites, etc. It is announced by edema and by minute, hard, red streaks running from the wound up the extremity. Suppuration may occur.

Septic or infective lymphadenitis, or inflammation of the glands, may follow lymphangitis or may be due to the deposition of infective material, the lymph-vessels not being inflamed. In this form of lymphadenitis there are pain, tenderness, and swelling; in severe cases there are a chill and a septic fever. Suppuration may arise. The *treatment* is to drain and asepticize the wound, to apply iodine, blue ointment, or ichthyol over the glands and vessels, and to employ rest, heat, and compression. Internally, milk-punch, quinin, and nourishing diet are required. If the glands do not rapidly diminish in size after disinfection of a wound, and if they are in an accessible region, excise them. If suppuration of the glands occurs, incise and drain.

Acute lymphadenitis, or acute inflammation of the lymphatic glands, may be due to tubercle, syphilis, glanders, cold, or traumatism. Suppuration may or may not occur. In inflammatory lymphadenitis there are pain, heat, and nodular swelling. In severe cases there is fever.

The *treatment* is to asepticize any area of infection, place the glands at rest, apply heat and ichthyol ointment, or inject into the gland every day 5

minims of a 3 per cent. solution of carbolic acid to prevent suppuration the glands do not rapidly shrink, extirpate them. If pus forms, evacuate it, drain, and asepticize.

Chronic lymphadenitis is almost invariably syphilitic or tuberculous. It requires constitutional treatment and the local use of ichthyol, iodine or blue ointment. If these remedies are not rapidly successful, tuberculous glands should be removed, but syphilitic glands will rarely require such radical treatment.

Lymphangiectasis (*varicose lymphatics*), or dilatation of the lymphatic vessels, is due to obstruction. Many external causes may produce obstruction;

Fig 726 — Spurious elephantiasis. No filariae found. Born and lived in Philadelphia.

tion; for instance, the removal or suppurative annihilation of a considerable group of lymphatics; pressure of a tumor or of a new-growth upon lymph-vessels; tuberculosis or neoplasm of a group of glands. In many cases of external pressure upon lymphatics there is no lymphangiectasis because the lymph finds other channels. In fact, it has been proved that ligation of a large lymphatic trunk is not of necessity followed by lymphangiectasis. Even when the condition arises from external pressure, it is usually temporary, although, particularly if glandular tumors exist, it may be permanent.

The persistent cases are usually due to obstruction within the ducts, for instance, endothelial proliferation as a result of chronic lymphangitis.

or recurrent attacks of acute capillary lymphangitis (erysipelas) or ordinary acute lymphangitis; or tuberculosis and other chronic infections. There may be such a condition as primary intralymphatic endothelial proliferation ("Med. Record," Sept. 6, 1902). Blocking with *filarial* worms may occur, and if it does, the lymphangiectasis is usually situated in the axilla, the inguinal, or the scrotal region, or on the inner side of the thigh. There are two forms: the *varicose*, in which the vessels have a tortuous outline, like varicose veins, but are covered only with surface epithelium, and *lymphatic warts* (*lymphangioma circumscriptum*), in which wart-like masses spring up, these masses being covered with epithelium and filled with lymph. In most cases of lymphangiectasis there is considerable hard edema. Periodic attacks of pain and redness occur in the area of disease, and usually at such

times fever develops. Rupture of the dilated vessels causes a flow of lymph (*lymphorrhœa*). Infection and erysipelas are apt to occur; it may be over and over again. It is uncertain whether these repeated attacks of erysipelas cause and maintain or are predisposed to by lymphangiectasis.

Treatment.— If the entire area can be removed, it should be extirpated. Maitland ("Brit. Med. Jour.," Jan. 25, 1902) shows that many varices are local and can be removed. If the varices are only partially removed, lymphorrhœa will probably develop.

Lymphangioma is an advanced stage of lymphangiectasis (page 362).

The **treatment** in mild cases is to pierce each vesicle with the negative pole of a galvanic battery and pass a current. In severe cases destroy the mass with the Paquelin cautery or excise it with a knife or with scissors.

Elephantiasis. —

True elephantiasis (*elephantiasis arabum*) is chronic hypertrophy of the skin and subcutaneous tissues following upon a lymphangiectasis produced by a nematode worm (the *filaria sanguinis hominis*).

Spurious elephantiasis (Fig. 728) is hypertrophy of the skin and subcutaneous tissue due to chronic inflammation (for instance, in a leg which possesses an ancient ulcer, or in the scrotum of a man with urinary fistula).

The **treatment** is massage and bandaging, sometimes ligation of the artery of supply, extirpation, or amputation.

Fig. 729 — Hodgkin's disease (Patterson).

Tuberculous Glands.—(See page 253.)

Lymphadenoma (*Malignant Lymphoma*; *Hodgkin's Disease*; *Pseudo-leukemia*). —The term lymphoma is used loosely to designate any persistent swelling of a lymphatic gland or glands. Lymphadenoma means a swelling of lymph-glands or lymphadenoid tissue, which swelling is progressive in character, involves group after group of glands, is associated with anemia, and often accompanied by secondary growths in the abdominal viscera.

Fig. 729 exhibits a case of Hodgkin's disease.

This disease is most common in those under forty, and affects males far more frequently than females. In many cases the disease arises slowly in apparently healthy glands, and exists for some time before it takes on signs

of malignancy and invades distant glands. In some cases the disease has a tendency to generalization from the start; in others it appears to remain localized for many months. A gland enlarged from irritation or from tuberculous disease may become lymphadenomatous, and tubercle bacilli can sometimes be found in lymphadenomatous glands. Lazarus asserts that the disease is lymphosarcoma and the tuberculosis accidental. Musser, Sternberg and others believe that tuberculosis is the disease. Some few believe that lymphadenoma is really tuberculosis, but this view seems to have been definitely disproved.

That the disease is at least similar to sarcoma seems certain. That it is a variety of sarcoma is highly probable. There is a form of tuberculous disease strongly resembling Hodgkin's disease, but I do not believe that the two processes are identical. The glandular and splenic enlargements are neoplastic and not hyperplastic. The new tissue formed is called lymphadenoid tissue and, according to Banti, it is often atypic, tends to invade glandular trabeculae and capsules, sometimes adjacent tissue, and gives origin to metastases.

Leukemia and pseudoleukemia are closely related, and both, according to Banti, are sarcoma. In leukemia the influence that stimulates proliferation falls chiefly upon the bone-marrow; in Hodgkin's disease, upon the lymph nodes (Neumann, quoted by Coley, in a forceful article maintaining that Hodgkin's disease is a type of sarcoma, "Transactions American Surg. Assoc.," 1902).

Symptoms. The glands in the neck are usually involved first but the disease may begin in the axillary glands, the thoracic glands, or the intra-abdominal glands.

Two or more regions are sometimes involved simultaneously or almost simultaneously.

When the disease begins in the neck it affects at first one side and after many weeks or months the other side becomes involved. The glands are at first hard, separated from each other, movable, and the skin moves freely over them. Later the large glands weld together and form great masses upon both sides of the neck and in the axilla, which may obstruct respiration.

After a time a very large mass may break through its capsule and invade adjacent structures, and in very rare cases the skin becomes adherent and finally breaks. Intrathoracic symptoms point to involvement of the thoracic glands. It may be possible to palpate enlarged abdominal glands.

The leukocytes may be increased to 20,000 or more, but in many cases the count is normal and the relative proportion of the varieties remains normal. In a certain percentage of cases, without any increase in the number of leukocytes, there is great relative lymphocytosis. Early in the disease the number of red cells may be unaffected, but after a time anemia develops. A fall in hemoglobin is noted early and this fall is somewhat more rapid than the decrease of erythrocytes ("Clinical Hematology," by J. C. Dacie, 1910).

The spleen is enlarged, the thyroid may be enlarged. When adenopathy becomes marked there are the ordinary symptoms which go with it: viz. palpitation, breathlessness, indigestion, vertigo, headache, pallor, and sometimes epistaxis. Occasionally, without obvious reason, the glands suddenly increase in size or rapidly undergo a notable but temporary diminution.

Slight fever exists at times in many cases, and ague-like paroxysms may occur. During the existence of fever the glands usually increase rapidly in size.

Diagnosis.—In a wide-spread case the diagnosis is easy; in a localized case it is difficult. True tuberculous glands are most apt to first appear in the submaxillary triangle; lymphadenomatous glands, in the root of the neck or in the occipital triangle. Tuberculous adenitis is most common in children. As a rule, tuberculous glands caseate, but they may remain localized for years if caseation does not occur. The tuberculous glands usually soon become adherent and immovable. Lymphadenoma is most common after twenty, rarely remains localized for more than a few months, rarely softens unless very large, and the glands are separated and movable until a huge mass forms. Early softening, prolonged limitation to one region, and absence of pronounced anemia in a person under twenty point to tubercle. In doubtful cases a gland should be removed for microscopical and bacteriological study.

In widespread tuberculous lymphatic involvement, simulating Hodgkin's disease, fever is far more likely to be present than in Hodgkin's disease. La-Roy ("Archives Internat. de Chir.," 1907, vol. iii) points out that tuberculous glands are but little improved by the x-rays, whereas, enlargements in Hodgkin's disease may be greatly benefited, and that in tuberculous conditions there is no particular tendency to hemorrhage and there often is in Hodgkin's disease. Coley shows (Ibid.) that the patients with Hodgkin's disease react strongly to the toxins of erysipelas.

Prognosis.—The disease is almost always, if not invariably, fatal. Most cases die within three years, some die within six months, some few live four or five years or more.

Treatment.—If the glands are localized to one side of the neck, or even to both sides of the neck, remove them. Early removal before dissemination has occurred may possibly save the patient. If early or radical removal is not possible, do not operate, but treat the patient with nutritious food, tonics, course of arsenic, the mixed toxins of erysipelas and the bacillus prodigiosus, and applications of the x-rays. Coley treated a case with the mixed toxins and after two months the lymphatic and splenic enlargements entirely disappeared. Seven months later the patient was still well ("Transactions of Am. Surg. Assoc.," 1908). Efforts are now being made to obtain a curative serum. Beck makes nucleoproteid serum from the glands of cases of Hodgkin's disease.

XXXIV. BANDAGES.

A **BANDAGE** is a fibrous material which is rolled up and is then employed to retain dressings, applications, or appliances to a part, to make pressure, or to correct deformity. It may be composed of flannel, of calico, of unbleached muslin, of plain gauze, of gauze infiltrated with plaster of Paris, or soaked in silicate of sodium, or of gauze wet with corrosive sublimate solution. Unbleached muslin, which is the best material for general use, is washed to remove the sizing, is torn into strips, and the edges are stripped of selvage. One end is folded to the extent of six inches, this is folded up on itself again and again until a firm center is formed, and over this center the bandage is rolled. In a well rolled bandage the center cannot be pushed out of the roll. A roller bandage is divided into the initial end, which is within the roll, the body or rolled part, and the terminal end, which is free. In applying a bandage the outer surface of the terminal end is first laid upon the part.

A *cylindrical* part of the body may be covered by a *circular* bandage, each turn exactly covering the previous turns. A *conical* part may be covered by a *spiral* bandage, each turn ascending a little higher than the previous turn. As each turn of a spiral bandage is tight at its upper and loose at its lower edge, the *reverse* was devised to correct this inequality, hence a conical part should be covered by a *spiral reversed* bandage. To make a reverse, hold the roller in the right hand, start the bandage obliquely up the limb (do not have more than six inches of slack), place the thumb across the first turn, fold the bandage down without traction, and do not make traction until the turn has been carried well around the limb. A projecting point is covered with *figure-of-eight* turns. The groin, shoulder, breast or axilla can be covered by figure-of-eight turns, each succeeding turn ascending and covering two thirds of the previous turn and forming a figure like "the leaf on an ear of corn." Such a figure is called a "spica." In bandaging an extremity the peripheral turns should be tighter than the turns nearer the body. Never apply a tight bandage to the leg or the arm without including the foot or the hand. In firm dressings of the forearm and arm it is well to leave the ends of the fingers exposed, and use them as an index of the condition of the circulation in the part. In firm dressings of the leg and thigh leave the toes exposed.

Spiral Reversed Bandage of the Upper Extremity.—To apply this form of bandage use a roller two and a half inches wide and eight inches long. Take a circular turn about the wrist, and a second turn to hold the first, pass obliquely across the back of the hand to the extremities of the fingers, ascend the hand to the root of the thumb by several spiral turns.

Fig. 730.—Spiral reversed bandage of the upper extremity.

cover the wrist by ascending figure-of-eight turns, ascend the forearm by spiral reversed turns; cover the elbow by a figure-of-eight, and the arm by spiral reversed turns; end the bandage by two circular turns, and pin them together (Fig. 730).

Spiral Bandage of All the Fingers (Gauntlet).—The gauntlet bandage requires a roller one inch wide and three yards long. Take two circular turns around the wrist, pass obliquely across the wrist to the root of the

Fig. 731.—Gauntlet bandage.

Fig. 732.—Demi-gauntlet bandage.

thumb, and descend to its tip by spiral turns; cover in the thumb by ascending spiral turns, and return to the wrist. Cover successively each finger in the same manner, and terminate by two circular turns around the wrist (Fig. 731).

Spiral Bandage of the Palm or Dorsum of the Hand (Demi-gauntlet).—The demi-gauntlet requires a roller one inch wide and three yards long.

Fig. 733.—Spica of the thumb.

This bandage has only a limited value; it must not be applied tightly, as it makes much pressure at the finger roots, but leaves the fingers free. If it is desired to cover the palm, supinate the hand; if to cover the dorsum, pronate the hand.

Take two circular turns around the wrist, sweep around the root of the thumb, and return to the point of origin. Treat each finger in the same way. End by circular turns around the wrist (Fig. 732).

Spica of the Thumb. For this bandage use a roller one inch wide and three yards long. Start at the wrist, and reach the tip of the thumb as in applying a spiral bandage of a finger. Make a series of ascending figure-eight turns between thumb and wrist, each ascending turn overlying two-thirds of the previous turn; terminate with a circular of the wrist (Fig. 733).

Selva's Thumb Ban-

lage (Fig. 734).—Lay the

terminal end of the bandage

in the outer side of the sec-

ond phalanx of the thumb,

near the base of the pha-

lanx. Carry it over the

palmar side of the pulp of

the last phalanx to the inner side of the second phalanx. The surgeon holds this

turn in place with his left thumb and index finger. The roller is returned in a

recurrent manner to its place of origin, overlaps the preceding turn, and is placed

as much as possible on the dorsum. The roller is carried over the dorsum

Fig. 734.—Selva's thumb-bandage applied

long. Apply as a spiral reversed bandage of the lower extremity until the metatarsus is well covered. Carry the bandage, parallel with the margin of the foot (the inner or outer margin, according as to whether it is the left foot or the right), around the posterior aspect of the heel, along the opposite margin of the foot to cross the original turn at the median line of the dorsum. Make a number of these ascending turns, each turn covering in three fourths of the previous turn; terminate by circular turns above the ankle (Fig. 738).

Crossed Bandage of Both Eyes (Figure-of-eight of Both Eyes).—Take a roller two inches wide and six yards long. Make a circular turn around the forehead from right to left, a second turn to hold the first, a turn downward over the left eye, under the left ear, around the back of the neck, and upward under the right ear and over the right eye; repeat these turns, and terminate by a circular turn of the forehead (Fig. 739).

Barton's Bandage (Figure-of-eight of the Jaw and Occiput). Take a roller two inches wide and five yards long. Place the initial extremity of the bandage behind theinion; pass over the right parietal bone, across the

Fig. 739.—Crossed figure-of-eight bandage of both eyes

Fig. 740.—Barton's bandage or figure-of-eight of the jaw.

vertex, down the left side in front of the ear, under the chin, up the right side in front of the ear, across the vertex, and across the left parietal bone to the point of origin. A turn is now taken forward along the right side of the jaw to the chin, and backward along the left side of the jaw from the chin to the nape of the neck; repeat these turns, and pin the points of junction (Fig. 740). In Barton's bandage the ear lies in an uncovered triangle. The bandage may be finished by circular turns around the forehead. Barton's bandage is used for fracture of the lower jaw.

Borsch's eye-bandage is convenient and useful (Fig. 741). A narrow bandage is laid along the head and permitted to hang down the face in front of the sound eye. A circular bandage is applied around both eyes and over the narrow bandage (A). The narrow strip is lifted and pinned, and the sound eye is thus uncovered. Of course, the posterior end of A should first be pinned to the circular turn.

Gibson's Bandage.—Take a roller two inches wide and six yards long. Make three vertical turns around the head and the jaw in front of the ear;

Bandages

Carry the bandage above the level of the ear, and carry it horizontally around the forehead and head three times; drop the bandage to the nape of the neck, and take three turns around the neck and jaw; terminate by carrying from the nape of the neck a half turn upward, carrying the bandage forward to the forehead, and pinning it over the neck and over the forehead.

Fig. 741.—Borsch's eye-bandage. A, First step; B, second step.

Pin each point of junction (Fig. 742). Gibson's bandage is used for fracture of the lower jaw.

Crossed Bandage of the Angle of the Jaw (Oblique Bandage of the Jaw).—Take a roller two inches wide and six yards long. Make a circular turn around the forehead toward the affected side, and a second turn to hold the first; take the turn to the back of the neck; carry it forward on the sound side, under the ear and chin; now make a series of turns around the head and jaw, in front of the ear on the injured side, but back of the ear

Fig. 742.—Gibson's bandage.

Fig. 743.—Oblique or crossed bandage of the angle of the jaw.

on the sound side: these turns successively advance on the injured side until terminate by going backward under the ear of the sound side to the nape of the neck, and then by taking two circular turns around the forehead (Fig. 743). This bandage is used for fractures of the ramus of the jaw and for holding dressings upon the face and the cranium.

Spica of the Groin (Figure-of-eight of the Thigh and Pelvis).—For one groin the roller is three inches wide and seven yards long; for both groins, three inches wide and ten yards long. Take two circular turns, from right to left, around the waist, then down over the front of the right groin, around the back of the thigh, up over the front of the right groin, around the waist, down over the front of the left groin, round the back of the thigh, up over the left groin, and around the waist. The map being thus laid out, the

Fig. 744.—Spica of the groin.

Fig. 745.—Spica of the shoulder.

turns are continued and ascended, each turn overlying one-third of the previous turn, and the bandage is completed by a circular turn around the waist (Fig. 744). Pin the crossed pieces.

Spica of the Shoulder. Take a roller two and a half inches wide and seven yards long. Make a circular turn and several spiral reversed turns around the upper arm; then, coming from behind forward, carry the bandage over the shoulder, across the front of the chest, through the opposite arm-pit, and return across the back to the shoulder. Make successive and advancing turns (Fig. 745).

Fig. 746.—Figure-of-eight bandage of the elbow.

Fig. 747.—Posterior figure-of-eight of both shoulders.

Figure-of-eight bandages of the elbow, both shoulders (posterior figure-of-eight), the neck and axilla are shown in Figs. 746, 747, and 748. A figure-of-eight of the breast is shown in Fig. 753.

Velpeau's Bandage.—Take a roller two and a half inches wide and

ten yards long. Place the palm of the hand on the shoulder of the sound side, interposing cotton side. Start the bandage at the axilla of the injured side. It crosses the back to the shoulder of the injured arm and under the arm just above the elbow, and repeat this turn, but, on reaching the axilla of the sound side, pass around the chest, including the arm

Fig. 748.—Figure-of-eight of neck and axilla.

each alternate turn going over the injured side. On circling the arm and the body, the first turns are ascending (Fig. 749). Pin the crossed piece of bandage to the skin over the fracture of the clavicle.

Desault's Apparatus.—This apparatus consists of a pad, a roller, and a sling. Each roller is two and a half inches

Fig. 750.—Desault's bandage, first roller.

Fig. 7

The pad, which is wedge-shaped, is inserted under the arm. The *first roller* is used to hold the pad in place and binds the arm to the side over the pad. This is the weight, the arm is the lever, and the second roller corrects the inward deformity of a fractured clavicle. The second roller corrects the downward and forward displacement of the sound side anteriorly, crosses the chest

side, runs down the back of the arm, around the elbow, and crosses the chest to the point of origin, forming the anterior triangle; it is now carried through the axilla of the sound side to the back, crosses the back to the shoulder of the injured side, runs down the front of the arm, around the elbow, and across the back to the axilla of the sound side, forming the posterior triangle (Fig. 752). The formula for the Desault bandage is: start in the axilla of the sound side anteriorly, run from the axilla to the shoulder, from the shoulder to the elbow, from the elbow to the axilla, and pass to the back; from the axilla to the shoulder, from the shoulder to the elbow, from the elbow to the axilla, and pass to the front. Pin the crossed pieces and hang the hand in a sling (Fig. 752).

Recurrent Bandage of the Head.—Take a roller two inches wide and six yards long. Make two circular turns horizontally around the forehead and head; when the middle of the forehead is reached, catch the bandage, take a half turn, carry the bandage to the occiput, let an assistant catch it, take a half turn, bring the roller forward to the forehead, covering a portion of the preceding turn; continue this process until the scalp is well covered:

Fig. 752.—Desault's bandage, third roller.

Fig. 753.—Figure of eight bandage of the breast.

terminate with two circular turns around the forehead and head (Fig. 754). It is often advisable to take a turn around the head and chin. Pin the crossed pieces.

Recurrent Bandage of a Stump. Take a roller two inches wide and six yards long. Make two light circular turns around the root of the stump, make recurrent turns covering the stump as is done in covering the head; take a circular turn around the root of the stump, oblique turns to the top of the stump, circular turns around the tip, and apply an ascending spiral reversed bandage (Fig. 755).

T-Bandage of the Perineum. Pass the transverse part around the body above the iliac crests, and pin it in front; bring one of the tails over the dressing and up between the thigh and the genitals of one side, and the other tail over the dressing and up between the thigh and the genitals of the opposite side; secure these tails to the horizontal band.

Handkerchief Bandages. Take unbleached muslin one yard square. The muslin folded once makes an *oblong* bandage; bringing its diagonal angles together makes a *triangle* bandage; a *cravat* is formed by folding a

triangle bandage from summit to base; a *cos* triangle makes an admirable sling.

Fixed Dressings. Plaster-of-Paris Bandage.—With a cotton or flannel bandage or with a wool roller infiltrated with plaster and place it end of the water covering the plaster. When bubble bandage and apply it *without much tension*, on a moistened hand. As each bandage is taken one into the water. Apply four thicknesses of bandage by sprinkling dry plaster over the bandage hands. The ordinary plaster will set in from it is desired to have it set more rapidly, put a pint of water used; if to have it set more slowly. The plaster bandage is removed by sawing it with dilute hydrochloric acid and then *cut* line with a strong knife. Gigli has devised

Fig. 754.—Recurrent bandage of the head.

enables us to remove the dressing with ease. around the limb. A piece of parchment paper shaken out is placed over the cotton. A cord upon the paper in a position corresponding to through the plaster. Apply the plaster bandage the cord project beyond the bandage. When *cut* take a steel wire, make nicks on one side of it the string to the wire. Pull the wire under the of the wire to a wooden handle and saw through

Silicate of Sodium Dressing.—Protect the bandage. Bandage the limb *loosely* with an of this bandage with silicate of sodium, apply a and so on until six layers are applied. Give ordinary bandages to take up silicate of sodium from twelve to eighteen hours to dry, and *cut* with warm water and then cutting

XXXV. PLASTIC SURGERY.

PLASTIC surgery includes operations for the repair of deficiencies, for the replacement of lost parts, for the restoration of function in parts tied down by scars, and for the correction of disfiguring projections. Many reparative operations have been devised. Among them are: cheiloplasty, or the construction of a new lip; the closure of a cleft in the palate, the lip, or the penis; the making of a new nose; skin grafting; grafting of muscle or tendon; nerve grafting; the introduction of celluloid or metal into the tissues to act as supports, the injection of paraffin into the tissues to amend a de-

Fig. 756. Injuries caused by crush and burn. Healed by granulation in eight months. Showing a condition after removal of scar of the palm which has been repaired by stitching in an autoplasmic graft (free flap) from the thigh (Geo. S. Brown).

pression; the diminution in the size of a lip or a nose; the amendment of protuberant ears; the correction of distortion due to cicatrices, excision of scars; closure of congenital sinuses and of fistule, removal of disfiguring growths.

The subject of plastic surgery is very extensive, and a treatise upon it should be consulted if one wishes to obtain detailed and comprehensive information.

A plastic operation can be successful after lupus only when the disease has been cured. It is useless to do a plastic operation during active syphilis,

and a plastic operation for a syphilitic loss of substance is to be performed only after the patient has been thoroughly treated and the disease has been apparently cured. The first step of a plastic operation consists in making the surfaces which are to be brought together raw, the second step is the complete arrest of bleeding; the third step is the approximation of the surfaces without tension; the fourth step is to close any gap from which tissue may

have been transplanted, and the final step is the application of the dressing.^{*} The following are the methods used:

Displacement is the method of stretching or sliding. (1) approximation after freshening the edges (as in hernia), (2) sliding into position after transferring tension to other localities (linear incisions to allow of stretching of the skin over large wounds). *Interpolation* is the method of borrowing material from an adjacent or a distant region or from another person. (1) *transferring a flap with a pedicle*, which flap is put in place at once & is gradually gotten into place by a series of partial operations (as in rhinoplasty, when a flap is taken from the forehead).

Fig. 757. Back of hand from burn. A flap with a pedicle was taken from the chest. The pedicle was cut on ninth day.

transplanting without a pedicle, which is performed by placing in position and by fixing there portions of tissue recently removed from the part, from another part of the same individual, or from a lower animal (as replacement of a button of bone after trephining, transplanting a piece of bone from a lower animal to remedy a bone defect in a human being, or the grafting of a piece of nerve from a lower animal or an amputated human limb to remedy a loss of nerve in a human being in nerve grafting, or skin grafting). *Resection* is the removal of redundant material and the production of cicatricial contraction.

Skin-grafting. As long ago as 1847 Dr. Frank Hamilton partly cured an ulcer with a pediculated flap, and trusted that the uncovered portion would be healed by new skin from the flap. We may graft small pieces of epithelium taken from the patient, or another person, or one of the lower animals, or we may graft large pieces of epithelium. The grafts should, if possible, come from the person to be grafted. The epidermic scales may be scraped

* "American Text book of Surgery."

off the sound skin and grafted. Lusk has blistered the skin with cantharides and grafted portions of the epidermis. The shavings of a corn have been used. The best plan is to cut off and transplant small bits of epidermis.

Grafts may come from another person or from a lower animal, but such grafts are not so apt to grow as grafts obtained from the individual, and even when they do grow, fail to furnish a secure cicatrix. Frog-skin furnishes unsatisfactory grafts. Some surgeons have used bits of sponge; others the skin of rabbits, guinea-pigs, or pups. Arnot has employed the lining membrane of a hen's egg, cut in strips and applied upon the wound with the shell-surface uppermost. Small bits of epidermis taken from a recently amputated foreskin or leg may be used.

Reverdin's Method.—This operation was devised by Reverdin in 1869. Small bits of epithelium are used and they are taken preferably from the person himself. The surface to be grafted should possess healthy granulations level with the skin. Cleanse the skin from which the grafts are to come, the ulcer, and the skin about it, and, if corrosive sublimate is used, wash it away with a stream of warm normal salt solution. Thrust a sewing-needle under the epidermis to raise it, cut off the graft with a pair of scissors, and place the raw surface of the graft upon the ulcer. After applying a number of grafts, place thin pieces of gutta-percha tissue over them and extending on each side of the ulcer, and so placed as to have distinct intervals between them, the gaps permitting drainage. This tissue, after being asepticized, is moistened with warm normal salt solution. Dress with a pad of aseptic gauze moistened with salt solution; place over this gauze a rubber-dam, and over the latter absorbent cotton and a bandage. In the case of children apply a light silicate bandage. Put the patient in bed. In forty-eight hours remove all the dressings except the gutta-percha tissue, irrigate with normal salt solution, and reapply the dressings. All signs of the grafts will often have disappeared. In a day or two, at the site of grafting, bluish-white spots should appear, which are islands of epidermis. Each graft is capable of forming about half an inch of cicatrix. Grafting also stimulates the edges of the ulcer to cicatrize and contract. At the end of seven days the special dressings can be dispensed with. The spot from which the grafts are taken is dressed antiseptically. Reverdin's method does not limit cicatricial contraction to any great degree, and the new skin is apt to break down.

The Ollier-Thiersch's Method.—Ollier, of Lyons, in 1872 succeeded in transferring large pieces of epidermis. In 1886 Thiersch, of Leipzig, set forth the technic practically as it is employed to-day. The Ollier-Thiersch method is performed as follows: Thoroughly asepticize the ulcer, the surrounding skin, and the site from which the graft is to come (the inner side of the arm or the thigh), and wash away the mercurial preparation with normal salt solution. Apply dressings wet with salt solution. On bringing the patient into the operating-room remove the dressings from the ulcer, scrape the ulcer and its edges, irrigate with salt solution, and compress to arrest hemorrhage. Grafts are then obtained by putting the prepared skin upon the stretch and cutting strips with a razor. While the razor is being used the part is constantly irrigated with salt solution. Mixer's apparatus enables one to perform this operation with great neatness and speed. This apparatus consists of a knife and an open square with sharp points on the under surface.

The square is forced down upon the front of the up in the opening to above the level of the m be cut with ease. The graft contains the ep the true skin. In Halsted's clinic the skin of pressing upon it with a piece of asepticized w along, and is followed closely by the sharp c cuts long grafts. The grafts are pressed into and each graft overlaps a little the edges of grafts. The skin-wound is dressed anti-septic dressed as in Reverdin's method. Recently a ring of aseptic gauze be made to encircle the and another ring above the grafted area; on the wrapped in aseptic gauze are so laid as to m cage the dressings are applied (moist chamber p

Wolfe's Method.—It was pointed out by W of skin, comprising the entire thickness of that transplanted without a pedicle. The ulcer is a bleeding is arrested. The flap is cut one-six be covered. Fat is kept out of the graft. T

Fig. 758.—Mayer's dressing for Thiersch's method of skin surgery.

the wound, the edges of the graft being brought area. It is not necessary to employ sutures chamber. If the graft perishes, remove it

Subcutaneous Injection of Paraffin

—The principle of injecting solidifying oils into effects was first laid down by J. Leonard C paraffin was introduced by Gersuny to amen nose. It has been used to limit incontinence in women, to prevent reunion of nerves after to obliterate smallpox marks, to narrow a hel of the cheek after removal of the upper jaw, a kowicz, in "Wien. klin. Woch.," June 20, 2 Its injection may produce some swelling and cold quickly control inflammation. In two or comes hard like cartilage and encapsuled I not it is subsequently destroyed and replaced times sloughing takes place in the skin above it.

Prepare the paraffin as follows: In Gersuny's with liquid paraffin. The melting point of the F. It is rendered sterile by boiling is injecte

a semisolid, the skin having been first warmed by a hot sponge. After injection it is molded into proper shape. It sets in half a minute. It is not wise to use a mixture with a much higher melting-point, because it would possibly cause thrombosis of veins. There are difficulties and even dangers in the use of paraffin for saddle-nose. It should only be used when the skin is loose and elastic. It should never be used if there is great deformity, because then the amount required would surely cause dangerous tension. It is difficult to prevent the injected material from passing down the sides of the nose and up into the forehead. Cases of embolism causing blindness have been reported. The skin may slough if the injection is too hot or if it produces much tension.

Correction of Saddle-nose by the Insertion of a Plate.—

Saddle-nose is a condition in which the bones and cartilages have been destroyed by ulceration or collapsed by injury. It is useless to attempt correction by skin flaps alone. Paraffin injections (page 1262) may be used in the less severe cases. In a bad case we must transplant bone flaps or insert a plate for sup-

Fig. 759.—Indian method of rhinoplasty.

Fig. 760.—Italian method of rhinoplasty.

port. The bone-flap operation is seldom satisfactory and of necessity creates a hideous scar. The insertion of a plate may give an excellent result, although the future is always uncertain. In 2 cases I have seen sloughing occur over the plate months after the operation. In one of these cases the sloughing was due to a blow from a cow's tail.

The plate used may be of silver, gold, or celluloid. An incision is made to permit the insertion of the plate. I agree with Leonard Freeman ("Annals of Surgery," August, 1907) that the incision along the bridge and the incision in the septum below the tip are both objectionable. The first leaves an unsightly scar and does not allow for stretching of the skin. The incision at the tip gives unsatisfactory access to the tissues requiring separation and is liable to infection from the nostril.

The best incision is Freeman's. This is a short incision across the root of the nose between the eyes. The skin is undermined along the bridge to the tip and along the sides. The undermined skin can be stretched if necessary.

Rhinoplasty. -The complete operation may be performed by transferring a flap from the forehead. This is known as the Indian operation. It was employed for centuries in India, and interest in it was awakened in England about 1820 by Mr. Carpue. The edges of the defect are made raw. A model of the desired nose is made out of gutta serena, and its outlines are marked upon the forehead, and the cut is made one quarter of an inch outside of the outline so as to allow room for retraction. The flap is turned down and sutured in place (Fig. 759), care being taken not to cut off the blood-supply in the pedicle. Plugs of gauze or tubes are inserted to support the flap.

The complete operation can be performed by the Italian method (Tagliacozzi's method). This method was first described in Tagliacozzi's book, which was published in 1597. In this operation the flap is marked out on the arm, is made twice the size of the desired nose, and is left attached by a broad pedicle. The nasal surface is rendered raw at proper intervals, and the flap is sutured in place, the hand being held upon the head in a special apparatus (Fig. 760). The raw surface upon the arm is dressed. In about three weeks the flap is cut loose from the arm, and is pared and corrected as may be necessary.

The operations for harelip and cleft palate, and plastic operations on muscles, nerves, tendons, and bones, are considered in other portions of the work.

XXXVI. DISEASES AND INJURIES OF THE GENITO-URINARY ORGANS.

Hematuria. By this term is meant the voiding of bloody urine, i. e. pure blood, the blood arising from any portion of the urinary apparatus, and the condition being a symptom and not a disease. Hematuria may be a symptom of disease or of injury of some part of the urinary system, or of disorganizations (purpura, scurvy, or variola), or of metallic poisoning (mercury, lead, or arsenic). The color of the urine in hematuria may be anything between a light red and a decided black, but these colors may be produced by agents other than blood. Senna and rhubarb make urine red; carbolic and salicylic acids, brown or greenish black; beet root and water, the color of blood; methylene-blue, blue. In jaundice, melanosis, and spotted fever the urine becomes brown. Be sure that bloody urine in the female is not due to admixture with menstrual blood.

Tests for Blood. - Spectroscope Test. - Bloody urine, if fresh and diluted with water, shows the two absorption bands of oxyhemoglobin. The addition of ammonium sulphid causes the two bands to give place to the band of reduced hemoglobin. If bloody urine stands for some time the four bands of methemoglobin are discovered (v. Jaksch).

Heller's Test. Add potassium hydrate to the urine, and heat a red precipitate of earthy phosphates and hematin forms. Throw the precipitate upon a filter and treat it with acetic acid; a red solution is produced, and soon fades.

Rosenthal's Test. - Take the precipitate from caustic potash, dry it,

and test it for hematin; put some of the dry sediment on a slide, add a crystal of common salt, apply a cover-glass, and cause a few drops of glacial acetic acid to flow under the glass; warm, but do not boil. Teichmann's crystals will appear on cooling.

Struve's Test.—Test the urine with hydrate of potassium, and add acetic acid in excess; a dark precipitate forms, which will yield crystals of hematin when treated with sal ammoniac and glacial acetic acid.

Almen's Test. Take 10 c.c. of urine, and pour upon its surface a mixture of equal parts of tincture of guaiac and old oil of turpentine; at the point of junction of this fluid with the urine there forms a white ring which turns blue.

Microscopic Test.—The microscope shows numerous corpuscles except in a very alkaline urine, when but few corpuscles may be found.

In hemoglobinuria—a condition sometimes occurring in burns, acute maladies, and metallic poisoning there is present blood-coloring matter, which is shown by Heller's test and by Almen's test. The spectroscope shows methemoglobin. The microscope shows no corpuscles or only a few, but discloses masses of pigment.

Bleeding from the Kidney-substance.—Bleeding from the *pelvis* of the kidney and from the *ureter* may be due to inflammation, congestion, contusion, stone, vicarious menstruation, hemorrhagic diathesis, powerful diuretics, fevers, purpura, tumors, catheterization of the bladder, etc. Blood is thoroughly mixed with the urine, and no sediment forms (smoky urine). The corpuscles are profoundly altered, are devoid of coloring-matter, and show pale yellow rings. The severity of the hemorrhage is measured by the number of the corpuscles. Von Jaksch states that the diagnosis between renal and ureteral hemorrhage rests on the nature of the casts and the epithelium present. From the *pelvis* of the kidney and from the ureter comes small epithelium, the cells from the superficial layers being polygonal or elliptical, those from the deeper layers being oval or irregular. In hemorrhage from the ureter the cells are few; in hemorrhage from the *pelvis* they are plentiful and rest upon one another like "tiles on a roof" (v. Jaksch). Cells from the tubules of the kidney are small, granular, and polyhedral, have large nuclei, and are often so arranged as to form cylinders (epithelial casts). The urine during and immediately after a renal hemorrhage is apt to be acid unless alkalis have been administered, unless the bleeding has been severe, or unless pus is present in the urine. A very large renal hemorrhage may cause the passage of almost pure blood. In renal hematuria there are aching in the loin, numbness of the corresponding leg, and often renal colic. The use of the cystoscope enables the surgeon to determine if the hemorrhage is vesical or renal, and if it comes from one or both kidneys. If the bladder-fluid is kept clear, the blood can be seen flowing out of the ureter of the damaged organ, or if both ureters are catheterized a sample of urine can be obtained from each kidney.

Ureter-catheterism.—Catheterization of the ureters may give information of the greatest value. It enables the surgeon to obtain the urine from one kidney unmixed with urine from the other kidney and uncontaminated by material from the bladder or urethra. By this method we can determine if pus, blood, bacilli, etc., come from the ureter or kidney, and from which

ureter or kidney. A stricture or a calculus of a ureter can be located, hydronephrosis and pyonephrosis can be diagnosticated, the presence of both kidneys, and if either kidney is diseased or if both are diseased, and the secretory capacity of each kidney in a given time, can be ascertained. The method is also employed to treat various conditions of the ureter and kidney.

Kelly impressed upon the profession that the ureters in women can be catheterized, when the patient by the knee chest posture permits the atmospheric distention of the bladder, so that the ureteral orifices can be inspected through a speculum. Light is reflected into the speculum, a forehead mirror and an electric light being employed. It may be necessary to dilate the ureter before inserting the speculum. It is rarely necessary to give a general anesthetic. Kelly moistens a bit of cotton wrapped on a metal rod or a

Fig. 761.—Nose's instrument in use (J. Berl. klin. Wochenschr.).

10 per cent. solution of cocain, introduces it just within the external urethral orifice, and holds it there for five minutes before beginning the operation. When the ureteral orifice of one side is found by inspection through the speculum, he introduces a sterile flexible silk catheter lubricated with hydro-glycerid and it is pushed up from four to six inches in the ureter. A second tube is introduced into the other ureter and the separated urines are collected in test tubes. (See Kelly's "Operative Gynaecology.") The catheterization of the ureters by this method can be performed only by a dextrous and experienced man; but such an individual can do it with ease and celerity. Practised by Kelly himself, it seems, until one tries it, the perfection of simplicity.

Kelly has catheterized the ureter in man by inserting a straight speculum, placing the patient in the knee chest position to inflate the bladder with air,

and introducing a metallic catheter. For a discussion of the technic of catheterizing the ureters see Cystoscopy, p. 1297.

Segregation of Urine.—Professor Harris, of Chicago, has devised an excellent instrument (Fig. 762) which in many cases greatly simplifies the

Fig. 762.—Harris's instrument fitted for use.

problem of obtaining unmixed urine from each ureter. The double catheter is passed into the bladder. The lever is inserted in the rectum of the male and the vagina of the female. The lever is fastened to the perforated frame from the double catheter. The double catheter is now opened in the bladder, and the blades of the instrument are held in position by a spring. The end of the lever in the vagina or rectum humps up the floor of the bladder

Fig. 763.—Lewis's ureter-cystoscope.

between the separated ends of the divided catheter, and forms a longitudinal septum or watershed between the ureteral orifices. The end of each catheter lies in the bottom of a pocket in the side of the watershed. "By producing a very slight exhaustion of the air in the vials by means of the bulb, the urine

as fast as it escapes from the ureters, drop catheters and flows at once into the vials, right

In using this instrument, place the patient the thighs and legs being flexed, and the feet same level. Irrigate the bladder thoroughly 150 c.c. of fluid in the bladder when the instrument in place for thirty minutes. It is anesthetic. In some cases cocaine must be used if there is a growth of the bladder that is contracted, or if there is a very large prostate

In catheterization of the ureters there is a

Vesical hemorrhage, including hemi may follow the relief of retention of urine, may tumors, etc., or may arise from traumatism, h

* Jour. Cutan. and Gen. Urin. 1

† M. I. Harris, in Medicine, Apr

color of the urine is usually bright red, but if long retained in the bladder it becomes black and often tarry. The reaction is alkaline. The clots, when floated out, are large and without definite shape. In micturition the urine is clear or only a little colored at the beginning, but becomes darker and darker as micturition ends, at which time the flow may consist of almost pure blood. In very small vesical hemorrhages the urine may be smoky. Crystals of triple phosphate indicate bladder disorder. The microscope shows colorless and swollen corpuscles and many polygonal cells. Symptoms of bladder mischief usually exist, but cystoscopic examination or exploratory suprapubic cystotomy may be required for the diagnosis.

Urethral Hemorrhage.—In urethral bleeding blood appears independently of micturition, or blood comes out first and is followed by clear urine. Urethral hemorrhage arises from acute urethritis, from an inflamed stricture, from the passage of an instrument, or from some other traumatism.

The source of urethral hemorrhage can be ascertained by the use of the endoscope.

Pain in Genito-urinary Diseases.—Pain as a symptom of genito-urinary disease may be found at some point distant from the seat of lesion. A stone in the bladder causes pain in the head of the penis just back of the meatus; stone in the kidney induces pain in the loin, the groin, the thigh, and the testicle; inflammation of the testicle causes pain in the line of the cord in the groin. In other cases of genito-urinary disease pain is felt at the seat of lesion, as in urethritis and prostatitis. Pain felt before micturition, and being relieved by the act, is found in cystitis and in retention of urine. Pain is felt during micturition in inflammation of the bladder, prostate, and urethra, and in the passage of gravel or stone. Pain which is acute at the end of micturition is noted in stone in the bladder, in inflammation of the neck of the bladder, and in inflammation of the prostate gland. The pain of stone in the bladder, it may be observed, is ameliorated by rest and is aggravated by exercise. The pain of acute prostatitis is intensified by defecation.

Frequency of Micturition.—Frequent micturition arises from irritation of the sensory nerves, from phimosis, contracted meatus, inflammations, very acid urine, calculi, urethral stricture, and hyperesthesia of the urethra. Frequency of micturition may be due to spinal irritability from concussion or from sexual excess, from contraction of the bladder rendering the viscus unable to hold much, from worry, anxiety, fear, or from excessive urinary secretion, as in diabetes or in the first stage of contracted kidney. Frequent micturition exists in obstruction by enlarged prostate and in atony of the bladder-walls. Hypersecretion of urine plus bladder intolerance is known as "nervousness," and is found in hysteria. Frequency of micturition increased by movement is observed in stone and tumor of the bladder. Nocturnal frequency of micturition is present in cases of enlarged prostate and atony of the muscular walls of the bladder. Frequency of micturition with diminution of stream-caliber suggests a constriction of the urethral diameter; frequency of micturition with diminished force suggests a posterior stricture, enlarged prostate, or bladder atony. Slowness of micturition hints at enlarged prostate, atony, or urethral stricture.

Sir Henry Thompson's diagnostic questions are as follows:

"1. Have you any, and, if so, what, frequency in passing water? Is frequency more manifest during the night or the day? Is frequency more manifest during motion or rest? Does any other circumstance affect it?

"2. Is there pain on passing urine, and, if so, is it before, during, or after the act? What is its character—acute, smarting, dull, transient, or continuous? What is its seat? Is it felt at other times, and is it produced or intensified by sudden movements?

"3. What is the character of the stream? Is it small or large, twisted or irregular; strong or weak; continuous, remitting, or intermitting? Does it come by the meatus, or partly or entirely through fistula?

"4. Is the character of the urine altered? What is its appearance—color, odor, reaction, and specific gravity? Is it clear or turbid, and, if turbid, is it so at the time of passing? Does it vary in quantity? Are the normal constituents increased or diminished? Does it contain abnormal elements as albumin or sugar? What inorganic deposits are found? What organic materials are met with?

"5. Has the urine ever contained blood? If so, was the color brown or bright red; were the blood and urine thoroughly mixed; was the blood passed at the end or at the beginning of micturition, or did it come only with the last drops of urine; or was it passed independently of micturition?

"6. Inquire as to pain in the back, loins, and hips, permanent or transitory, and for the occurrence of severe paroxysms of pain in these regions."

The Determination of the Excretory Capacity of the Kidneys in Health and in Disease. The Phloridzin Test.—This test is made with comparative ease and often aids the surgeon in determining whether he is justified in performing some operation of convenience. It enables him to estimate with a fair amount of accuracy the capacity for elimination possessed by the kidneys. The test depends on the fact that the healthy epithelium of the glomeruli and tubes, when stimulated to activity by phloridzin, forms saccharine from that drug and thus produces temporary glycosuria. When the epithelium is diseased, little or no glycosuria occurs. The test is applied as follows: The dose is about 5 to 10 milligrams of phloridzin, according to the body weight of the patient. It is administered hypodermatically, the bladder having been emptied beforehand. If the eliminating powers of the kidneys are at a healthy level, sugar should appear in the urine within half an hour of the injection. If at the end of this time only a small amount of sugar can be detected, one may assume that the kidneys are affected, and if no sugar can be found, a serious renal disease may be assumed to exist.

The actual standard that is to be considered as the normal amount of sugar which should be eliminated after the administration of phloridzin is a matter of some uncertainty. It is usually estimated at 0.3 per cent., a less amount of sugar than this being taken as an evidence of renal difficulty (Watson and Bailey, in "Report of Boston City Hospital for 1902"). The sugar is separated from the phloridzin in the epithelium of the glomeruli and tubules of the cortex of the kidney. The drug seems to be entirely harmless.

It is because phloridzin is acted upon by the kidney epithelium that this test is better than the methylene-blue test. The latter does not really measure the excretory power of the kidney-epithelium: it merely shows to what degree

the kidney is permeable in the mechanical sense. Personally, I should not be disposed to set aside older and more thorough methods of urinary analysis for the phloridzin test, although I believe that it has a range of distinct usefulness.

The Methylene-blue Test (The Method of Achard and Castaign).—When methylene-blue is injected hypodermatically it normally appears in the urine within half an hour and disappears in from thirty-six to forty-eight hours. If the blue color is not manifest in the urine for an hour or more, there is impairment of renal permeability. Accuracy in the test is not possible unless the amount of the methylene-blue actually passing into the urine in a given time is determined. The dose given hypodermatically is 0.05 gm. in 1 c.c. of sterile water. The test is unreliable and the blue color may appear in the urine in half an hour in some cases of marked kidney disease.

Cryoscopy (Korányi's Method).—Cryoscopy is the determination of the freezing-point of a liquid and the comparison of this with the freezing-point of distilled water. It is applied particularly to blood and urine. This method is complex and difficult of application, and requires a considerable amount of fluid. The freezing-point of a fluid depends upon the number of molecules it contains. The freezing-point goes hand in hand with molecular concentration—great concentration gives a low freezing-point, little concentration a high freezing-point. Cryoscopy of the blood and urine is used to determine the adequacy of renal activity. Normal blood freezes at about -0.56° or -0.57° C. Healthy urine freezes between -0.9° and -2° C. In renal inadequacy the freezing-point of the blood is lower than normal and the freezing-point of the urine is higher. It is held that surgical operation is contraindicated if there is such a degree of renal inactivity that the freezing-point of the blood is at or below -0.6° C. and if the freezing-point of the urine is at or above 1° C.

DISEASES AND INJURIES OF THE KIDNEY AND URETER.

Tumors of the Kidney.—Tumors, innocent or malignant, may arise in the kidney. Among the innocent tumors are fibroma, lipoma, angioma, and adenoma. Hypernephroma of the kidney arises from fragments of adrenal tissue included in the kidney. They were thought to be renal lipomata until 1883, when Grawitz showed they contained adrenal elements ("Virchow's Archiv.," xciii). The name hypernephroma was suggested by Birch-Hirschfeld in 1896. A hypernephroma may arise directly from the suprarenal gland or it may arise from an adrenal "rest" or aberrant gland. Such rests may be met with in the substance of the kidney, under the renal capsule, in the perirenal tissue, in the testicle, the ovary, the liver, the inguinal canal, the mesentery, among the spermatic vessels, in the broad ligament, in the renal plexus, or in the solar plexus (W. W. Keen). The term hypernephroma is applied to any growth which arises from adrenal cells "whether the growth be adenoma, carcinoma, or sarcoma in type" (Duffield in "N. Y. Med. Jour.," May 1, 1909). The tissue of a hypernephroma is identical with the adrenal gland, and it contains fat and glycogen. The exact nature of such a tumor is unsettled. It is probably an adenoma, but some consider it to be a sarcoma and others a carcinoma. Some tumors give no evidence of malignancy; some are very

malignant. A malignant hypernephroma greatly attains a large size, and is sometimes painful. Hospital from whom I removed a hypernephroma in the left side and occasional attacks like renal bloody urine. The tumor could be easily palpated. The kidney was removed and resembled a huge kidney, nodular in outline. Dr. Coplin found it to be malignant. There was no increase of arterial tension. The patient was a woman of forty-five, who was brought to the hospital. She had suffered from pain in the loin for months.

Fig. 765.—Sarcoma of kidney with metastases.

the radiation of renal colic. Hematuria appeared. It was persistent, but small in amount. The x-rays showed enlarged kidney. The arterial tension. Recovery followed nephrectomy. The patient proved fatal within six weeks after symptoms began. She had lived three years. A hypernephroma may invade adjacent structures, and gives rise, after a time, to metastatic deposits of the blood. The bones are most liable to be invaded. Deposits may occur in the lungs, liver, and other organs. I operated for a supposed adenomatous hypernephroma. Hypernephromatosis.

in the kidney than anywhere else. They tend particularly to occur in middle life. Sarcoma or carcinoma may arise in the kidney. Sarcoma is most common in the young, and may reach an enormous size (Fig. 765). A malignant tumor of the kidney produces hematuria, the urine often containing blood-casts of the ureter, kidney, and pelvis, and sometimes, though rarely, characteristic cells. Pain is often present in the loin and thigh, and there may be colic-like attacks when clots are passing through the ureter. Emaciation is rapid and pronounced. A tumor can usually be palpated. The only possible treatment for a malignant growth is early nephrectomy. In some few cases an innocent tumor can be removed by a partial nephrectomy. A malignant tumor requires a complete nephrectomy. In making a diagnosis of renal tumor use the cystoscope. If blood is coming from a ureter, note if it is from only one or from both. Blood from both would contraindicate nephrectomy. Before removing a kidney it is necessary to be sure that the patient is possessed of two kidneys. Note if urine flows from each ureter, or, if uncertain, catheterize the ureters.

Nephroptosis, Prolapse of the Kidney, or Mobile Kidney.—

There are two forms of this condition: (1) *Movable kidney*, which is an organ freely moving back of the peritoneum, either within the cavity of its fibro-fatty capsule or entirely without its capsule (this condition is acquired); and (2) *floating or wandering kidney*, an organ having a mesonephron and lying within the peritoneal cavity (this rare condition is always congenital). Keen states that there may be drawn a clear theoretical distinction between movable and floating kidney, but practically there is no rigid line of demarcation, as a movable kidney may have as large a range of movement as a floating kidney. The kidney is normally somewhat mobile, and nephroptosis is considered to exist only when the range of movement exceeds distinctly what is normal. Normally, on inspiration the kidney descends about half an inch. It is seldom that a normal kidney can be palpated in men, but in most women the right kidney can be palpated, and in some women the left organ can also be felt. Harris ("Jour. Amer. Med. Assoc.," June 1, 1901) describes three degrees of movable kidney. In cases of the first degree, one-half of the organ can be distinctly grasped and the kidney can be made to recede. In cases of the second degree both hands can be brought together above the kidney. In cases of the third degree the kidney has descended as low as the pelvic brim or has moved to or beyond the umbilicus. The organ may drop below the brim of the pelvis, may cross the vertebral column, or may reach the anterior abdominal wall. When a movable kidney becomes fixed in an abnormal situation, the organ is spoken of as *dislocated*.

Women suffer from movable kidney more often than do men. Kuster estimates that 4.41 per cent. of women examined in general surgical practice have movable kidney. Edebohls finds it in 20 per cent., and Harris in 50 per cent., of cases in gynecological practice. In about one-half of the cases it gives rise to little or no trouble. A movable kidney is found in the great majority of cases upon the right side. In many cases it is bilateral, the right kidney being usually the most mobile. Splanchnoptosis may be associated with acquired nephroptosis. Floating kidney is always congenital. The condition is occasionally, but rarely, found in children, though congenital cases occasionally occur. In a congenital case there is not splanchnop-

tos. Tuffier has reported 3 cases in children of 1, 2, and 3 years of age respectively, and J. Cromby reported 18 cases in children, the youngest patient being three months old ("Jour. Amer. Med. Assoc.," June 1, 1901). The conditions which are to be named traumatic nephropathy, laxity from pregnancy, removal of a tumor, or displacement of peritoneal fat from wasting disease (Edwards), and displacements; and enteroptosis leading to traction of the colon. The condition is certainly often associated with abdominal viscera (enteroptosis, gastropoptosis, etc.).

Traumatism is rarely the immediate and exclusive cause of a movable kidney. In some cases people assert that pain, a blow, an attack of coughing, violent vomiting, or a fall, or a fall in parturition, or a fall. In such cases the pain is before the accident. Again, pain is not proof of mobility. It is probable, however, that trauma may induce mobility and that mobility may subsequently develop. In normal relations cannot be rendered mobile by force. Loosening can be induced only by a distinct injury. Harris makes out a strong case for mobility due to the relation existing between the location of the kidney and the form. He divides the body into three zones: the upper zone contains the lungs and heart. The middle contains the liver and the greater part of each kidney. The lower zone contains the lesser part of each kidney. When the capacity of the middle zone is diminished, the kidney is displaced. The right kidney is pressed upon by the heart, the left kidney is pressed upon by the colon. A movable kidney is more common on the right side. The upper pole of the kidney is first pushed forward and then descends (M. L. Harris, in "Jour. Amer. Med. Assoc.," June 1, 1901). Harris maintains that the amount of mobility is determined by the contraction of the middle zone and upon intercostal breathing, coughing, etc.).

Symptoms of Both Forms.—There may be no symptoms. The patient may be a confirmed invalid. The pain (just to the left of the middle line), which is replaced, dragging pain in the loin, and sudden attacks of violent pain in the kidney which are accompanied by nausea, vomiting, vertigo, chills, and subsequently elevated temperature. These crises are due to kinking or twisting of the ureter or to inflammation of the kidney. They may be caused by a constriction in diet and may be followed by hemorrhage of the renal vessels. A few years ago I operated on a patient with a violent and prolonged crisis and found a kink in the ureter. In a Dietl's crisis there is congestion or strangulation of the kidney. An incomplete or temporary twist of the renal vessels causes pain in the abdomen and loin, hematuria, albuminuria, etc.

The question as to whether or not abdominal pain is due to movable kidney is sometimes in doubt. The localization of the pain may lead us to suspect appendicitis. Some surgeons think that catarrhal appendicitis is often associated with movable kidney, but I do not think the association is common. "Dr. Kelly has shown us how to solve this doubtful question between appendicular pain and the pain of movable kidney. He catheterizes each ureter separately, and introduces into each catheter as much as the renal pelvis will hold without causing pain. He then measures this fluid from each side, and determines whether it is in excess of an estimated average. If it is in excess, he is sure that dilatation has begun. He then injects the kidney again, with the deliberate purpose of producing pain; and if the patient recognizes this pain due to the distention as of the same character and in the same position as that which he has previously felt, Dr. Kelly assumes that the pain has been due to the kidney, and not to the appendix, and recommends an operation to fix the kidney" (the author, in "New York Med. Jour.," August 4, 1906). Usually in a case of movable kidney there is a sense of a moving body in the abdomen, and the patient has aggravated indigestion, often accompanied by vomiting. Constipation is the rule, and violent attacks of cardiac palpitation are common. Most subjects of this kidney mobility are extremely nervous—many of them hysterical or hypochondriacal. Persistent vasomotor paresis causes cold hands and feet and often albuminuria. Temporary jaundice is not uncommon. There is frequently irritability of the bladder. Vertigo and insomnia are present in many cases. The patient cannot sleep when lying on the sound side (Goelet). In women the sexual organs are almost invariably deranged, and menstruation aggravates the pain and discomfort. All the symptoms are intensified by exertion and are modified by rest. The urine is normal, except after violent exercise, when it may contain blood. Splanchnoptosis may also exist, and if it does, the pulsations of the abdominal aorta are strongly noticeable because that structure is bared by gastropptosis. The proof of the existence of movable kidney is the finding of a tumor, movable on respiration, change of position, and palpation, shaped like that organ, pressure upon which occasions no sensation or causes pain or a sickening feeling. A "lumbar recess" (Morris) may sometimes be found, and percussion over the loin gives resonance. In some cases a movable kidney can be readily detected when the patient stands up, but is difficult to find when he is recumbent. Franks's method of examination is very satisfactory. The patient is placed recumbent. If dealing with a right kidney, the surgeon stands to the right side and pushes four fingers of his left hand in the loin below the twelfth rib, and rests the thumb lightly in front just below the ribs. The patient takes a full breath and holds it a moment, and just before he empties his lungs the surgeon presses his thumb up deeply below the ribs. During expiration the thumb follows the liver, and the fingers press toward the front. If with the right hand the kidney can be felt entirely below the left hand, the case is one of movable kidney. If such a condition is detected, press hard with the right hand, and gradually loosen the grasp of the left hand, and the kidney will slip between the fingers and ascend. A normally mobile kidney descends so that its lower end can be felt, but it moves back during expiration.* (Goe-

* Brit. Med. Jour., Oct. 12, 1895.

let uses Kendal Franks's method of palpation, but has the patient stand, with the weight resting on the leg of the sound side and with the leg of the impaired side slightly flexed and resting on the toes. The body leans a little forward. A movable kidney must not be mistaken for a distended gall-bladder, a tumor of the mesentery, stomach, or omentum, a phantom tumor, an ovarian tumor, or a cancer of the pancreas. A distended gall-bladder can be pushed upward, but not backward, and not downward unless the liver is movable, it is extremely tender, and cannot be pushed out of reach. A kidney can be pushed upward and backward—in fact, in all directions. An enlarged gall-bladder can always be palpated. A movable kidney which is not enlarged can be felt at times and not at others (Henry Morris). A movable kidney may pass between the examiner's fingers, and if pushed into the loin, it tends to remain; but if a distended gall-bladder is pushed into the loin, it springs out as soon as pressure is relaxed (Henry Morris). It is important to remember that in about one-half of the cases of movable right kidney the left kidney is also movable, but to a less degree. Appendicitis is thought by some to be more frequent in individuals with movable kidney than in those who do not suffer from it. Sometimes a movable kidney endangers life, rupture of the kidney, twisting or rupture of the ureter, or strangulation of the renal

vessels occurring, the ultimate cause of death being albuminuria, uremia, or hydronephrosis.

Treatment.—Mobile kidney is treated as follows: If the kidney is but slightly mobile and there are no local symptoms, the treatment should be non-operative. (1) *The rest-treatment of S. Weir Mitchell* may be tried; it often markedly mitigates the symptoms, but does not seem to cure. (2) *Mechanical support* should always be tried. The most satisfactory mode of applying it is by the corset recommended by Gallant ("Amer. Jour. Obstet.," July, 1901). This corset is straight in front, and when applied fits firmly over the hips and lower abdomen, less firmly at the waist and least firmly above.

Gallant directs that the patient be down, the head being on a pillow and the knees drawn up. While in this

Fig 766.—A H Goelet's method of palpation for the detection of a prolapsed kidney.

attitude the corset is put on and it is laced from below up. If the attempt to apply the corset develops tenderness, keep the patient at rest in bed until it can be applied without pain. In some cases conservative treatment is not indicated; in others it fails.

In every case of very movable kidney and in some cases in which movability is not great operation is indicated.

"In a case in which the kidney exhibits trivial movability, but in which

the range of mobility is found to be gradually and certainly increasing, or in any case of kidney movability in which there are distinct local symptoms, operation is indicated. The distinct local symptoms mean the beginning of actual harm to the kidney, and the progressive increase of movability means the ultimate attainment of a wide range of movement. A kidney which is widely movable may at any time twist upon the ureter and the renal vessels; and it is certain to suffer from partial or slight twists, probably many times repeated in the twenty-four hours, even if a severe twist does not occur. A deduction from the foregoing statements is that a patient suffering with nephroptosis, even when the mobility is slight, should be examined at regular intervals, to note whether the area of movement is extending, or whether local symptoms have arisen. Three local symptoms that should be regarded as indications for operation are severe pain in the renal region, distinct tenderness of the kidney, and enlargement of the kidney" (the author, in "New York Med. Jour.," August 4, 1906). Billington ("Brit. Med. Jour.," May 1, 1909) formulates the following indications for operation:

1. When renal pain is so severe or persistent as to cause serious inconvenience. The ordinary dragging pain in the loin is not an indication. Billington refers to severe pain due to perirenal inflammation, ureteral obstruction, or impeded venous return.

2. When there are harassing and depressing gastric and colonic troubles (gross lesions being absent).

3. Cases of spinal and cerebral neurasthenia.

4. Cases of lunacy. Personally I do not operate on groups 3 and 4 unless there are signs of grave renal disaster.

The usual operation chosen will be nephropexy, very seldom nephrectomy. (1) *Nephropexy* is the operation employed in most instances (page 1293). It is the author's experience that if the patient has had marked nervous symptoms for a long time, nephropexy will rarely cause them to pass away permanently, even though the kidney remains firmly anchored. (2) *Nephrectomy* is necessary only in very rare cases; it may be done for dislocated kidney, when grave kidney disease exists, or when nephropexy has failed in a case of great severity.

In many cases of this trouble no operation should be performed, the use of Gallant's corset securing, perhaps, decided or complete relief. I do not operate if the kidney is only slightly movable and if there are no local symptoms or if there are merely the general symptoms of hysteria. If the mobility is slight and the hysterical and neurotic condition is pronounced, anchoring the kidney will not cure the nervous condition. In these nervous cases, associated with prolapse of the kidney, there is usually, also, prolapse of the other abdominal viscera; and both kidneys are, as a rule, movable, the right, however, being decidedly more movable than the left.

If there is but slight mobility of the kidney, but the range of movement is, week by week and month by month, increasing, or if we find a case of movable kidney in which there are distinct local symptoms, an operation should be performed. The existence of definite local symptoms means beginning harm to the kidney; and if we find the area of movement gradually increasing, we know that eventually it will become extensive. Any widely movable kidney may twist the ureter and the renal vessels, producing serious trouble

or even disaster, and consequently should be fixed by operation. Even if a severe twist does not take place, it is bound to suffer from partial or slight twists. Such kidneys will eventually become hydronephrotic. The meaning of the term slight mobility is indicated on a previous page (p. 1273).

One is not unusually in doubt in cases of movable kidney whether a pain indicates local trouble with the kidney or catarrhal appendicitis, because the pain may be located in the appendix region. Kelly, of Johns Hopkins Hospital, has shown how to solve this problem (p. 1275).

There are many operations for movable kidney. In all of them the kidney is exposed in the loin. Some make a vertical and some an oblique incision. Edebohls makes a vertical incision, forces the kidney out of the wound, incises the fibrous capsule longitudinally, turns a cuff down on each side, and applies sutures. These sutures traverse the kidney-substance and the fold of capsule on each side. The upper suture catches the peristoleum of the last rib; the other sutures catch the lumbar fascia. Drainage is not required, and the suture material employed is kangaroo-tendon or carbonized catgut.

Many surgeons simply pass sutures through the uncut capsule and the kidney-substance and thus fasten the kidney to the lumbar fascia. Others split the capsule and pass sutures through the edge of the capsule and the wound-edges, but not through the kidney-substance.

To promise success, an operation ought to restore the kidney nearly to its normal position and fix it permanently in place. It is undesirable to inflict damage on the kidney itself, and I do not believe in any operation that passes sutures through the kidney-substance. In cases in which decapsulation is performed, the kidney will grow fast without any special method of suturing.

Most of the operations suggested do not place the kidney sufficiently high up to get it into a fair position. Kelly's operation gets it higher than most of them, and Goelet's operation gets it well into place. In many of the suture operations the sutures are placed in the convex surface of the kidney or the kidney capsule, and on fixing the kidney by tying the sutures there is a permanent quarter twist of the ureter—a condition that may be responsible for great pain. This may be obviated entirely by the ingenious method of Goelet ("Annals of Surgery," Dec., 1903). I believe, however, that the suture operations which do lift the kidney well up toward its proper place and in which the sutures are applied on the posterior surface and not the convexity, tilt the upper pole forward into a permanent and perhaps disastrous position. Such operations lift the kidney from below its mid-line and thus lift the lower half of the organ, but leave the upper half unfixed. I believe, too, that in many cases in which kidneys have been sutured they get loose again and that the best operation, after all, is that by the use of slings of iodoform gauze (page 1293).

Injuries of the Kidney.—**Laceration or rupture** is caused by falls and by blows upon the back or the belly.

Symptoms.—In some cases the parenchymatous structure is torn, but the capsule is not torn, and in consequence urine and blood are not extravasated into the perineal connective tissue or into the peritoneal cavity. In other cases the parenchyma and capsule are both torn and urine and blood are extravasated. The laceration may be trivial, may be considerable, or

may tear the kidney apart. The symptoms depend on the gravity of the injury. A slight tear without involvement of the capsule may produce practically no symptoms at all. A more severe injury produces shock, and, if profuse bleeding occurs, the general symptoms of hemorrhage. In intraperitoneal rupture there is profuse and usually fatal hemorrhage. In laceration of the kidney there are severe pain in the loin, which shoots into the testicle, and lumbar tenderness. If there is considerable perirenal bleeding, the loin will be full, and dull on percussion, and if the hemorrhage is large, a palpable mass will form after a time and after

Fig. 767. — "Purse string suture" applied to a perforation (after Schachner).

some days the skin will become discolored. There is frequent and painful micturition and sometimes suppression of urine. Hematuria occurs in renal laceration unless the rupture was intraperitoneal or the ureter was torn, in which case there are evidences of profuse internal hemorrhage, abdominal rigidity, etc. (Daniel N. Eisendrath, "Jour. Amer. Med. Assoc.," Oct. 25, 1902). It is important to remember that hematuria can arise from simple renal contusion, and that kidney damage does not of necessity cause bloody urine. If there is hematuria, the use of the cystoscope or catheterization of the ureters, or the employment of Harris's segregator, will demonstrate from which kidney the blood comes. A kidney-laceration may be followed by secondary hemorrhage, perirenal suppuration, hydronephrosis, or pyonephrosis, and may cause kidney displacement.

Treatment.—In an intraperitoneal rupture laparotomy should be performed because of abdominal hemorrhage. As a rule, nephrectomy is necessary, but it may be possible to arrest hemorrhage by packing. If the shock is pronounced and if there is increasing fulness in the loin, whether hematuria exists or not, or if blood comes profusely from the ureter, whether or not there is much shock or lumbar fulness, make an exploratory lumbar incision and stop the bleeding by packing or by a purse-string suture (Figs. 767, 768), or, if necessary, perform partial, or even complete, nephrectomy. Ordinarily, when there is not great shock, increasing lumbar swelling, or severe hematuria, treat by rest in bed and by feeding with liquid food or by nutritive enemata to prevent vomiting. Opium, tannic acid, or gallic acid may be used. Apply ice-bags to the loin and the side of the abdomen, and after bleeding ceases strap the loin and apply a binder. If large blood-clots in the bladder cause pain or retention of urine, introduce a catheter and inject the bladder with boric acid, or use the tube and evacuator of a Bigelow apparatus. If this procedure fails, open the bladder by a suprapubic incision and drain.

Results of Operation.—Up to 1894 there had never been a case of intraperitoneal rupture operated upon; since then 6 have been operated upon and all recovered (Daniel N. Eisendrath, "Jour. Amer. Med. Assoc.," Oct.

25, 1902). Küster collected 47 cases of a recovered. Keen estimates the mortality of p at 20 per cent, and of secondary nephrectom operation intraperitoneal rupture is inevitable operated upon recovered. Of extraperitoneal without operation (Eisendrath). Francis S. Surg. Jour.," July 16, 1903) has collected 66 the kidney. The following statistics are of int cases with 81 deaths, a mortality of 29.6 per other than nephrectomy: 99 cases with 7 de Treated by nephrectomy: 115 cases with 25 cent.

Perforating wounds of the kidney, if p the peritoneum; if anterior, they do. The

and urine by the wound; hematuria is usual rupture; the patient may be unable to mictur constitutional signs of hemorrhage exist. Tr abscess, or general sepsis may ensue. Confi with the finger. Extraperitoneal injuries g a bad, prognosis.

Treatment—If the wound of the kidney lumbar wound to permit of drainage, and ar hot water or by a purse-string suture (Figs. 76 insert a drainage-tube down to the kidney, d keep the patient in bed on a low diet, and give cases nephrectomy, partial or complete, will t wounds perform an abdominal section and, s organ (see Nephrectomy).

Wounds of the Ureters.—Rupture fi tremely rare accident. There are 3 undoubt Eisendrath, "Jour. Amer. Med. Assoc.," C wound from accidental violence is almost in serious injuries. The ureter may be wound during the performance of an abdominal op intentionally, as in Morris's cases, in which

porated with the ureter. There is particular danger of injuring the ureter in operations upon intraligamentary growths, because the ureter is displaced and often resembles an adhesion. The rule of surgery is that when working about the ureter the surgeon neither clamps nor cuts any structure without a careful preliminary examination. Rupture causes severe shock and extravasation of urine around the kidney or into the peritoneal cavity. In extraperitoneal rupture a palpable mass forms in the loin. When the ureter is divided in an operation, a flow of urine is seen.

Treatment.—The upper three-fourths of the ureter can be reached by an extraperitoneal incision, which is a prolongation of the incision for lumbar nephrectomy, running from the twelfth rib downward, and forward to one inch anterior to the anterior superior spine of the ilium, and then parallel to Poupart's ligament until a point is reached above its middle (Fenger). Israel's incision begins at the anterior edge of the erector spinae mass, one finger's length below the twelfth rib, is taken forward parallel with the rib until it reaches the line of the rib's tip, and is then carried toward the middle of Poupart's ligament until the line for ligation of the common iliac artery is reached, and is then taken toward the middle line as far as the outer border of the rectus muscle. The lower one-fourth of the ureter can be reached by abdominal section or by sacral resection (Cabot), but best by an incision like that for extraperitoneal ligation of the iliac vessels. If it seems probable that the ureter is wounded or ruptured, explore, and if this is found to be the case, endeavor to restore the continuity of the tube. A longitudinal cut can be sutured with fine catgut. If the ureter is cut across near the bladder, implant the proximal end into the bladder and ligate the distal end (Van Hook, Penrose, Kelly). If it is cut above the bladder portion, perform lateral implantation by Van Hook's method (page 1296).

A longitudinal wound of the ureter inflicted during an abdominal operation should be sutured, but if the duct cannot be readily reached, simply make a posterior incision and drain with rubber tissue, as the longitudinal wound will heal by granulation if no sutures are inserted (Van Hook). In a case of transverse division perform uretero-ureterostomy or vesical implantation; or, if neither of these methods is feasible, make a urinary fistula or perform nephrectomy.

Renal Calculus.—A stone in the kidney is formed by the precipitation of urinary salts into the renal epithelial cells and the gluing together of these salts and cells by material from mucus or blood clot, this mass serving as a nucleus on which accretion takes place. Most calculi escape when small, as gravel. The cause is a highly acid urine, which induces catarrh of the renal tubes. Such high concentration of urine is favored by a sedentary life, by the ingestion of much alcohol or nitrogenous food, by constipation, by an inactive skin, and by a torpid liver. The children of poverty are liable to calculi because of the use of unsuitable foods and the formation of great amounts of nitrogenous waste. Males suffer more often than do females; certain locations favor the development of the malady, and a family tendency sometimes exists.

Symptoms.—The symptoms of stone in the kidney may not appear for years, but generally they are manifested early. There may be no pain. There had been none in 13 cases out of 24 which came to autopsy and were reported

by Clark. Usually there is pain; the severity of the pain depending upon the roughness and movability rather than upon the size of the stone. A hard stone in the kidney and a smooth stone in the pelvis may cause little or no pain. A rough stone in the pelvis causes severe pain. The patient usually complains of pain in the loin, and sometimes of pain in the iliac region. Deep percussion over the kidney causes pain in the loin, even when pressure is painless (Jordan Lloyd's symptoms). Pain is aggravated by exercise and pressure, and the kidney is usually enlarged. The urine is often somewhat albuminous, and may from time to time contain blood. Frequency of micturition is noted during the day, but not at night. The urine may be purulent. *Nephritic colic* is due to the washing of a calculus into the orifice of the ureter which it blocks, tears, or distends. The pain is either sudden or gradual in onset, is fearful in intensity, and runs from the lumbar region down the corresponding thigh and spermatic cord (the testicle being retracted), and into the abdomen and back. There are nausea, vomiting, collapse, sometimes unconsciousness or convulsions. Frequent attempts at urination are productive of pain, but of little urine. Rectal tenesmus is common. The urine is often, but by no means always, smoky from blood. Blood may be found by the microscope when it cannot be detected by the naked eye. In rare cases fatal hemorrhage occurs. Blood is present in about one half the cases. After a time the pain vanishes, the stone having passed into the bladder or having fallen back into the pelvis of the kidney. Slight attacks of colic occur in the passage of small stones or of plugs of mucus. A calculus retained in the kidney eventually excites pyelitis, pus appears in the urine, and soreness or pain in the loin exists. Kelly says: Even if pus is found, we are not always sure from which kidney it came. Pain or swelling may point to one side, but we are not sure that the other organ is not also affected. The cystoscope must be used. Bloody or purulent urine may be seen coming from one ureter. It is able to pass the renal catheter into one ureter, attach a syringe, and by making suction, draw out any pus which may be present. In renal calculus cases the fluid is apt to contain fragments of uric acid. By using a renal bougie coated with dental wax it may be possible to make scratches on the instrument when it comes in contact with a concretion.* When a stone is impacted in the pelvis the point of greatest tenderness on pressure is below the last rib, by the side of the erector spinæ muscle. In septic cases there may be chills and irregular fever, and often there is leukocytosis. In most cases a stone in the kidney or ureter can be skiagraphed. Nephrolithiasis may cause death by exhaustion, by sepsis, by rupture of a hydronephrosis, or by amyloid degeneration.

Treatment.—For the gravel of the uric-acid diathesis use alkalis, especially the liquor potassii citratis, and reduce the amount of nitrogen in the diet to a minimum, at the same time washing out the organs by copious draughts of Poland water or Londonderry lithia. Piperazin, in doses of gr. v to gr. viij three times a day, is highly commended. Exercise is to be insisted on. When gravel is phosphatic, order strychnin, the mineral acids, and rest at the seaside. When oxalate of lime is found, restrict the diet, use the mineral acids, recommend travel or rest amid new surroundings, and give an occasional course of sodii phosphas, ʒss three times a day, drunk in Buffalo lithia water. Nephritic colic is relieved by hypodermatic injection of morphin and atropin, the hot bath, diluent drinks, or the inhalation of ether.

* Howard Kelly, in Med. News, Nov. 30, 1895.

After an attack use the cystoscope, and if a stone is found in that viscus, wash out the bladder with an evacuator. If a stone impacts in the ureter, perform the operation of *ureterolithotomy*. The diagnosis of this impaction is in many cases aided by the x-rays, but is sometimes possible only after exploratory laparotomy. If the symptoms point to stone in the kidney, medical treatment having been used without avail, always take a skiagraph. If this shows a stone and if there are no evidences of organic disease of the kidney, operate. If in doubt in spite of the skiagraph, make an exploratory lumbar incision; feel the surface of the kidney with the finger, sound the inside of the organ with a needle, and if a stone is detected, incise the kidney and remove the stone. Keen is of the opinion that operation should not be performed if the urea is below 1 per cent. If, after nephrolithotomy, suppression of urine occurs, cut into the other kidney, as in one-half of all cases a stone will be found lodged there. I agree with Brewer ("Med. Record," March 20, 1909) that "a kidney containing one or more calculi, and also the seat of an advanced septic process, should be removed if the opposite organ is healthy. To leave such a kidney is to invite subsequent trouble from recurrence of stone, pyonephrosis, or long-continued sepsis." I agree with him when he says: "It is also often safer to remove a kidney with multiple calculi imbedded in its substance than to inflict the trauma necessary to remove them, as alarming primary or secondary hemorrhage is apt to occur." In a recent case of my own a most persistent postoperative hemorrhage forced me to perform nephrectomy to save life.

Calculus in the Ureter.—A ureteral calculus comes from the kidney, sometimes dropping, but more often being forced, into the tube. A stone may be arrested at any one of these points of constriction. There are three points of constriction in the ureter: one point is about 2 inches below the renal pelvis, another is at the pelvic brim, another is about $\frac{1}{2}$ inch from the bladder orifice of the ureter. The highest point has a diameter of about $\frac{3}{4}$ inch, the middle point a diameter of about $\frac{1}{2}$ inch, the lower point a diameter of about $\frac{1}{10}$ inch. A small stone may completely block the ureter. A large stone may fail to completely block it because the ureter dilates above, the stone acts as a ball-valve, and urine trickles by.

Symptoms.—Attacks of violent pain of the nature of renal colic, and not unusually a rigor with the attack and fever after it. Such an attack may be followed by hematuria. The urine should be examined microscopically during several days after a colic to see if it contains blood cells. Tenderness can be developed at the point of impaction, the point of greatest tenderness being in the loin *below* the level of the kidney or in the iliac region (Perkins). In stone in the ureter pain is not developed by pressure in the loin at the level of the kidney. If a stone partly obstructs the ureter, the urine is pale, of low specific gravity, and free from albumin. Impaction near the bladder causes symptoms similar to stone in the bladder (Jordan Lloyd). These symptoms are frequent micturition, pain, pain in the head of the penis, and bloody urine. If a stone is impacted in the lower end of the ureter a finger in the vagina or rectum will find tenderness and perhaps will feel the stone. In a woman, a stone lodged in front of the broad ligament may be felt by a finger in the vagina. Back of this region and up to the pelvic brim a stone may be felt by a finger in the rectum. A cystoscopic examination, in unusual cases, may show a portion of stone projecting from a ureter (Kelly). Impaction near

an ice-bag to the loin, followed in forty-eight hours by hot fomentations. When the diagnosis is clear, incise the loin, open and stitch the kidney to the abdominal wall, or, if the organ be badly damaged, remove it.

Pyelitis and pyelonephritis, which usually affect only one gland, are caused by urethral stricture, by stopping of the ureter by blood-clot, by vesical paralysis, by stone in the bladder or in the kidney, and by enlargement of the prostate gland.

Symptoms.—A patient who has, or who has had, retention of urine develops high fever, often preceded by a chill, and headache, stupor, and dry tongue are noted. Unlike acute Bright's disease, there is neither edema nor dry skin, convulsions do not occur, and the urine is plentiful and contains pus and but rarely blood. The **prognosis** is very bad.

The **treatment** is to remove the obstruction if possible. If the urine be acid, give liquor potassii citratis; if alkaline, give benzoic acid. Gallic acid, eucalyptol, and small doses of copaiba or cubebs are recommended. Venice turpentine, camphor, and opium may be given in pill form. Quinin is used to stimulate the patient. The bladder is to be washed out every day with boric-acid solution (gr. iij to 3j of water). Cups, dry or moist, and hot sand-bags or bran-bags are to be applied to the loin. Alcohol may be sparingly administered. Urotropin is a useful drug.

Perinephritis is an inflammation of the perinephric fatty tissue produced by cold, febrile disease, slight traumatism, or the spread of inflammation from another part.

The **symptoms** of this condition are rigidity of the spine, the inclination being toward the affected side, flexion of the thigh, pain in the loin and iliac region, and often pain in the knee. The symptoms resemble those of hip-joint disease in the second stage. Suppuration may or may not take place.

The **treatment** is wet cups to the loin, ice-bags to the loin, rest, purgation by salines, morphin for pain, and, after the acute stage, potassium iodid internally and ichthyol locally.

Perinephric Abscesses.—An abscess in the perinephric fat is known as a perinephric or perirenal abscess. *Primary abscess* is caused by chills, acute febrile disturbances, or by pus flowing from some other part, as the spine. Slight traumatisms, by producing hemorrhage, make the perinephric region a point of least resistance and lead to abscess. The causative injury may be produced by digging, stamping, coughing, falling, carrying a burden, lifting a weight, riding on a horse or on a jolting wagon. *Consecutive abscess* is secondary to kidney inflammation, suppuration, calculus, tuberculosis, or cyst. In the consecutive form the symptoms may be masked by the malady to which perinephric abscess is secondary. As a rule, in perinephric abscess there are found the constitutional symptoms of suppuration. The local symptoms are a deep aching and paroxysmal pain in the loin, intensified by lumbar pressure. There may be pain in the iliac region and pain in the knee. Edema of the corresponding foot and lameness are not unusual. The thigh is often drawn up. The spine is rigid and inclined toward the diseased side. Edema of the skin is usual, but fluctuation is not. The exploratory incision will settle a doubtful diagnosis.

The **treatment** is to lay open the abscess, wash it out, and drain.

Stricture of the Ureter.—This is usually the result of gonococcic infection, or tuberculosis. The symptoms, as in those of a vesical or renal inflammation. The ureteral catheter. We may be unable to insert it with difficulty and find that the pelvis of the kidney in which the urine obtained is slightly acid or even alkaline, and that the urine from the other kidney, and perhaps the ureter causes hydronephrosis or pyonephrosis.

Treatment.—Dilatation with bougies, resection and anastomosis, resection of the diseased pelvis and sound end into the bladder, or division of the ureter. In tuberculosis the diseased kidney and ureter may be removed.

Hydronephrosis is a condition of the kidney in which there is an impediment to the outflow of urine by obstruction of the ureter, the urethra, the calyces of the kidney become dilated, and the glandular tissue being absorbed by the pelvis. Described by Albarran that secretion of urine ceases in a few days, distention being due purely to congestion. It may be congenital, due usually to twisting of the ureter or to a kink in the ureter at its point of junction with the bladder, or it may be produced because the ureter passes in an abnormal natural angle. Occasionally imperforate pelvis may be present in both kidneys. The causes of the acquired form are growths or pregnancy, inflammation or tumor of the bladder, kidney, or ureter, twisting or kinking of the ureter, enlargement of the prostate gland, etc. Acquired hydronephrosis may involve both kidneys or only a part of a single gland.

Symptoms.—Hydronephrosis is most frequently unilateral. If the tumor is absent, there may be no symptoms, or a dull ache in the back and abdomen, frequent micturition, a purulent discharge in urine, or even occasional anuria. A tumor which grows is dull on percussion and may contract and occasionally occurring when it disappears. Even if both kidneys be involved, but death occurs from uremia, from rupture into the peritoneal cavity. The use of the cystoscope and by catheterizing the ureter.

Treatment by aspiration may cure, but it must be done repeatedly. Tapping on the left side is done in the 11th intercostal space; on the right side the tap is made between the 10th and 11th ribs and the crest of the ilium. Some few cases are cured by catheterizing the ureter (Pawlik). The proper operation is a lumbar incision, stitching the edges of the cut kidney, the pelvis has been opened, explore the ureter by means of an elastic bougie. A healthy ureter will permit the passage of the size of from No. 9 to No. 12 of the French catheter. The opening of the ureter into the pelvis cannot be

open the ureter. A valve should be slit longitudinally and sutured vertically (Fenger). If a permanent suppurating fistula ensues or if the organ is found extensively damaged, nephrectomy is to be performed, provided the other kidney is in reasonably good condition.

Pyonephrosis or surgical kidney is a condition in which the pelvis and the calyces of the kidney are distended with pus or with pus and urine. The whole kidney may be destroyed. This condition has the same causes as has hydronephrosis, for it is in reality usually an infected hydronephrosis. In some cases the inaugural malady is pyelitis, which causes blocking of a ureter. Watson, of Boston, has reported two cases associated with obliteration of the ureter by a mass of fibrous tissue (stricture of the ureter).

Symptoms.—At first the symptoms are those due to the obstructing cause, plus pyelitis. Pus may appear in the urine in incomplete obstruction, or it may intermittently come and go. Constitutional symptoms of suppuration are soon manifest. A tumor may appear in the loin, like the tumor of hydronephrosis. If only one kidney is involved, and if the disease is due to blocking of a ureter, recovery is to be expected. The diagnosis is rendered more certain by the use of the cystoscope and by catheterizing the ureters.

The **treatment** in the early stages comprises removal, if possible, of the cause of obstruction, and the employment of measures directed to the cure of the pyelitis. If obstruction is not complete, palliative measures may be employed for the tumor. If fever is continued; if there is great visceral derangement; if pain is severe and constant; and if the tumor continually grows, perform a nephrotomy, stitching the organ to the surface if possible, or removing it if it is hopelessly disorganized and the other kidney is in a good or a fairly good condition.

Chronic Tuberculosis of the Kidney.—This condition may begin in one kidney, no other area of infection existing in the body. In such cases the bacteria were deposited from the blood. Even when the bacteria are deposited from the blood there is, in most cases, a causal focus of tuberculosis somewhere in the body. The other kidney is usually involved subsequently, the process in the first kidney affecting the bladder and secondarily the other kidney. The important point is that tuberculosis of the kidney arising in this manner is at first a unilateral disease.

Tuberculosis of the kidney is seldom a primary disease and usually arises secondarily to tuberculosis of the prostate, bladder, or epididymis. In such a condition the kidney disease is bilateral. Renal tuberculosis is particularly common in the third and fourth decades of life, and is more frequent in males than in females.

Symptoms.—Renal tuberculosis of arterial origin may exhibit no symptoms until the disease is far advanced. Renal tuberculosis secondary to disease of the bladder or prostate always presents symptoms.* A very common symptom of renal tuberculosis is the sudden onset of polyuria and frequent micturition. The patient is annoyed day and night, and in some cases micturition is distinctly painful. Paroxysms of renal pain are not unusual. The urine is acid, and may contain pus or blood. Tubercle bacilli may be found in the urine or in the sediment, but they may be absent. Repeated examination should be made before it can be stated certainly that bacilli are

* F. Tuden Brown, New York Med. Jour., April 10, 1897

at in some cases the disappearance of symptoms has been too rapid to admit of the assumption that new vessels have caused it. In such cases seems much more probable that relief of tension is the real curative factor. The capsule of the kidney is only slightly elastic, and tension may be brought out by an increase in the blood-supply, by edema, and by cell proliferation. Increased tension causes pain and perhaps hematuria, and tension is relieved by Harrison's plan of incising the capsule. Simple incision is easier, safer, and at least as useful as stripping the capsule off of the kidney. Edebohl advocates capsulation and says that the polyuria begins about the tenth day after operation; that improvement begins in one month and is gradual; that the cure is due to vascular adhesions, that the adhesions contain more arteries than veins; that the free blood-supply absorbs exudate and products of inflammation, frees the tubes and glomeruli from pressure and constriction, assures the re-establishment of a normal circulation and the regeneration of epithelium ("Med. Record," Dec. 21, 1901).

The exact status of the operation is not as yet determined. It does, however, seem to be proved that operation is in some cases followed by apparent cure or great amelioration of the condition. Whether permanent cure is ever thus obtained is doubtful, and the part played by rest in bed and drugs in effecting an improvement must not be lost sight of. Cases with pain and bloody urine are often much improved by incising the capsule. Post-operative suppression and the anuria of acute infectious diseases may be favorably influenced by the operation. An important fact which Rovsing maintains and Edebohl proves is that chronic nephritis may be for some time unilateral disease. (Read the views of Schmidt in "Med. Record," Sept. 1, 1902; of Rovsing, of Copenhagen, in "Mittheilungen aus den Grenzgebieten der Medicin und Chirurgie," vol. x, 1902, and editorial in "Journal of the Med. Assoc.," Jan. 11, 1902.)

The operation as practised by Edebohl may be done on both kidneys, or one sitting or in two sittings. In some cases only one kidney is subjected to operation. Edebohl takes a very radical view and would operate on any case free from incurable complications—if an anesthetic can be given and if the life-expectancy without operation is not less than one month ("Med. Record," Dec. 21, 1901). Ether is given or nitrous oxide and oxygen. Lay the patient prone with an air-cushion under the belly and expose the kidney by a vertical incision at the edge of the erector spinae mass, which cut does not open the sheath of the muscle. Remove the fatty capsule from the true capsule, continuing the dissection around each pole until the pelvis of the kidney is reached. The kidney is extruded from the wound, the true capsule is incised along the convex border and around each pole, is separated from the kidney, and is cut away close to its junction with the kidney pelvis. The kidney is then returned to its bed of fat, and the wound is closed. (See "Med. Record," Dec. 21, 1901.) Edebohl does not drain unless there is considerable edema. Edebohl reports 18 operations without a death. In 9 of the cases the operation was done more than one year ago, and 8 of them are said to be cured. Personally I do not believe that the operation can really cure Bright's disease. It cannot restore altered connective tissue and epithelial cells. The new blood-supply must be through scar tissue, and we have yet to learn that such a blood-supply can be good.

The operation should be restricted to acute and in chronic cases, to conditions with severe albumin percentage, or persistent and notable urine voided (Ertzbischhoff, in "Archiv. génér.

Nephrotomy.—Nephrotomy means incision, sometimes, though wrongly, applied to the exposure without incision. When the kidney wound is made without incision, the operation should be called **nephrostomy** to evacuate infectious material, relieve tension of the pelvis or exploration of the ureter, and for diagnosis. *Instruments* required are scalpels, a blunt-pointed forceps, a grooved director, hemostatic forceps, a fountain syringe, an Allis dissector, needle-holder. If looking for a stone, have a pair of forceps and a scoop to remove the stone, and a pair of forceps to remove adherent calculi. The patient lies upon his back or a cylindric air bag being placed under the back, the incision being made $\frac{1}{2}$ inch below the last rib and close to the vertebral mass, and runs obliquely downward and forward for 3 inches, the incision being enlarged later if necessary. The superficial fascia, the fat, the external oblique, the internal oblique, and the outer edge of the transversus abdominis muscle are exposed. Push aside the external oblique, when the perirenal fat will bulge out. If layers of fat exist. Tear this fat through with a pair of forceps. Use an Allis dissector to expose the kidney, which can be felt by the hand of an assistant.

Kocher's incision for nephrotomy is between the sacrolumbalis muscle and the twelfth rib, and runs upward and outward to the axillary line (Fig. 229). The layers exposed are the subcutaneous tissues, lumbar fascia, the latissimus dorsi muscle, and the posterior inferior iliac fossa.

Lidebohl's method enables the surgeon to examine the kidney thoroughly because this organ is brought outside the body. The patient is prone, with a large cylindrical inflated rubber bag under the back. A vertical incision is made close to the border of the back from just below the last rib to just above the iliac crest. The muscle is not opened. The fibers of the latissimus dorsi muscle are cut by blunt dissection. The iliohypogastric nerve and the ilioinguinal nerve are cut. The transversalis fascia is incised and the fatty capsule of the kidney is torn through and the kidney is well separated from the kidney capsule. The kidney is pulled by the legs toward the foot of the table. This change of position brings the pad beneath the kidney. When reposition takes place, the kidney is forced into the wound and drawn and thoroughly examined. A common mistake is to make a longitudinal incision through the back to admit the finger into the renal pelvis. This is unnecessary until the kidney is split in half.

close the kidney wound completely with a round needle and catgut, unless drainage is necessary or packing is required. Another incision is placed longitudinally a little posterior to the convex border. This goes through the bloodless zone of Hyrtl, and causes less hemorrhage than the incision along the convexity. Marwedel's incision is a transverse cut at the middle of the convex border of the kidney into the renal pelvis. It is doubtful if this incision is accompanied by less bleeding than longitudinal incision of the convexity. After the completion of our work on the kidney the lumbar wound is closed completely or is partially closed to permit of drainage.

Operation for Stone in the Kidney.—(*By Pyelotomy or Nephrotomy*)—It used to be held that incision of the pelvis of the kidney is far more apt to be followed by fistula than incision of the substance of the kidney. The Mayos, Bevan, and others have proved that this conviction is untrue. In many cases pyelotomy is preferred to nephrolithotomy. It is used for single stones of moderate size in the pelvis and unaccompanied by suppuration. When we have a large branched stone, coral-shaped stones, multiple stones, and stones accompanied by distinct and gross evidences of infection, then nephrotomy should be preferred to pyelotomy (Bevan and Smith, in paper read before the American Surg. Assoc. in 1908). In both operations the patient is placed on the sound side with a sand-pillow or cylindric air-bag under the flank. In both cases the incision recommended for nephrotomy is used. In both cases the kidney is lifted into the wound or brought out of the wound so that it may be satisfactorily palpated. In both cases bleeding is controlled by having an assistant grasp the pedicle with his fingers or with a pair of forceps, each blade of which is covered with a bit of rubber tube, while the surgeon opens the pelvis or the kidney tissue, removes the stone, and explores with the finger.

Pyelotomy.—Remove the fat from the posterior surface of the pelvis of the kidney. We may then be sure that no aberrant vessel is in our way. The normal vessels are all in front of the pelvis. The posterior wall of the pelvis is now opened, the stone is extracted, the pelvis explored, the cut in the pelvis sutured with fine catgut sutures, the kidney is restored to place, a cigarette drain is introduced, and the wound in the loin is closed.

Nephrolithotomy.—The methods of incision, exposure, and opening the kidney are described on page 1290, under Nephrotomy. When the kidney has been opened, loosen the calculus with the nail, and remove it with the finger, with a scoop, or with forceps. After removing the stone, suture the incision with catgut, and release the pressure on the pedicle. Hemorrhage will rarely occur. If in spite of this plan bleeding occurs, take out the stitches and apply pressure and hot water, or in some cases plug with iodoform gauze for twenty-four hours. When hemorrhage ceases, put a large drainage-tube down to the kidney. Close the wound in the muscles and integument and dress antiseptically. The dressings must be changed frequently and the tube should be shortened daily. In some cases nephrectomy is necessary (page 1291). Formerly in these cases I always drained for a time and removed the kidney secondarily, believing that the patient would gain strength in the interval and stand the severe operation of nephrectomy better. I am satisfied that in most cases this view is wrong, because removal of a kidney bound down by adhesions is one of the most perilous and difficult operations of surgery.

Nephrectomy.—Nephrectomy is the removal of a kidney. There are two

methods of nephrectomy—the *lumbar* and *thoracic*—the *lumbar* and *thoracic* was performed, according to Watson, in 1869. The operation was transperitoneal and was performed on the right kidney. Simon, in 1869, performed the first successful nephrectomy. Before performing the operation, the competence of the kidneys must be ascertained. If at least one kidney is competent, it is very unsafe to operate. Before operating on the kidneys. Examination of the bladder by catheterization, a strong indication that both kidneys are diseased when we reflect that a horseshoe kidney has two ureters. Catheterization of the ureters is advisable if the patient is probably require a specialist to perform it. The examination of two kidneys consists in feeling both of them before the operation and if uncertain as to the competence of the kidneys, each kidney during the operation and before the operation preliminary exploratory laparotomy.

Lumbar Nephrectomy. The instruments required are: a scalpel, a blunt-pointed bistoury, forceps, a clamp, retractors, spatula, blunt hooks, a needle, a grooved director, stout silk, an A. Paquelin cautery. The patient is placed on the side, the back under the loin. Several incisions are made. In some cases the oblique incision is first made to the right of the spine. The incision is begun half an inch below the last rib, and is carried downward and outward. In some cases a kidney can be removed through the cut must be enlarged. It can be enlarged by adding to it one inch below the origin of the oblique cut. The incision consists of a vertical cut by the edge of the bistoury to the iliac crest, from which point it is carried outward and is carried to or even through the rectus abdominis. In this position lift the kidney and separate it from the surrounding tissues with the finger; clamp the pedicle; pass an artery forceps over the vessels of the pedicle; ligate in two places and arrest hemorrhage permanently by ligature. If the kidney is healthy, ligate it with silk and drop it into a bowl of pure carbolic acid, and then either ligate it at the pedicle or at the base of the wound. If hemorrhage persists from the wound, insert a drainage-tube and close the wound. If the pedicle is diseased, close it with Lembert sutures. Kocher's method is to feel the opposite kidney before removing the diseased one. The incision is begun as in the lumbar method, and is carried forward so as to expose the reflected colon in the posterior axillary line (Fig. 229). The colon is opened, and the surgeon's hand is inserted into the peritoneal cavity to feel the other kidney. If another kidney is diseased, it is removed.

* Kocher's Text-book of Opera-

the diseased organ may be removed. Brewer's personal statistics show 53 cases of nephrectomy with 2 deaths, a mortality of 3.8 per cent. ("Med Record," March, 20, 1909).

Abdominal nephrectomy is more dangerous than the lumbar operation. The same instruments are required as are used in the preceding operation. The position is supine. The incision is that of Langenbeck—four inches long in the linea semilunaris, its center corresponding to the umbilicus. Open the abdomen, introduce a hand, feel the kidneys, and if both show serious disease, do not perform nephrectomy. If we decide to remove one kidney, keep the small intestine away by pads, push the colon toward the umbilicus, incise the outer layer of the mesocolon, and bare the kidney. Strip off the peritoneum from the kidney and its vessels, and ligate the vessels by passing strong silk through the center of the pedicle with an aneurysm-needle. Ligate the ureter if healthy, and divide it. If the ureter is septic, fasten it to an opening made in the loin by cutting onto forceps pushed to the outer edge of the quadratus lumborum. Stop bleeding, irrigate the belly cavity, and dress as usual, employing drainage only when septic matter has passed into the peritoneal cavity or when oozing of blood is persistent.

Nephrectomy in Children.—The operation is proper in certain non-malignant troubles. Jepson did a successful nephrectomy for a congenital cystic kidney on a patient four months and fourteen days of age. Rovsing did it successfully for congenital hydronephrosis, the patient being nine months old. Roswell Park did a successful nephrectomy for congenital cystic kidney on a child twenty-three months of age. The value of nephrectomy for sarcoma is more than doubtful. The operation never really cures, and if an operative recovery is obtained, the disease appears after a time in the other kidney. Jessup performed nephrectomy in eleven children and every case died within two and one-half years of the operation. The operation often prolongs life and relieves discomfort, but does not cure.

Partial Nephrectomy.—This operation may be performed in some cases for wounds, cysts, and innocent tumors. After removing the damaged or diseased part, bleeding points are ligated with catgut. The wound-surfaces are approximated as well as possible by catgut sutures. Drainage is introduced. The value of partial nephrectomy in some cases seems certain, and we should apply it when possible instead of the complete operation,* except in cases of malignant disease.

Renipuncture.—This is an operation devised by Reginald Harrison for the relief of albuminuria due to elevated tension. The kidney is exposed in the loin, the capsule is incised, and punctures are made in the kidney. Simple incision of the capsule will usually relieve nephralgia. (See Operations for Chronic Nephritis.)

Nephropexy is fixation of a movable kidney. The term nephrorrhaphy, so long used for the operation, really means suturing a wound in the kidney.

The Author's Modification of the Elder Senn's Operation. Many surgeons feel that it is not desirable to pass sutures through the kidney-substance, and I have entirely abandoned the use of them in operations

* See Oscar Bloch in Brit. Med. Jour., Oct. 17, 1896, also reports of Czerny, Bardenheuer, Tuffier, and Kummell.

for movable kidney. Urinary fistula has for value of such sutures is very doubtful. The and if it is suspended by sutures, they are certain operations the kidney when restored to place is has its ureter and vessels looking forward; in other twist in the ureter. In operations like Goylet's kidney much nearer its proper level and which do vessels, the upper pole is not anchored and tend Senn's operation fixes the kidney without using a

The patient lies upon his abdomen, Edelbohls beneath the lower abdomen. A vertical or slight made, the perirenal fat is exposed, and its two kidneys kidney is reached. The fatty capsule is thorou

Fig. 769.—Gauze slings, each composed of two pieces sutured

organ. The kidney is brought out of the wound pulling the patient toward the foot of the bed, a ribs, when traction on the fibro-fatty capsule will from the wound. The posterior fatty capsule is of fatty capsule up to the hilum. The true capsule if necessity exists, the organ is decapsulated. It is by suturing together with the finest plain catgut form gauze. Two such strands are prepared (Fig. 770) gauze is placed under the upper end of the kidney lower end, the sling in each instance being direct suture line external and not in front as the kidney the back (Fig. 770). When the kidney is replaced front (Fig. 771). The kidney is replaced and will two pieces of gauze, the ends of which protrude from

is placed below the lower renal pole to fill up the space which always exists there and to stimulate granulation. This space below the kidney is a frequent cause of subsequent loosening in most suture operations, because the kidney hangs in it unsupported, as a bucket hangs in a well. Harris recognizes this, and in his operation closes the space by sutures. Gauze is packed in over and about the kidney, and over this the two long slings are tied. Several sutures are inserted to close the lumbar aponeurosis; some are tied and some are left untied. A large gauze pad is placed upon the abdomen over the anterior surface of the kidney, and the lumbar wound is dressed with gauze. The dressing and gauze pad are held in place by a binder. In about eight or ten days the gauze should be soaked with salt solution during half an hour and the packing removed. At this

Fig. 770.—Right kidney projecting from wound. Observer standing on right side of patient: 1 and 2, Slings in place, with sutures external; 3, skin of the back; 4, upper renal pole; 5, lower renal pole; 6, convex border of kidney; 7, external surface of kidney. (Slings should be broader than is shown in cut.)

Fig. 771.—Right kidney restored to place, seen from in front. 1 and 2, Slings in place, sutures anterior; 4, upper renal pole; 5, lower renal pole; 7, anterior surface of kidney. (Slings should be broader than is shown in cut.)

time the catgut is destroyed and the gauze can be easily pulled out. The tied sutures are cut and removed, the sutures left unfastened are tied, and a small piece of gauze is inserted as a drain between the granulating surfaces. If a continuous piece of gauze was used, ether must be given before removal is attempted. Further, in the old operation, a large wound was left to granulate and weeks were often required to obtain healing. In this operation the wound is usually entirely healed in from eighteen to twenty one days. After the performance of nephropexy the patient remains in bed for three weeks. By this operation the kidney is placed in a proper situation, is surrounded with granulations, which are converted into scar-tissue, and the organ becomes encased in a box of fibrous tissue. I believe that a kidney so treated will probably remain fixed.

Ureterolithotomy.—If the stone is impacted in the upper two-thirds or three-fourths of the tube it may be reached by an incision from the twelfth rib downward and forward to just anterior to the anterosuperior spine of

the ilium and then parallel to Poupart's ligament until above its middle. The peritoneum is stripped up as in extraperitoneal ligation of the iliac vessels. The ureter adheres to the peritoneum. The operation is strictly extraperitoneal. The tube is opened by a longitudinal incision. The stone is removed. The ureter is explored by means of a sound to see if it is free and may then be sutured with catgut, but will heal perfectly well without sutures. The tissues above the ureter are sutured and a bit of rubber tissue is carried to the distal. Gauze packing must not be carried down into the ureter, as it would make a urinary fistula. Whenever possible—and usually it is possible—reach the ureter by the extraperitoneal route, and even well below the brim of the pelvis the peritoneum can be stripped and the ureter opened from behind. If the stone cannot be reached by the extraperitoneal method, open the peritoneal cavity and incise the ureter. After removing the stone, suture the wound in the ureter with inversion-sutures, fasten an omental graft over the suture-line (Fenger) and drain. In a woman a stone near the vesical opening can be reached by a vaginal incision. Stone in the vesical portion of the ureter may be removed after the performance of a suprapubic cystotomy or by an operating cystostomy.

My colleague, Dr. John H. Gibbon, advocates a combined intra- and extraperitoneal route for stones anywhere in the lower two-thirds of the ureter. The peritoneal incision permits of exploration and exact localization of the stone, allows the surgeon to push the calculus from an inaccessible into an accessible position, and makes the removal vastly easier. The stone is removed by extraperitoneal incision of the ureter, and the peritoneum is closed (John H. Gibbon, in "Annals of Surg., Gynecology, and Obstetrics," May, 1908).

FIG. 774.—Van Hook's method of ureteral anastomosis.

Uretero-ureterostomy (Van Hook's Operation)—In this operation ligate the lower end of the divided ureter with silk or catgut. About one-half of an inch below the ligature make an incision in the long axis of the tube. This incision is in length equal to twice the diameter of the tube. Each end of a piece of fine catgut is threaded to a fine needle. This thread is passed through the upper end of the ureter (Fig. 772). The needles are

made to enter the lower end of the tube through the door made by the surgeon. They are pushed through the wall of the ureter one-half an inch below the door (Fig. 772). Traction upon the strings causes invagination, and the ligature-ends are tied. If the operation is intraperitoneal, the ureter is wrapped about with peritoneum.

Intestinal Implantation of the Ureters.—This operation may be employed in exstrophy of the bladder and in vesical cancer, in which it is necessary to remove the bladder. After this operation there is danger of infection of the ureters and consequent ascending ureteritis and pyelonephritis, and the presence of urine in the bowel usually causes inflammation of the rectum and incontinence of urine may take place.

Maydl asserts that a piece of the *bas fond* should be removed with the ureter, and implanted with it into the intestine, the flange hanging free in the lumen of the gut. If this is done, the relations of the ureter to the muscular coat of the bladder are not interfered with, stricture is less likely to occur, ascending infection is antagonized, and suppurative conditions arise at the margin of the flange, rather than, as in other methods, directly in the cut ureter. Maydl has collected the records of fourteen cases operated upon by this method, with two deaths.* In vesical exstrophy Peterson transplants a vesical flap containing both ureteral orifices into the descending colon.

Cystoscopy.—Cystoscopy is the employment of the cystoscope for the study of the interior of the bladder, the prostate, the ureteral orifices, and the appearance of the fluid coming from each kidney.

The cystoscope is an instrument of great value in the hands of an experienced man, but is practically useless when employed by a novice. In using a cystoscope the mucous membrane may be burned with the lamp. This causes inflammation, and if an eschar forms, it will be cast off, exposing a granulating surface. Schmidt calls attention to this injury, speaks of the condition as *ulcer cystoscopicum*, says it is in the fundus, has the shape of the instrument, and heals in from fourteen to twenty-one days ("Jour. Amer. Med. Assoc.," July 19, 1902).

Cystoscopic examination of the bladder owes its present position to Messrs. Max Nitze and Joseph Leiter, who were the first to introduce a practical instrument. The great obstacle in former years was the danger of burning the mucous membrane by overheating of the lamp. The invention of the cold lamp eliminated that danger, and was a great step forward. Nitze was the first to recognize the futility of examination by reflected light and constructed an instrument with the light on the end which to-day is copied by all of the modern instruments.

Cystoscopes may be divided into several types: (1) The examining instrument; (2) the instrument carrying ureteral catheters or the catheterizing cystoscope; (3) the operating cystoscope. They all have certain mechanical features in common, but differ in their construction and lens arrangement.

The examining instruments are of two fundamental types—the direct and the indirect. In the direct there is a straight telescope with a series of wide angle lens that give the picture of the bladder in front and slightly to the side. In the indirect the lens is so ground and set as to enable the operator to look backward toward the prostate.

* Editorial in Jour. Amer. Med. Assoc., May 6, 1899.

Catheterizing cystoscopes are also of two and the indirect. In the direct catheterizing from the carrying tubes to the ureters. In the

Fig. 773.—Marks' air-dilating endoscope for exam

directed by a lever on the end of the instrum on the penile end. By raising or lowering the altered to facilitate its introduction into the us

Fig. 774.—Marks' air-dilating endoscope for exam

It is obvious that the bladder should be a cystoscopic examination. For this purpose. The modern tendency is in favor of water dis instruments, notably that of Prof. Lewis, use

Water as a dilating medium is superior to air, unless operative work is to be done through the instrument, in which case the inevitable hemorrhage precludes the use of water. The air instruments show but a small field and the distention causes pain and often a mild cystitis.

From the foregoing it is plain that one type of instrument is not suited to all cases, and each has its claim to practical utility. Some cases can be most readily catheterized by the direct, while others are only reached by the indirect, plan. It has been our experience that if the ureteral orifices are normally placed, the direct method is quicker and more readily learned by the beginner. Where from any cause the ureteral orifice turns backward (which only happens in a very small percentage of cases) the indirect cystoscope is indispensable, it being practically impossible to reach the ureteral orifice by the direct instrument.

There are at present many different forms of cystoscopes on the market, notably among them are the Nitze, Casper, Tilden Brown, Cabot's modi-

Fig. 775. — Universal cystoscope, after E. Tilden Brown.

fication of the Tilden Brown, Berger, Albarran, Bransford Lewis, and the so-called Universal. In the selection of an instrument best suited to the needs of the general surgeon, the Universal, shown in Fig. 775, will answer in most cases. It combines both the direct and indirect systems of catheterization and the retrograde and direct systems of examination. The universal instruments of Bransford Lewis and Tilden Brown possess features of great practical utility.

The lamp is so situated in the vesical end and the fenestra so arranged that they throw light both on the concave and convex sides of the tip. Hence, all systems may be operated through a single tube and changed without removing the light from the bladder. They provide the following: (1) Direct examination and lateral view, depending upon the angle of the lens and the instrument. The lateral view can be had by withdrawing or extending the cystoscope and also swinging it from side to side. (2) Indirect examination of the trigone, prostatic pouch, and prostate. (3) Double direct catheterizing.

(4) Double indirect catheterizing. (5) Retra (6) Provision for continuous irrigation. The necessary provision, for, in many cases, a succu zation can only be accomplished during contin and pus.

Sterilization of Cystoscopes and Ureteral C the cystoscope before using, place it for five m oxycyanid (1:1000) or formaldehyd (1:500). Some operators use a 5 per cent. solution of ph immersed for twenty-four hours, after which i both neutralizes the phenol and lubricates the solution is easily used and is thoroughly satisfi formalin gas be used, always wash the instrum to prevent irritation by the sterilizing medium.

Ureteral catheters can be sterilized by boill open shallow dish in a saturated solution of chlorid. The following precautions must should be wrapped in gauze and the bottom to touch each other or curl upon themselves t ruin the instrument. They may also be steri cystoscope, care being taken (if formalin was germicide, especially from the lumen of the c

Contraindications to Cystoscopy. The least 100 cc. of fluid. Examination is eith if the prostate is greatly enlarged. Contract smaller than No. 24 of the French scale at Papillomata, tumors, and foreign bodies of the acute Bright's disease, instrumentation may be following are further contraindications, as s Henry G. Spooner, in "Med. Record," July that operative intervention would be useless; acute cystitis, in tuberculosis in which the cysto-scope.

Technic of Cystoscopy.—The patient s sounded for several days previous to the cyst lishes a tolerance in the urethra. He should such as that devised by Tilden Brown or Brand

General anesthesia is rarely necessary prov manipulations. There are, however, some hy necessary to anesthetize. Cocainization of t the posterior portion of the canal of a dram d through the Keyes-Ultzmann syringe will of depositor devised by Prof. Lewis will answer preliminary lavage of the bladder should be through the cystoscope sheath or by means of bladder is not diseased, it is merely necessary t urine has been withdrawn, the cystoscope she held in place. The thumb of the left hand pr finger presses upward on the under surface o

raises the beak of the instrument from the sensitive trigone, where most of the pain and hemorrhage are produced by vesical tenesmus.

In regard to a selection of the distending medium, the operator may use sterile water, normal salt solution, boracic acid solution, or mercury oxycyanid solution (1:5000). The bladder should be moderately distended and, if possible, from 8 to 10 ounces are left in the viscus. In contracted or hypersensitive bladders it is well to elevate the hips and so relieve the pressure on the sensitive vesical neck and trigone.

The temperature of the distending fluid is of great importance, particularly if there is difficulty in finding the ureteral outlet. If this is the case, the temperature of the fluid should be about 60° F. This enables the operator to see a

Fig. 776.—Tilden Brown's cystoscopic table with patient in position for examination.

so-called swirl when the warm jet of urine mixes with the cold water in the bladder. It is sometimes advisable to give methylene-blue before examining for the same reason. The blue stream from the ureter at once identifies it.

After the bladder is filled the telescope containing the catheters is inserted and the light turned on. The instrument is then held in the median line and pushed gently back, well into the bladder, always making pressure to keep the peak from impinging upon the floor. The cystoscope is now slowly withdrawn, a careful watch being maintained through the telescope for the *interureteral bar*. This structure (about which there has been much argument as to whether it really exists) marks the posterior border of the trigone. The examiner has still another guide in the blood-vessels which run in a general way anteroposteriorly. There is quite a distinct line of demarcation between the fish-net loop arrangement of the sides and base of the bladder from that described in the trigone. Fig. 777 gives a general idea of the vascular arrangement. When the *interureteral bar* or posterior border of the trigone has been located, the instru-

ment is gently and slowly moved laterally, so that until the end of this structure is reached. At that moment and a sharp lookout is kept for the ureteral orifice is thus indicated. Should the field be obscured by the lens, or should the solution in the bladder be turbid, continuous irrigation must be kept up through the catheter.

The Ureteral Orifices.—As before mentioned, the ureteral orifices are located at the termination of the interureteral band, forming the apex of a triangle found by the vesical outlet and the ureters, usually about 1 to 1½ centimeters from the mouth of the ureters from the vesical end of the urethra. The orifices are often slits or tubercles on the surface of the mucous membrane, but are not always the same. Some of the abnormal

Fig. 777.—The interior of the bladder, showing arrangement of the ureters. A, B, interureteral band.

with are as follows: one ureter close to or fused with the other, both ureters emptying into the bladder close to the vesical outlet and in some very rare instances both ureters emptying into the bladder at a distance from the vesical outlet. Secrecion and pocketing of the bladder with debris often makes localization difficult. It is often necessary to use a solution of methylene-blue or indigo-carmin may enable one to locate them.

After locating the ureteral orifice the vesical catheter is inserted directly over the entrance and the catheter is allowed to remain for a moment in order to distend the bladder and relax the sphincter muscular fibers. The patient is instructed to hold his breath and the orifice is carefully watched until a jet of urine is seen. Then the catheter is gently inserted in the orifice, and greatly facilitates the passage of the instrument. After the catheter has passed the sphincter muscle it should be carried

pressure. The practice of passing the instrument quickly, so commonly resorted to by the novice in order to gain time, is pernicious, and almost invariably causes laceration and hemorrhage. Before inserting the catheter some operators prefer to coat it with paraffin in order to render it absolutely smooth and further to assist in the detection of calculus. This is not necessary. Any instrument with an imperfect eye should be discarded.

The round-pointed catheter should be used wherever possible, as with it there is less danger of injuring the delicate mucous surfaces of the canal. The sharp-pointed olivary tipped instrument often causes blood to appear. If possible, insert the catheter into the pelvis, for then hemorrhage from trauma is less likely to invalidate the examination, and spasm of the ureter, with sucking in of the mucous membrane in the eye, is less likely to occur. Having finished the catheterization of one side, the instrument handle is swung to the opposite side and a similar procedure is carried out. Always have a distinguishing mark upon the catheters. A very good method is to use different colored instruments, so that there may be no confusion after withdrawal of the cystoscope. In some cases only one ureter can be catheterized. In these cases the bladder should be thoroughly washed and the other catheter, left on the floor of the bladder, will collect the urine from the uncatheterized side and give a fair idea of the condition of that kidney.

Removal of the Cystoscope.—The light should be turned off and a small amount of fluid allowed to escape through the barrel. The lens system carrying the catheter is then loosened and gently rotated from side to side to free the catheters. During this procedure the catheters are fed gently backward, but not with sufficient force to cause kinking, and the lens system removed. Next the sheath is withdrawn by carrying it straight up over the abdomen.

Collection of the Urine.—The catheters are carefully wiped with sterile gauze and permitted to drain into separate bottles or test-tubes, marked respectively right and left. The orifices of the receivers should be plugged with sterile absorbent cotton, which will collect and prevent any admixture of urine or water coming from the bladder by capillary drainage. The bottles should also be held in such position as to prevent such capillary drainage reaching them. With regard to the collection of the samples, there are certain precautions that should be observed: (1) The samples should, if possible, be collected in three separate bottles from each side, allowing each set to remain in position a definite time, generally one-half hour. These should be carefully watched and marked first, second, and third half-hours. They should each be examined separately, and by a summation of the examinations the opinion should be reached. Almost invariably microscopic blood can be found in the urine drawn by catheterization of the ureters. In a study of 15 cases of normal ureters where blood was not present in the combined urine, after the greatest care in catheterizing, microscopic blood was present in all but 3. The erythrocytes are usually most numerous in the first bottle, gradually diminishing, until in the third there are but very few or none. Should the blood increase in amount in the bottles, it is an important clinical fact.

In some instances one or both catheters fail to drain. This may be due to a bubble of air in the instrument, impinging of the mucous membrane upon the eye, plugging by blood-clot, mucus, pus, or particles of gravel. A syringe is then essential. The blunt needle should be inserted into the catheter and

suction applied; should this fail, not over 4 cc. may be injected through the catheter. This procedure must be done very gently, because of the danger of overdilating and causing colic.

A uropyknometer is used for taking the specific gravity of urine removed by the ureteral catheter.

The Operative Cystoscope.—The most perfect cystoscope that devised by Prof. Bransford Lewis. This cystoscope is used for the removal of small portions of stone and for the removal of ureteral orifices. It is also most useful for the removal of ulcerated areas. It is not wise to remove papillomatous or most villous papillomatous growths sooner or later, but to remove them if malignancy and should have their pedicles removed. This can only be safely done after suprapubic cystostomy.

Practical Value of Cystoscopy and Ureterocystoscopy.—The cystoscope has attained a very important position in the urologic armamentarium. It undoubtedly affords the best method for the diagnosis founded on pathologic findings. By the use of the cystoscope the presence and character of cystitis, stone, foreign bodies, and ureteral orifices could be determined. Without it the presence of ulcerations could not be determined. Its greatest field is in the early diagnosis of carcinoma of the bladder and vesical hemorrhages. In the detection of carcinoma of the bladder it has revolutionized surgery. It makes possible the removal of growths before malignancy has signed the patient. In the case of prostatic hypertrophy, in which the lobes project into the bladder, it is rarely diagnosed without the cystoscope, with the clinical diagnosis positively confirmed. It is also used for the removal of foreign bodies, such as stone, pieces of cotton, etc., from the urethra, thus saving formidable cutting operations. It has also solved the great difficulty found by surgeons in former years of the treatment of symptomless hemorrhage, a problem which has now found its solution.

Ureteral catheterization makes possible the examination of the pelvis of the kidney in cases of ureteritis and pyelitis.

The technic of lavage is as follows. A glass syringe of 50 cc. capacity is equipped with a blunt needle that can be inserted into the ureter. About 5 to 10 cc. of the irrigating fluid is instilled into the ureter and allowed to run out. In introducing the fluid care must be taken that the renal pelvis be overdilated. Overdilatation causes pain. The following solutions may be used. Saturated solution of boric acid is generally used as a cleanser before any other fluid is used. In suppurative conditions by a solution of potassium permanganate (stronger as the case requires). The injection is made through the catheter while irrigating. Subsequently, the patient is given a genito-urinary antiseptic and the patient given a urotropin.

A differential diagnosis must sometimes be made between acute appendicitis and movable kidney with dilated pelvis, thus determining the carrying capacity of the pelvis.

producing marked symptoms, the renal pelvis is usually dilated. When the trouble is due to the kidney the pain induced by the distention is similar to that from which the patient has suffered. If a stone is present in the ureter the x-ray picture will usually reveal it, but here again there may arise doubt as to the exact course of the canal. Catheters passed into the ureters with a lead wire in them and the case skiagraphed will enable the radiographer to determine their exact course. Fig. 778 demonstrates the practical utility of such manipulation. Phleboliths, fecal masses, concretion, and calcified lymph-nodes have been mistaken for ureteral stone. Appendices have been removed when the source of trouble has been impacted stone in the right ureter. An impacted stone in the ureter may often be dislodged by passing a catheter into the ureter and, if possible, beyond the stone. A few minims of sterile olive oil

Fig. 778.—X-ray photograph, showing the course of the ureters by wires in the catheters. (Taken by Dr. W. E. Manges.)

are then injected through the catheter, which act as a lubricant and assist in the passage of the stone. Dilatation of the ureteral orifice, by leaving the catheter *in situ* or passing a second instrument alongside of the first, will often cause the stone to pass into the bladder.

Disinfection of Urethral Catheters. Metallic instruments are cleansed by boiling. Soft-rubber and elastic catheters can be sterilized by mechanical cleansing with soap and water and boiling for five minutes. The common custom of immersing a soft-rubber or elastic catheter for five minutes in a 1:2000 solution of corrosive sublimate is a useless waste of time, as such a procedure will not sterilize an infected instrument. Of course, a catheter coated with varnish or resin cannot be boiled in water or placed in steam. The best method of sterilization for woven or varnished catheters is formalin vapor. Catheters, after being cleansed mechanically, should be placed in a

glass cylinder the bottom of which is perforated and placed for twenty-four hours in the vapor of formalin. Instruments are kept ready for use in a glass of formalin (R. W. Frank, in "Berliner klin. Wochenschr."). After using, the catheters are washed in sterile water, then scrubbed with soap and water, dried, and finally placed in the vapor of sulphurous acid for forty-

DISEASES AND INJURIES OF

Retention of Urine in the Male.

course, a disease: it is rather a result of one of the diseases of the urinary tract. By this term is meant an absolute inability to void urine. Retention may be *complete*, not a drop emerging, or *incomplete*, a dribbling setting in after a time, due to paralysis of the bladder. It becomes unable to contain more fluid, expels the urine by ureters being produced by atmospheric pressure, or by the engorgement, the overflow, or the incontinence of the retained urine in a man with enlarged prostate. This is not retention, and the urine is voided. This is not retention, and the urine is voided. Of course, true retention may be caused by prostate. Retention may be caused by urethral stricture, hypertrophied prostate, impacted calculus, or foreign body, urethral abscess, imperforate prepuce, congenital tumor of the prostate, prostatic abscess, abscess of the bladder, and pressure from a large pelvic tumor. Cause is spasm of the membranous urethra, urethral stricture, acute gonorrhea, or gleet. (2) *Neurogenic* Retention. Impairment of the nervous apparatus for indirect cause in men. We see retention with fractures or spinal concussion, in certain diseases, in shock and peritonitis, often in the diseases characterized by muscular wasting, from the use of opium, or cantharides, and after certain operations about the rectum. The last-named form of retention is inhibition of the expulsores or to reflex action, causing it to remain firmly contracted suddenly and is sometimes the first thing that causes a stricture to seek a surgeon.

Symptoms. In *acute retention* there is a sudden onset, the patient making acutely painful straining efforts, and often passing. There are severe pain and tenderness of the perineum, and penis. All the symptoms rapidly inaugurated, and death closes the scene unless relieved. In *chronic retention* is from time to time alleviated by the passage of small amounts of urine. The symptoms are slower in evolution and are less intense, and are often accompanied by some cases of gradual onset, due to atony, and the patient feeling no particular pain and complaining of

really the overflow of retention, and is not a sign that the bladder is successfully emptying itself. In any case of retention the bladder rises above the pubes, and there is found a pyriform, elastic, fluctuating mass in the hypogastrium, which mass is dull on percussion and gradually enlarges until the bladder is evacuated or incontinence sets in. The flanks give a clear percussion-note, and the tumor is more prominent when the patient is erect than when he is recumbent. Long continuation of obstructive disease, producing partial retention with or without attacks of complete retention, disorganizes the kidneys. Acute and complete retention may induce rupture of the urethra or urinary suppression.

Fig. 779.—Gouley's tunnelled catheter threaded on a filiform bougie

Fig. 780.—Points of Gouley's whalebone guides (filiform bougies)

Treatment.—Place the patient upon his back, keep him warm, and if instrumentation does not rapidly succeed, give an anesthetic. Never attempt to use a catheter when the patient is erect. To do so may cause serious or possibly fatal shock. Be sure that every instrument is aseptic. In *organic stricture* try to pass an elastic, olivary-pointed catheter (Fig. 782, a). Do not use any force until the neck of the catheter engages in the stricture. Then an experienced operator may warily use a certain amount of force, but never much. When the instrument enters the bladder, draw off but half of the urine, withdraw the instrument, wait a few hours, insert it again, and then empty the bladder and wash out the viscous with warm boric-acid solution. To

Fig. 781. Nélaton's catheter.

draw off all of the urine at once is dangerous, because the sudden relief of the pressure upon distended veins leads to bleeding from the mucous membrane and hemorrhage into the bladder-walls. After the bladder has been emptied the patient is wrapped in blankets, a bag of hot sand or of hot water is placed against the perineum, and a hot-water bag is laid upon the hypogastric region; when he recovers from the effect of the anesthetic he is given suppositories of opium and belladonna, and tablets of salol and boric acid are administered for several days. If it is found impossible to insert a rubber instrument, make an attempt to carry a filiform bougie into the bladder. Fig. 780 shows filiform bougies. If the stricture is

known to be organic from previous history. **a** On this bougie, after it has been inserted, **G** be threaded (Fig 779) and carried into the **b** the catheter, we can simply leave the filiform. The filiform bougie will act as a capillary d empty the bladder. Then insert another bot for several days, using also opium, ordering attempt to dilate the stricture forcibly until r mation has subsided. If no bougie can be p totomy (suprapubic or perineal). In *spasms* metal catheter firmly against the face of the occur and the instrument will eventually pas curve of a metal instrument. An individual which has given but little trouble may devel

Fig 782. *a*, French olive gum catheter, *b*, Mercier's elbowed catheter, *c*, Mercier's double elbowed catheter, *d*, curved gum catheter.

gent, pass a soft catheter. In the *occluded* with a tenotome. In a *congenital cyst of th* bougie, which will rupture the cyst. In *com* puce. In *impacted stone* try to pull out the if this fails, cut the urethra, or, in rare ca the bladder. In *fecal impaction* scrape out *enlarged prostate* try to pass an instrument, an ordinary Nélaton catheter (Fig 781) stre filiform bougie nearly to the beak. If, how enters markedly into the urethra, Mercier's cou or his double elbowed instrument (Fig. 782, *c*), fail, a metal instrument with a large curve may ous tool and one capable of inflicting grave injg *defect* use a soft catheter (Fig. 781). Cases of require warmth, confinement to bed, the admin of the skin, and the use of such drugs as salol, b to asepticize the urine. In some few cases no i bladder. In most of such cases aspirate—wh if necessary—and in a day or two, when swd instrument can be passed. A small asepticia pushed into the bladder, the trocar or needle be

just above the pubes, and taking a course downward and backward. The parts are first prepared antiseptically, and the puncture is dressed with iodoform and collodion. Only half the urine is withdrawn at a first aspiration. Rectal puncture is now obsolete. The perineal incision is the one usually employed for retention. It may be done with or without a guide. In prostatic retention, not relievable by a catheter, make suprapubic drainage or do prostatectomy.

Congenital Defects of the Bladder.—Exstrophy of the Bladder (*Ectopia Vesicae*). Exstrophy of the bladder is a condition of defective development commoner in males than in females. The anterior abdominal wall having failed to close, the anterior wall of the bladder being absent, and the arch of the pubes not having developed, epispadias exists, and in many cases the testicles do not descend into the scrotum. In this condition the posterior wall of the bladder projects into or beyond the gap in the abdominal wall, the urine constantly flows and renders the condition of the patient

Fig. 783.—A B C shows the proper curve, reduced in size, for modeling male urethral instruments, D E shows an improper curve.

dreadful. The condition shortens life and only 30 per cent of the victims live beyond the twentieth year, death being due to pyelonephritis.

The only treatment which offers hope is operation, and operation often fails. If possible, operate when the patient is about five years of age. Various operations have been suggested for this condition, viz.: covering with skin-flaps; implanting the ureters into the bowel (Maydl, Albert, Roux, Simon, and others); division of the posterior ligaments of the sacro-iliac joints, bringing the arch of the pubes forcibly together, the patient wearing a support

Fig. 784.—English silk-web catheter

until the parts become firm, when the greatly narrowed defect is closed in by integumentary flaps and suturing the bladder edges (*Trendelenburg's operation* or *synchondroscotomy*); osteotomy through one ilium or both ilia instead of separation of the sacro-iliac joints (*Berg's operation*), or after extirpating the bladder, loosening the ureters from the bladder, drawing them down, and attaching them to the end of the penis (*Sonnenberg's operation*).

A bladder closed in by autoplasty, by Trendelenburg's operation, or by Berg's operation is never really continent, although when the patient is erect

and wears a light compress he may perhaps be hours. The above methods are suited to young is ureteral transplantation. Tuffier showed, transplantation of the cut ureters into the bo by fatal infection of the kidney, and that the retain the ureteral orifices which contain valve

Maydl introduced his operation in 1892. the ureters into the sigmoid flexure, extirpat have twice performed a modified Maydl's ope recovery, and in the latter case the result wa ("Surg. Gynecol., and Obstet.," Feb., 1900) collection there were 23 deaths (28.7 per cent, pyelonephritis. Bergenhem, in 1894, devised the ureters and a portion of bladder through rectum.

Diseases and Injuries of the Bladder situated, and the abdominal walls are so elastic empty. If the bladder be full and the abdom in alcoholic intoxication force applied upon bladder.

Contusion of the Bladder.—In this cor hematuria, tenesmus, severe cystitis, and an in because of clots. Hemorrhage may be very even causing death. When contusion exists of a clean soft catheter; if this fails because catheter with blood-clot, there must, from the catheter from a fountain syringe a solut cooled boiled water. Gross's blood catheter of Bigelow may be employed. The patient is applied to the hypogastrium, morphin is ad the bladder is washed out several times a day integrate and remove blood clots, and the urine by the stomach administration of salol, boric fluids. Hemorrhage usually ceases on relief some more radical measure must be employed.

Wounds of the Bladder. Besides being injured by bullets; by stabs or punctures thro or the uterus; or by penetration by a fragme The symptoms of such conditions are those of In any intraperitoneal wound at once open th in the bladder wall, irrigate the peritoneal ca means of a retained catheter, a perineal secti In an extraperitoneal wound drain the wound b by a retained catheter, a perineal section, or a c

Rupture of the bladder occurs in three rupture involving the peritoneal coat, (2) exta tion of the bladder not covered by peritone rupture of the mucous and muscular coats, peritoneal investment. The causes are of tw

citing. *Predisposing* causes are: distention of the bladder; drunkenness; cystitis; ulceration; degeneration or atony of the bladder-coats; prostatic enlargement, and urethral stricture. Distention of the bladder is the great predisposing cause. It causes the bladder to rise from the pelvis and so become exposed to a direct blow, it places the organ under tension, and force tends to rupture the weakest point. In about one-third of the cases collected by Bartels the individual was intoxicated at the time of the accident. Drunkenness predisposes because a drunken man is very liable to injury and is apt to have a distended bladder. Males are much more liable to rupture than females (10 to 1). Most cases are between the ages of twenty and forty. Of Besley's 23 cases, 1 was a child of three, 1 a man of forty-nine, 3 were in the first and second decades, 5 were between twenty and thirty, 7 between thirty and forty, 6 between forty and fifty, and in 2 the age is not given (paper before Chicago Surg. Soc., Feb., 1907). The condition is very rare in children, but one of Besley's cases was three years of age, and King recorded the accident in a fetus with imperforate urethra.

Exciting causes are: obstruction to the outflow of urine (by stricture or enlarged prostate); external violence; falls upon the feet or the buttocks, as well as upon the abdomen; lifting, straining at stool, in micturition, or during parturition; and the forcing of injections into the bladder. A distended bladder may be ruptured by a concussion. The most usual cause of the injury is a crush. The mechanism of the injury is in dispute. It is certain that the bladder must have lost its elasticity by distention. When force is applied to fluid (and fluid is incompressible) the bladder tears at its weakest point. The weakest point is not identical in all individuals. It may be weak anywhere from disease. The most common site of the tear is at the posterosuperior aspect, but it may be in front, at the sides, or at the pubic or prostatic ligament (Staubenranch). The mucous membrane or the peritoneum may give way first and the tear may be anteroposterior, oblique, or longitudinal. Alexander maintains that the most usual cause of the injury is a crush which forces the distended bladder against the sacral promontory, but Besley's (*Ibid.*) experiments do not indicate this to be the case. A common complication, especially of extraperitoneal rupture is fracture of the pelvis, due to the same force that ruptured the bladder.

Symptoms, Diagnosis, and Treatment.—The symptoms are not always definite, and every characteristic one may be for a time absent, the patient seeming in some rare instances of extraperitoneal and intraperitoneal rupture to possess the power of retaining his urine and of voiding it. As a rule, however, there are found some or all of the following symptoms, following an accident or occurring during the progress of a causative disease: severe abdominal pain, collapse; inability to walk or great difficulty in walking; excessive desire to urinate, but inability to do so; a catheter, when used, brings away pure blood or a very little bloody urine; the catheter occasionally slips through the tear into the cavity, and more bloody water comes away. In some reported cases clear water has been withdrawn. If a measured amount of boric acid solution is injected, it is improbable that all of it can be withdrawn by the catheter, although in some cases it may all come away (Alexander, in "Annals of Surgery," Aug., 1901). Injecting fluid fails to lift the bladder into the hypogastric region so as to be recognizable on percussion. Severe hypogastric pain and

rectal tenesmus come on after a temporary Shock in vesical rupture is so severe that death there is delirium, often septicemia and peritonitis may occur. In *intraperitoneal rupture* general but its appearance may be postponed for several days. In these cases the extravasation is noted as on one side only. In *extraperitoneal rupture* the scrotum, the thighs, and under the inguina, the back, and may soon induce sloughing. In *extraperitoneal rupture* is apt to arise.

In doubtful cases pump air or hydrogen in a bicycle pump can be used (Brown), or a Davidson's directions are to insert a catheter, empty the bladder, the catheter a disinfected Davidson's syringe being fastened over the distal end of the syringe through the cotton is pumped into the bladder. In *intraperitoneal rupture* the bladder will not so rise. In *intraperitoneal rupture* pass into the general peritoneal cavity and distention. In *extraperitoneal rupture* injection will produce connective tissues. On removing the syringe the bladder is unruptured, but little if any comes under considers gaseous distention unreliable shock and disseminates infection. His rule is in a case of suspected rupture of the bladder and inspect the prevesical space for signs of *extraperitoneal rupture* is not found, open the bladder.

Treatment.—In *extraperitoneal rupture* after insert a drainage-tube. In *intraperitoneal rupture* the Trendelenburg position, expose the bladder opening in the viscus.

Results. Baron Larrey was the first surgeon all the coats of the bladder might be followed by ruptures if operation is not performed the mortality is performed many cases recover. Of the and Papin, in 1904, 34 died, a mortality of 43 *extraperitoneal rupture* without operation the with operation 30 per cent (see Daniel N. B. Assoc., Oct. 25, 1902; Samuel Alexander, "As

Atony of the bladder is a condition in which the bladder is diminished or lost because of fatty degeneration. Sometimes the viscus is very small. A slight degree of atony is physiological. **Causes** are senility, distention from true prostatic obstruction, and acute overdistention.

Symptoms.—In atony of the bladder the stream of urine (a symptom probably existing for some years) may even do so while asleep. The stream, w

projection, but drops at once from the end of the penis. Residual urine exists for years and may at any time set up cystitis, and retention with incontinence is apt to occur. This condition is *not* vesical paralysis resulting from a lesion of the nervous system.

Treatment.—In treating atony of the bladder measure the residual urine: if it amounts to four ounces, use a soft catheter night and morning, if it amounts to six ounces, use the catheter every eight hours; if it amounts to eight ounces, use the catheter every six hours (J. W. White). The patient should be taught how to use the catheter and how to keep it sterile. (For methods of disinfecting catheters see article on page 1305.) The bladder is from time to time washed out with gr. iij to the ounce of boric-acid solution at a temperature of 100° F. Strychnin, electricity, ergot, and urotropin may be ordered.

Vesical Calculus, or Stone in the Bladder. The salt normally in solution in the urine may deposit as calculi and may be imprisoned in any portion of the urinary tract. The commonest calculi are those composed of uric acid, urates, calcium oxalate, and fusible phosphates. The formation of uric acid and urate calculi is explained under Renal Calculus (page 1281). Vesical calculi are usually renal calculi that have passed the ureter and become enlarged by new accretions. Phosphatic calculi may be formed in the bladder when chronic cystitis causes and maintains an alkaline urine. Uric-acid calculi are smooth, round or oval, and hard, but easily broken. On section they present the color of brick dust and are marked by concentric rings. Their nuclei are dark by comparison. They are soluble in dilute potassium hydrate, and with effervescence in nitric acid. They are combustible, and leave scarcely any ash. Urate of sodium and urate of ammonium often occur together in stones, and these calculi are not in rings, are not so hard as the uric-acid stones, and are fawn-colored on section. Oxalate-of-lime stones are round, with many projecting nodes like the mulberry, hence the term "mulberry calculus." They are very hard, and section shows the color to be brown or green and that they possess wavy, concentric rings. This form of calculus is soluble in hydrochloric acid. Fusible calculus, which is composed of magnesian ammonic phosphate with phosphate of lime, constitutes the commonest form of phosphatic stone and of large stone. It is light, soft, smooth, and white, and shows no laminae on section. Some rare forms of stone are composed of xanthic oxid, cystic oxid, calcium phosphate or carbonate, and magnesian ammonic phosphate (triple phosphate).

A stone may be formed having layers of different substances: for instance, there is often found a uric acid nucleus surrounded by phosphates, the latter surrounded by some uric acid or urates, and these again by phosphates. In some cases oxalate of lime alternates with uric acid, urates, or phosphates (Bowlby). Bowlby states that the alternating uric acid and phosphatic layers are due to the altering reactions of the urine; that when the urine is acid uric acid is deposited on the stone, but when cystitis makes the urine alkaline the stone receives a phosphatic coat.

Anything that favors the formation of an excessive urinary deposit may cause vesical calculus, and among such causes are defective digestion, failure in processes of oxidation, excess of solids and nitrogenous elements in the diet, deficient exercise, etc. If to the urinary condition established by the above

factors catarrh of the genito-urinary tract is a concentrated urine may induce stone. Children stones, and old people to phosphatic stones. prostate and chronic cystitis a stone forms nucleus. The nucleus may be phosphate crystal a blood-clot, uric-acid gravel, or a foreign body because of the shortness, the large diameter, and urethra. Stone is very rare in the negro. enlarged prostate, vesical atony, urethral stricture of the kidney, the ureter, and the bladder

Symptoms.—In not a few cases the vesical attack of nephritic colic. The severity of the depends more on the roughness of the stone the calculus will produce intolerable anguish, when will cause but moderate pain. A patient will plains of frequency of micturition, particularly sudden, uncontrollable, and invoked or aggravated is more positive in youth than in old age. acter is experienced at the end of micturition, empty bladder upon the stone or stones. It enters and distends the bladder. The usual se

face of the head of the penis, a little behind continue for some time. By pulling on the prepuce of a child may become pendulous. This worse during cystitis and after exercise; it may it may even almost disappear, and it is always old Stone in chronic cases of atony and in neither marked pain nor frequency of micturition pain *precedes* the act of micturition, in urethral in stone, as already stated, it *follows* it. (P. J., Feb., 1898) The symptoms are somewhat of vesical calculus and prostatic hypertrophy, with calculus are spoken of as *attacks of stone* may during micturition roll into the urethral interruption of the flow of urine, the stream changes his position. This symptom is seldom rare in the old, the stone in them dropping in and *below* the urethral orifice. Even if this exclusive, as a stalked tumor, a blood-clot, or block the urethral orifice and cut off the stream not be noted; it is most usual after exercise, urinary act, the first urine passed being clear

•"American Text-book of

tinged, and at the end of the act some drops of pure blood emerge. It is not one of the earliest symptoms. When it occurs, it puts the patient in a great fright. It does not appear suddenly and profusely, but as gradual and trivial bleeding and with micturition. Blood appearing between acts of micturition comes from either the urethra or prostate (P. J. Freyer). The bleeding from a bladder tumor is profuse and the urine is mixed with blood and blood-clots and tumor fragments. Bleeding from a tuberculous ulcer of the bladder often resembles the bleeding caused by stone. Pus or mucopus will be observed if cystitis occurs with calculus disease. Priapism occurs in some cases. Pain of a reflex nature may be felt in the rectum, in the perineum, or in some distant part.

The above symptoms, even if all are present, do not prove that an individual has a stone in the bladder. To prove the presence of a stone, it must be touched with a sound and the contact must be felt and heard. To sound a patient, have the bladder well filled with boric-acid solution or salt solution, and place him recumbent, with the knees drawn up. Never sound a person while he is standing, because of the danger of syncope. In an ordinary case in a male use a sound with a very slight curve (Fig. 785); in a man with hypertrophied prostate use a sound with a short and decided curve. The caliber of a stone-sound is No. 13 of the French scale. The instrument is carefully boiled and anointed with yellow liquid cosmolin. Examine the entire bladder systematically, and be sure a stone is present only when contact with the sound is both heard and felt. The stone may be difficult to find, or it may clude the instrument entirely when it is encysted, when it rests in a diverticulum, when it is fixed to the roof or anterior wall of the viscus, or when it is crusted with lymph or blood-clot. In doubtful cases always insist on a second examination, giving ether if the first was very painful. Occasionally, as Freyer pointed out in 1884, a small stone will be found by using a Bigelow evacuator, the current causing the calculus to knock against the tube. In many cases stone in the bladder may be detected by means of the x-rays. If a stone is fixed in a diverticulum or projects from the ureter, or is in a sac back of the prostate, it may be missed by sound and evacuator tube but be shown by the x-rays. In such a case the bladder must be examined by means of a cystoscope. A stone, when it is detected, should always be measured by Thompson's instrument, an arrangement looking something like a small edition of a lithotrite, but having very delicate blades. The composition of the stone is assumed from an examination of fragments which pass by the urethra or which adhere to the measure. Remember that the outer layer of a calculus may be soft phosphate and the inner portion may be the harder uric acid, urate, or oxalate.

Stone in Females.—Calculus in the female is a rare complaint. In over 300 patients operated upon for stone by Freyer there were only 20 females. Pain and increased frequency of micturition, which are symptoms of stone in men and women, are in women caused by other conditions as well, notably by uterine disease and displacement. A straight sound is used to examine a female for stone. If the surgeon is still uncertain after sounding, he dilates the urethra and explores the bladder with his little finger.

Stone in Children.—Can occur at any age, and congenital cases have been placed on record. The uric-acid stone is most common. The symp-

toms are like those of the adult. The pain of the penis and the prepuce becomes pendulous. If the flow of urine is blocked from time to time, the edema increases, and after a time a hernia may form or prolapse.

Treatment.—In people predisposed to stone the physician should foresee the danger and prevent it by keeping the urine on the urine being kept dilute by the freest possible drinking. reduce to a minimum the amount of alcohol taken. Let the patient live chiefly on green vegetables, eggs, fish, poultry, weak tea or coffee, water, and wine. Continued purging does harm by causing constipation. A laxative may be employed when indicated. Fresh air, of immense importance, sunshine and fresh water are of great importance for a condition of imperfect oxidation power. Give piperazin, gr. xv to gr. xx daily, liquor potassae or borocitrate of magnesium. If the urine be acid, give mineral acids and strychnin, or, what seems better, Urotropin is given in gr. v capsules four times daily. If the urine be alkaline, with oxalate, use the mineral acids with an excess of sodium. Travel and rest at the seaside or in the country in all forms. Always endeavor to prevent stone when it does occur. When a stone is once formed, the best way of dissolving it. An operation must be done. Consider the age, the state of the bladder and the condition of the urethra, the kidney condition, the size and the number of calculi present (see Operations on the Bladder).

Cystitis.—Inflammation of the bladder may be the result of some other disease of the genito-urinary system, or it may be primary. It is often dry and wet. Traumatism from a catheter, the use of a urethral inflammation, pus infection, and the use of such a drug as cantharides may cause it. It is not unusually during an exanthematous fever, or after paralysis; it often follows retention, frequent catheterization and urethral stricture, and sometimes alone or accompanies bladder growths. Acute cystitis is characterized by swelling of the bladder-walls, and there is pus in the urine mixed with urinary elements, serum, mucus, and blood. Ulceration, sloughing, or false-membrane formation may follow. Cystitis is an inflammatory condition always due to stone in the bladder, or prostate gland, or tumor of the bladder. It may be chronic cystitis, but act by rendering the bladder more susceptible to infection. Among the causative organisms we find the bacillus coli communis, the gonococcus, the bacillus tuberculi, and the various pyogenic bacteria (Leonard). They gain entrance on instruments or by way of the blood-vessels, and possibly in rare instances by the lymphatics.

In chronic cystitis there is an enormous proliferation of the cells and the urine becomes alkaline. The excess

great number of bacteria convert the urea into carbonate of ammonium, and this product, being irritant to the bladder-walls, makes the inflammation worse. In chronic cystitis the bladder is contracted and has very thick walls, and the mucous membrane is thick, edematous, congested, and filled with large veins. The bladder may be ulcerated or encrusted with urinary salts. The urine contains bacteria, triple phosphate, pus, blood, and mucus, the blood emerging with the last drops of urine. Pyelitis may arise as a result of chronic cystitis.

Symptoms of Acute Cystitis.—Great frequency of micturition, with the passage, at each act, of a very small quantity of urine; the desire to urinate is almost constant, and there is intensely painful straining (*tencismus*). The pain is acute and scalding, and may be felt above the pubes or in the perineum; it often runs into the loins and the thighs and radiates over the sacrum. Pain above the pubes indicates involvement of the fundus, and pain in the perineum and in the head of the penis points to inflammation of the bladder-neck. The urine, at first clear, loses its transparency, becomes full of thick mucus, and often contains a little blood or pus. The patient not unusually has some fever. A rectal examination causes violent pain. If ischuria takes place, there will be a chill and high fever, and anuria may occur or vesical rupture may ensue.

Treatment.—In treating acute cystitis endeavor to remove the cause. By allaying an irritation or removing an obstruction the bladder will often become able to empty itself of retained urine, which urine causes congestion of the bladder and thus renders infection probable or may be itself filled with bacteria. If cystitis arises from the administration of cantharides, put the patient in bed and give him liquor potassii citratis. If it comes from the use of a clean sound, order rest in bed, suppositories of opium and belladonna, diluent drinks, and ammonii benzoas or lupulin. If the inflammation is septic (as from the use of a dirty sound) or is very acute, put the patient in bed, keep him warm, and use a hot sand-bag to the perineum and hot fomentations or poultices to the hypogastrium. Hot hip-baths may be used. The hips should be elevated and the bowels should be emptied by the administration of salines and by glycerin enemata. An exclusive milk-diet is desirable. The patient should drink copiously of sweetened water containing a few drops of aromatic sulphuric acid or of milk of almonds. Sterilize the urine by the administration of urotropin, giving a capsule containing gr. 7½ of the drug three times a day. Other remedies which may be of service in sterilizing the urine are quinin, boric acid, salol, borocitrate of magnesium, and salicylate of sodium. A valuable remedy consists of 15 grains of salicylate of sodium and 15 grains of benzoic acid, given three times a day in a little chloroform water. If the pain and straining still continue, order—

Pyuria is usually present, but fectly clear. In some cases the patient has duration and feels well between the attack the kidney, prostate, vesicle, or epididymis, tuberculous cystitis exists. The diagnosis is berculosis ulceration is most common in the tri of the urethra. A tuberculous ulcer is small brane is not inflamed, but contains grayish-w in "Jour. Amer. Med. Assoc.," July 19, 190

Treatment.—In treating chronic cystitis remove the cause, if possible (get rid of a stone, evacuate residual urine frequently, dilate a stricture, and remove a tumor). For chronic cystitis certain remedies are taken by the mouth. Water is drunk in large amounts, also iron spring-water (Marienbad, etc.). Salol and boric acid, gr. v of each four times a day, are very valuable. Salol in fluid extract of triticum repens does good; so does chlorate of potassium, gr. x daily. Either borocitrate of magnesium, quinin, or salicylate of sodium with benzoic acid may often be used with benefit. Alum, tannic acid, uva ursi, copaiba, cubebs, buchu, and turpentine have all been recommended, and possibly may be of some benefit. Urotropin is useful in many cases. This drug prevents the development of bacteria in the urine (Nicolaier) and antagonizes the tendency to sepsis and urinary poisoning. It is given in 5-grain capsules, from four to six being given daily. Whatever remedy is used, see that the bowels move once a day, and that the skin is active. Champagne and beer must be avoided. If residual urine gathers, a soft catheter must be regularly employed. If it is possible to introduce a catheter of considerable size, catheterization may be all that is needed in the case. In some cases of chronic cystitis the retention of a catheter from three to five weeks is of the greatest service. If the case is very severe, the bladder must be washed out daily with peroxid of hydrogen (25 to 40 per cent. solution), nitrate of silver (1 : 8000), boric acid (5 to 10 per cent.), carbolic acid (1 : 500), corrosive sublimate (from 1 : 20,000 to 1 : 5000), or permanganate of potassium (1 : 4000). If nitrate of silver or permanganate of potassium is used, first rinse out the bladder with distilled water. If any other agent is used, first wash out the bladder with either boiled or distilled water. The daily injection of a 2 per cent. solution of ichthyol may prove useful. Some surgeons occasionally employ, at intervals of a number of days, strong silver solutions (30 or 40 grains to the ounce). If a strong solution is used, after the drug flows away wash out the bladder with a solution of common salt. The bladder is usually washed out by attaching to the free end of a soft catheter, the other end of which is in the bladder, a tube which is connected with a graduated bottle, the force being obtained by elevating the reservoir (*fountain irrigation*). The bladder can be irrigated without using a catheter, the resistance of the compressor muscle of the urethra being overcome by the pressure of a column of water. The reservoir is raised to the height of six feet. The patient sits in a chair. The tube of the reservoir has upon it a clamp to control the flow, and in its end a large bulbous tip which will fill the meatus (Valentine's instrument). The tip is inserted into the urethra, the clamp on the tube is loosened, and the patient is directed to take a deep inspiration. In a short time the bladder fills with water, the tube is removed, and the patient empties the viscus naturally. In some cases it is necessary to wait quite a while for the column of water to tire out the muscle. If the fluid will not enter, direct the patient to make efforts, as in micturating, the pressure of the fluid on the anterior surface of the cut off muscles being kept up. If this fails, direct him to urinate, and then the surgeon makes another attempt to get the fluid to enter. After a little practice a patient learns how to admit the fluid.

In tuberculous cystitis Collin advises the instillation of 30 minims of the following mixture into the bladder and posterior urethra: 5 gm. of guaiacol, 1 gm. of iodoform, 100 gm. of sterile olive oil. About 30 minims of this are

injected once a day. If the cystoscope discloses a tuberculous ulcer, it is useless to operate on the ulcer formed on the kidney. Sometimes curetting the ulcer. In other cases the bladder must be opened, as in primary non-tuberculous cystitis Collin uses a zinc carbonate in oil.

If the ordinary methods of treatment fail, the bladder resents catheterization and irrigation, the urine does not become clear; and if there are constitutional patient and breaking down of his general health, a suprapubic cystotomy and through the incision wash the bladder thoroughly. If the persistent cystitis is due to gonorrhea, perform external perineal urethrotomy.

Ulcer of the Bladder. May be due to a malignant tumor, or gonorrhea. A form of ulcer in anemic women is a solitary, punched-out ulcer (Amer. Med. Assoc., July 19, 1902). Ulceration may perforate.

A perforation may occur into the peritoneal cavity or cellular tissue. In the former case, after the perforation there are shock, abdominal pain, and peritonitis, and extravasation of urine or abscess formation.

Tuberculous ulcer is discussed on page 1317.

Schmidt ("Jour. Amer. Med. Assoc.," July 19, 1902). In gonorrheal ulceration is apt to be multiple, and the urine is turbid. As a rule, when the bladder is ulcerated, the urine contains blood, blood-clots, or tissue debris, but the urine is not bloody in tuberculous ulcer or solitary ulcer (Schmidt, loc. cit.).

Diagnosis is usually made by the cystoscope or by exploratory suprapubic incision.

Treatment.—If there is one ulcer, or if there is only one operating cystoscope (Schmidt), use irrigation. In wide-spread ulceration perform suprapubic cystotomy, remove the mucous membrane, and insert a drainage-tube. If the growth the cautery is used as a palliative measure, as in rupture of the bladder (page 1310).

Tumors of the Bladder.—These grow rarely, but in Guyon's statistics they are found in 10 cases of genito-urinary disease. They are found in males as in females. They are most frequent between fifty and sixty, although myxoma is met with in the young (Lincoln Davis, 1906). Persistent vesical irritation may, perhaps, lead to tumor. Tumors of the bladder may be either benign or malignant. The benign being the commonest. Innocent tumors which are papillomata or villous tumors, adenomata, fibrous polypi, myomata, and angiomata. Malignant tumors are sarcoma (rare) and carcinoma.

boma, common). The majority of bladder carcinomata are secondary to growths of the rectum, prostate, or uterus. Adenocarcinoma and scirrhous carcinoma are practically always secondary to rectal, prostatic, or uterine tumors. Papillary cancer and epithelioma are not unusually primary (Mannlebaum, in "Surg., Gynecol., and Obstet.," 1907). Any tumor of the bladder, innocent or malignant, will eventually cause death if allowed to remain.

Symptoms.—The innocent tumors rarely cause cystitis or irritation, though by obstructing the ureters or the urethra they may induce disease of the kidneys. Hematuria is almost invariably present at some time in the course of a bladder tumor. It is apt to be profuse, and the urine contains blood, blood-clots, and perhaps fragments of tumor. The bleeding is intermittent, may occur even when the patient is at rest, and, except in malignant disease, is seldom preceded or accompanied by pain. Bleeding usually occurs at the termination of micturition, the first urine being clear and the last red or clotted. Often hemorrhage is the only phenomenon produced by a papilloma or a mucous polypus. Malignant tumors cause cystitis, and the urine contains mucus, blood, and pus. The growth may become crusted with salts from the urine. Cancer is distinctly and often horribly painful. In malignant disease ulceration may occur into the peritoneal cavity or gut. A malignant tumor progresses much more rapidly than an innocent growth, although in cancer metastases are not formed so early as in some other regions. Innocent tumors are felt with difficulty with the sound, but malignant tumors are easily felt. In some cases a tumor can be detected by a bimanual examination (a finger in the rectum and the fingers of the other hand on the abdomen). Make a careful study to determine whether or not a growth has infiltrated the prostate, the seminal vesicles, the rectum, or the perivesical tissues. Bleeding follows the use of a sound. There may be difficulty in starting the stream in micturition, or there may be interruption or "stammering" of the stream. The urine should be examined microscopically to see if it contains villi, portions of fibroma, colonies of cancer-cells, or fragments of epithelioma. A cystoscope should be employed in order to reach a diagnosis. If the urethra is too narrow for the cystoscope, this channel must be dilated. If there is profuse bleeding, an irrigating cystoscope must be employed. In doubtful cases exploratory suprapubic cystotomy is advisable.

Treatment.—Complete extirpation of the bladder for cancer has been performed by Bardenheuer and others. It is usually done in two stages, in the first operation the ureters of a man being transplanted into the rectum, the ureters of a woman into the rectum or vagina. About three weeks later the bladder is removed. The adjacent lymph-nodes along the internal iliac vessels and in front of the sacrum must be removed in all cases. The surgeon should bear in mind that scirrhous and adenocarcinoma are secondary growths, and if he cannot remove the primary growth he should not extirpate the bladder. The complete procedure has been carried out successfully at one operation (Tuffier and Dujarier, "Rev. de Chir.," April, 1898). Some surgeons prefer preliminary double lumbar nephrostomy; others transplant the ureters to the skin surface. The operation of complete extirpation is of questionable value.

In Rafin's collection of 30 cases there were five years after operation, 1 fifteen months, son's table of 25 cases shows 14 deaths and and free from recurrence after three years.

Complete extirpation should be employed bladder extensively. I agree with Berg ("A if less than one-third of the bladder is involved cystectomy with implantation of the ureters ing. The surgeon removes the anatomically mind that adenocarcinoma and scirrhous are Partial cystectomy saves the fatal operation is ordinarily done, or the dangerous operation of its unpleasant consequences. In Rafin's 21 deaths (a mortality one-half that of contracted—5 were well over three years and 16.

Many surgeons content themselves in vesicomy, removing the growth and a portion is not possible, curet, cauterize, and drain, and a portion of the bladder-wall are removed incision. The perineal operation only end move growths of small size, pedunculated growths of the bladder. (See Operations on the Bladder the following rule: "When an infiltrating growth of the *vaginam*, or with the sound, to be involving the wall, to be infiltrating its coats, especially the ureters and neck of the bladder, no operation unless the hemorrhage is copious or the growth is then an incision for palliative purposes ("System of Surgery").

Operations on the Bladder.—Lithotomy is the removal of a stone from the bladder. which is every year becoming less popular employed by surgeons, especially for stone should not be performed if the stone is over 100 grains it is rarely justifiable if the stone weighs 100 grains it must not be performed for encysted stone, prostatic enlargement, a narrow pelvic outlet, or an enlarged bladder. During the operation keep the patient in bed, wash with boric-acid solution, and administer salol and opium of each four times a day. The night before the operation a hot bath, and have the perineum, the scrotum, and sides of the thighs cleansed and dressed an enema is to be given. At the time of operation have ready several ounces of boric acid solution, a lithotomy knife, a straight probe point, a stone-sound, stone-forceps and scoops, a stone-scoop, a fountain-syringe, curved needles and a needle tube with chemise (Fig. 209), a Paquelin's cautery, and a lithotrite.

Place the patient upon his back, anesthetize him, and find the stone by sounding. If the stone is not discovered by the sound, *do not operate*. Place the buttocks so that they project beyond the edge of the table, introduce the staff into the bladder, flex the legs and thighs, and fasten the patient in the lithotomy position with a crutch. During the first incision the handle of the staff is held toward the belly; after the first cut the staff is set perpendicularly and is hooked up under the pubes. An incision is made, starting just to the left of the raphe of the perineum and one and a quarter inches in front of the edge of the anus, and passing downward and outward to between the anus and the ischial tuberosity, but one-third nearer the former than the latter. In the adult this incision is three inches long. The first incision is superficial and does not reach the staff, but it is this incision which may cut the rectum. After making the first cut the nail of the left index-finger feels for the groove of the staff, the staff is hooked up, the knife is entered into the groove and is pushed into the bladder, and as it is withdrawn the wound is enlarged. As the knife enters the bladder there is a gush of fluid. The finger follows the knife and stretches the wound, the staff is withdrawn, and the stone is felt for and extracted with forceps. Liston showed years ago the value of keeping the finger in the wound. This maneuver retains some water in the bladder, and as a consequence causes the stone to rest at the lowest part of the viscus, and when the forceps are introduced they at once come upon the stone. In withdrawing the stone make traction in the axis of the pelvis, and do not rotate the calculus until it is entirely out of the prostatic urethra. Wash or scrape away debris or incrustation from the wall of the bladder, see that no other stone is present, syringe out the viscus with warm salt solution, insert a tube, apply antiseptic dressings around the tube, and put on a T bandage. The end of the tube which is external to the dressings is fastened to the tails of the T-bandage. A rubber cloth is put on the bed, under the body and legs, and the patient's buttocks rest upon a mass of old linen, the scrotum being raised on a pad. The knees are bent over pillows. Change the linen as soon as it becomes wet. Remove the tube in forty-eight hours. The urine begins to come by the urethra from the eighth to the twelfth day. In children the incision is not so long, it is dilated with forceps instead of with the finger, and no tube is required. In lateral lithotomy the prostatic and membranous portions of the urethra are opened, the prostate gland is partly divided with the knife, and the wound is dilated with the finger. One objection to the operation is that it is possible to cut the rectum, and another is that inflammation may occlude the ejaculatory ducts.

Suprapubic Lithotomy. This operation is the removal of a stone through an opening above the pubes. It is in many instances the preferable operation. The mortality of this operation is higher in children than that of lateral lithotomy; in adults and in individuals beyond middle life the mortality is decidedly less than is that following the lateral operation. It is used for the removal of multiple calculi, for very hard stones, for stones above one and a half inches in diameter, for calculi in men with enlargement of the prostate, for foreign bodies incrustated with sediment, when the perineum is deep, when the pelvic outlet is narrow, for encysted stones, for calculi associated with a vesical tumor, and when the urethra will not permit the use of a

lithotrite. The patient is prepared as for la pubes are shaved, and the lower part of the the thighs are disinfected. During the opel a piece of antiseptic gauze. The instrument pointed bistoury, scissors, a tenaculum, b retractors, dissecting forceps, a dry dissect rectal bag, a brass syringe or a bicycle pump catheters, stone forceps and scoops, a blad needle-holder, and a graduated glass jar for

dressings as often as they become wet. Take out the tube in four or five days, and allow the wound to heal by granulation. The patient may get up in two weeks. Many Continental surgeons advocate immediate suture of the bladder after incision. Albert, Vincent, Bassini, DeVlaccos, and others advocate immediate suture. The suture material should be catgut. After suture, catheter is kept in the bladder to drain the viscus. Immediate suture may be employed in patients of any age, but should not be used if the urine is very septic or if pyelonephritis exists. In some cases the attempted closure will fail; in others it will only partially succeed; in many it will prove successful; but even if it only partially succeeds it will tend to

prevent dissemination of urine in the prevesical cellular tissue. The chief causes of death after suprapubic lithotomy are septicemia, secondary hemorrhage, cellulitis, peritonitis, and suppression of urine. J. W. White estimates the relative mortality of suprapubic and lateral lithotomy as follows: In children the suprapubic operation gives a mortality of 12 per cent., the perineal of 3 per cent. In adults the suprapubic gives a mortality of 12 per cent., the perineal from 8 to 12 per cent. In old men the suprapubic gives a mortality of 25 to 30 per cent., the perineal 30 to 40 per cent.

Crushing of Vesical Calculi.—This is now done in one sitting, the old operation of Civiale, which required repeated crushings, being obsolete.

Litholapaxy (Bigelow's operation, or rapid lithotrity) is the operation for removing a stone from the bladder in one sitting by thoroughly crushing

the stone and completely washing away the stone, is wonderfully successful if done by an expert, but it is often to learn how to perform it with great safety. It is the best operation in most cases, if performed by the operation in the majority of cases for even the general surgeon will have better results after suprapubic lithotomy than after litholapaxy. This method is suited to twenty nine cases out of thirty, employed if the bladder will hold at least four ounces in healthy condition; if the urethra is tolerant of instrumentation; if the stone is not too hard, does not weigh over two ounces, and is not over two inches in diameter. It is not employed for large and hard calculi, for encysted stones,

Fig. 787.—Bigelow's latest

enlargement of the prostate gland, with vesical disease, and easily dilatable stricture need not prevent the operation. The stricture can first be dilated, and later the stone can be removed, but firm, gristly strictures demand a more radical operation. If the urethra is intolerant of instrumentation, the operation is not attempted, but instead of cutting, the stone is removed by the operation of cutting (Cage). In diabetes, locomotor ataxia, and other conditions, patients are best treated by Bigelow's operation.

The Indian surgeons have had the most successful results in litholapaxy. It has often been claimed that such a high percentage of cures is due to the peculiarities of the patients and various factors related to the operation. The fact, however, that some of these very surgeons

repeated their successes in London, shows how large a part masterly dexterity played in obtaining success.

J. A. Cunningham* reports upon 10,073 Indian cases of litholapaxy. The mortality was 3.66 per cent.

Cabot, of Boston, in 116 cases had but four deaths, and two of these were due to pneumonia.

The preparation of the bladder is the same as for lithotomy. Be sure to measure the stone, and to ascertain also whether a lithotrite can readily be introduced and manipulated. The instruments required are a stone sound, lithotrites (several sizes, Figs. 788-790), an evacuating bulb and tubes (straight and curved, Figs. 787, 791), soft catheters, a glass irrigator to inject the bladder,

Fig. 788. Bigelow's lithotrite

Fig. 789. Thompson's lithotrite

Fig. 790. Forbes's lithotrite

and instruments in case the surgeon is forced to cut. The patient is anesthetized and is placed upon his back, a pillow is inserted under the vis, and he is well wrapped up. The urine is drawn and a measured amount of warm boric acid is allowed to flow into the bladder. This

* Brit. Med. Jour., Aug 7, 1887

plan is better than having the patient retain his urine, as in the latter case there is no certainty as to the amount of fluid in the viscus. It is well to introduce at least five or six ounces of fluid, if possible. If the bladder will not hold four ounces the operation is unsafe (Thompson). The lithotrite, preferably the instrument of Forbes (Fig. 790), is now introduced, the handle being gradually raised to a vertical position as the penis is drawn up on the shaft but not being depressed until the instrument has passed by its own weight into the prostatic urethra. Thompson's plan for catching the stone is as follows: After introducing the lithotrite, let its lower end rest for a few seconds on the bottom of the bladder, so that currents will subside, then draw it

Fig. 791 Thompson's evacuator.

the male blade, wait a moment close the blades, and in almost every instance the stone will be caught. If the stone is caught, press firmly to see that the calculus is well held, lock the instrument, and break the foreign body by squeezing. When resistance suddenly ceases the stone has either slipped or has been crushed, if crushed, the blades should have been felt forcing through the stone and the calculus should have been made to break. When resistance ceases again and crush again as above directed. Repeat movements with the lithotrite in proper, as they establish currents which are apt to push away the stone. The above maneuver does not catch the stone, see if the calculus be near the neck of the bladder. Pull the instrument close to the vesical neck, and open it, not by raising the male blade, but by pushing the female blade. If the operator still fails to catch the stone, or if, after crushing a large fragment knocks against the evacuator

which fragment cannot pass, conduct a careful search, turn the blades to the right side, open, and close, then to the left side, open, and close, next turn the point around behind the prostate and open, and close. After making a last search with the lithotrite, turn the instrument very slowly, so as to detect the catching of the bladder-wall if it has occurred, and crush the stone in the middle of the bladder with the blades up. After crushing several times proceed to evacuate. Fill the aspirator with warm saline fluid. Insert an evacuating catheter, its point being in the center of the bladder and the fluid and fragments run out, and attach the aspirator to the catheter, turn the valve, and compress and relax the bulb so that an current of fluid is forced in at each squeeze, the compression coinciding with contraction. The debris falls into a bulb, and the pumping is continued until the fragments cease to pass, whereupon the point of the catheter is pushed against the floor of the bladder and another trial is made. If fragments which gain exit are felt knocking against the tube, withdraw the evacuator and

again, and again use the aspirator. When no more debris comes away and no more fragments are felt, withdraw the tube and carefully sound the bladder. Keyes advises the operator to seek for a final fragment by listening with a stethoscope while pumping at the bulb and searching the bladder with the tube. This operation will rarely occupy over forty minutes, though Bigelow has protracted it for three hours, the patient recovering. A serious complication is severe bleeding, due to damage done with the instrument or to the presence of a tumor which easily bleeds. The injection of moderately hot water or of adrenalin solution (1 : 10,000) usually checks hemorrhage, but if bleeding is dangerous in amount the operation of litholapaxy should be abandoned and suprapubic lithotomy be performed.

If clogging of the lithotrite with fragments occurs, forcible pushing of the blades together repeatedly will probably amend it; but it will never happen if the surgeon uses a proper form of instrument. A lithotrite with a fenestrated blade will not lock. Forbes's lithotrite is a very powerful instrument, the blades of which will not lock. If the blades of a lithotrite should become forcibly and hopelessly locked, make a perineal section, clear out the blades, close them, and then withdraw the instrument.

After-treatment.—Put the patient to bed, apply a bag of hot water to the hypogastrium, and give him a hypodermatic injection of morphin as he recovers from ether. Give a hot hip bath every night, and administer liquor potassii citratis in moderate doses every day. If urethral fever occurs, use quinin and morphin, wash out the bladder several times daily with warm boric-acid solution, and tie in a rubber catheter. If retention occurs, use the catheter. If cystitis appears, treat as in an ordinary case. The urine ceases to be bloody in two or three days, and the patient may get up in a week.

Litholapaxy in Male Children. It was considered until quite recently that a child, because of the small size of the bladder, the small diameter of the urethra, and the readiness with which the mucous membrane is lacerated by even slight violence, was a bad subject for crushing. Lateral lithotomy is known to be eminently successful when performed upon children. The elder Gross did this operation upon 72 children with only 2 deaths. Keegan, however, has persuaded the profession that rapid lithotripsy is perfectly applicable to children. He shows that the bladder of a child of even less than two years of age is quite large enough to allow the surgeon to manipulate an instrument, that the mucous membrane is in no danger if the operator be careful, and that the urethra is by no means so small as was supposed. The urinary meatus must often be incised, and after doing this, Keegan states, there can be passed in a boy of from three to six years a No. 7 or 8 lithotrite (English), and in a boy of from eight to ten years a No. 10 or even a No. 14. It is, however, just to state that the operation is more delicate than a like procedure on older persons, and that no one is justified in doing it who has not had considerable experience in adult cases. Furthermore, it should be noted that Keegan's mortality by this operation has been 4.3 per cent., while Gross's mortality from lateral lithotomy on children was 2.67 per cent.

Special points of litholapaxy on male children are as follows: use well-fenestrated lithotrites; have a stylet to punch out the fragments blocking the evacuator, and crush the stone to a fine mass. There can usually be employed a No. 8 lithotrite and a No. 8 evacuating tube (English scale)

Perineal Lithotrity (Keith's Operation).—This operation is employed by some surgeons in dealing with very hard or very large calculi in male adults, or in cases in which it is impossible to introduce a lithotrite into the bladder. Keith's operation consists in opening the urethra from the perineum, passing a lithotrite through the wound, into the urethra and along the urethra into the bladder, and crushing the stone, introducing an evacuator and removing the fragments. In Keith's operation the incision is medial and opens the membranous urethra. In very large stones, Milton thinks the surgeon should open the bladder as in ordinary lateral lithotomy, introduce a lithotrite through the incision, and crush the stone before extracting it, thus avoiding the infliction of injury upon important structures.

Fig. 792.—Thompson's vesical forceps for removing growths in the bladder. For growths near the neck of the bladder, with separation of the blades, to avoid tapping the neck of the bladder.

Operation for Stone in Women.—If the stone be small, give the patient ether, place her in the lithotomy position, dilate the urethra with the gentle dilator until it admits the index finger, and remove the stone with the first the-scoop, or the forceps. If the stone is found to be too large to pass crush it with a lithotrite and get rid of the debris by the evacuator. Large stone (two ounces) may require suprapubic lithotomy. Vaginal lithotomy is never required. If done, it is very likely to leave as a legacy a vesicovaginal fistula. In female children dilate the urethra, crush the stone, and evacuate.

Cystotomy.—This term means the opening of the bladder, and it is usually applied to an opening made for drainage, for diagnosis, for the removal of stones or tumors, or for the treatment of ulcers. This opening may be done by (1) a suprapubic cut (as in suprapubic lithotomy) (2) a central

cut (as in lateral lithotomy), or (3) a median perineal cut (as in lithotomy).

operation may be completed in one sitting, or the bladder may be opened, the opening of it being delayed for several days until it becomes adherent to the margins of the wound (Senn's operation). Senn's operation involves infiltration of urine into the perivesical space, and it is advisable to select it if the urine is

pus may persist after suprapubic cystotomy, but usually the wound heals unless it is interfered with by some expedient.

The effects of suprapubic cystotomy are very beneficial in chronic cystitis associated with hypertrophy of the prostate gland, the urine being foul. Drainage of the urine to become clear and the mucous membrane of the bladder to become normal. If the opening is made as a permanent drain, there will usually be incontinence, as the new channel has no sphincter action (Fig.). Figs. 793, 794, 795, 796, have tubes for prolonged drainage.

Suprapubic Cystotomy.—The operation is employed to allow the surgeon to explore the bladder, to treat an ulcer, to provide drainage, or to remove a tumor. If the operation is for calculi, it is known as suprapubic lithotomy (page 1323). After the bladder is opened its interior can be illuminated by the rays of an electric lamp, which appliance is fastened with a mirror to the forehead of the operator. If an ulcer is found, it is scraped with a curet or a spoon. Most cases of tumor require suprapubic cystotomy. It is true that a small single growth at the vesical neck is accessible by median cystotomy, but the area for manipulation is very narrow and the growth cannot be seen. Every large growth, all cases of multiple tumors, and all cases of tumor in individuals with great depth of perineum or with enlarged prostate require suprapubic cystotomy, an operation which allows

Fig. 793.—Senn's silver tube

a.—Senn's tube applied. The instrument rests upon the sensitive neck of the bladder.

stand to see the growth, which gives room for manipulation, and which allows thorough exploration of the entire bladder. The patient is put in the Trendelenburg position if water distention is used, but is placed horizontally if air distention is employed. After opening the bladder as for stone

(page 1323) hold the edges of the incision apart by means of a speculum (speculum of Keen or Watson) or with retractors, and reflect the electric light into the wound. Growths when seen can be twisted off, a pair of forceps holding the base and another pair being used to twist. Broad growths should be transfixed, ligated, and severed. Some growths (as cancer) are removed piece by piece with Thompson's forceps (Fig. 792), the base of the tumor being scraped. Soft growths are scraped away with a curet, a spoon, or a finger-nail. If bleeding is severe, check it by pressure, by hot water, by a 1 : 10,000 solution of adrenalin chlorid, or even by the actual cautery. In some cases the wound is allowed to heal rapidly. In others the bladder is drained for a considerable time. In some it is kept open permanently. Permanent drainage is desirable in some cases of enlarged prostate, and in such cases Senn's tube may be employed (Figs. 793 and 794 or Stevenson's tube (Figs. 795 and 796).

Median Cystotomy. The same incision is made in the perineal region as in median cystotomy as for median lithotomy. A grooved staff is introduced and is hooked up under the pubes; an incision is made into the membranous urethra, and is extended backward for three quarters of an inch, and a finger is carried into the bladder. If searching for a growth, find it with the finger, catch it with Thompson's forceps, and twist it off. Soft growths can be scraped away. Stop bleeding by digital pressure or by injections of hot water or adrenalin chlorid (1 : 10,000). If median cystotomy does not give access to the tumor, perform suprapubic cystotomy.

Growths in the Female Bladder.—Dilate the urethra as in a case of stone, and scrape, twist, or pull the growth away or ligate it. If the growth is large or if there are multiple growths, perform suprapubic cystotomy.

DISEASES AND INJURIES OF THE URETHRA, PENIS, TESTICLE, PROSTATE, SEMINAL VESICLE, SPERMATIC CORD, AND TUNICA VAGINALIS

Injuries of the penis and urethra may arise from traumatism to the perineum or the penis, from cuts and twists of the penis, from the popular "beating" of a chordee, from tying strings around the organ, from forcing things over it, from the passage of instruments, or from the impaction of cancer.

Fig. 795 Stevenson's suprapubic drainage tube.

Violence inflicted upon an erect penis may fracture the corpora cavernosa. The writer saw one man with a glass rod broken off in the canal, he having been in the habit of introducing it at the dictate of morbid sexual excitement. A patient in the Insane Department of the Philadelphia Hospital pushed a rod of his penis, which organ ulcerated into the urethra. These injuries are treated on general principles.

Perineal Bruises. If the perineum be bruised without rupture of the urethra, the perineum and scrotum swell and become discolored, water is passed with difficulty because the extravasated mass of blood in the perineal and urethral tissues occludes the canal more or less, the water is not bloody and

there are pain and profound shock. Some authors designate as rupture those cases in which laceration of the spongy tissue occurs, without involvement of the mucous membrane or of the fibrous coat, but they are properly contusions.

Treatment.—Place the patient in bed and establish reaction, and when reaction is complete employ opiates for the relief of pain. Apply an ice-bag

to the perineum. If, notwithstanding these measures, swelling continues, introduce a silver catheter (No. 12 English), tie it in, and make pressure upon the perineum by a firmly applied T-bandage or by a crutch braced against the foot board of the bed. Even when swelling is slight, retention of urine may occur from projection of a submucous blood-clot into the canal of the urethra. In some cases it may become necessary to incise and evacuate the blood-clot. After twenty-four hours have passed, if hemorrhage has ceased, substitute a hot-water bag for the ice-bag, and empty the bladder regularly with a soft catheter. Occasionally, though rarely, an abscess forms. *Punctured wounds of the urethra* require ordinary dressings. *Incised*

Fig. 796.—Stevenson's suprapubic drainage-tube in place and attached to a receptacle for urine.

wounds of the urethra, when longitudinal, are closed by suture. Healing is rapid, and ill consequences are not to be feared. Stricture does not follow. When the wound is transverse, introduce a catheter, suture the wound over the instrument, and remove the catheter at the end of the third day. If a catheter cannot be introduced, employ sutures, but at the first evidence of extravasation open the wound, and if drainage is not free perform external perineal urethrotomy.

Rupture of the Urethra.—By this term is meant a lacerated or a contused wound of the urethra, destroying partially or entirely the integrity of the canal. A lacerated wound may be induced by fracture of the cavernous bodies during erection, the symptoms being severe hemorrhage, intense pain, retention of urine, and inability to pass an instrument, infiltration of urine occurs, and gangrene is a common result. The writer has seen one case of rupture of the penile urethra due to a man's slipping while shaving, the penis being caught in a partially open drawer, the drawer being shut by his body coming against it. Rupture, however, is almost invariably located in the perineum, and it arises when the urethra is suddenly and forcibly pressed against the arch of the pubes by a blow, by a kick, or by falling astride a beam or a

fence-rail. Retention of urine due to stricture may lead to extravasation of urine. The lesion of urethral rupture consists in some cases of laceration of the spongy tissue and the mucous membrane, a cavity being formed which communicates with the canal, and which fills with urine during micturition. In other cases not only the spongy tissue and the urethral mucous membrane are rent asunder, but the fibrous coat is also torn, the canal opens directly into the perineal tissues, among which a huge cavity forms, that fills with blood and later with urine and pus. The urethra may be torn entirely across, but in most cases a small portion at least of its circumference is uninjured. Rupture never occurs primarily and alone in the prostatic urethra; it is extremely rare in the membranous urethra unless due to pelvic fracture; and it is very unusual in the penile urethra. The seat of rupture

Fig. 797.—Rupture Urethra.

in the great majority of cases is in the region of the bulb. Very often the skin is broken. **Symptoms.** The symptoms of rupture of the urethra are considerable pain, aggravated by motion, pressure and attempts to pass water; great shock in some cases; micturition is impossible, blood passing and also discolored stream, for some blood usually runs into the bladder, retention of urine quickly arises, and a vast majority of the cases retention is absolute from the very first, and it is due to the interruption in the integrity of the canal and to the occlusion of the channel by blood clots. Bleeding, which is usually free, lasts for several hours, some little blood generally appearing externally and much being retained in the perineum, inducing progressive swelling. The presence of a large swelling is regarded as evidence of urethral rupture. The blood which is effused in the perineum may extend under the foreskin of the penis and scrotum (Fig. 797). The swelling soon becomes red, purple, or even black, pressure upon it is apt to cause blood to run from the meatus, and it is augmented in volume when attempts are made to urinate. After a time, if the surgeon does not act, the urine fills the perineal cavity and widely infiltrates, and there ensue gangrene, sloughing, and sepsis, life being endangered or fistulae being left as legacies. The course of the extravasated urine will often enable one to locate the seat of injury. In rupture of the membranous urethra, if uncomplicated, the urine remains between the layers of the triangular ligament until a channel is opened for it by sloughing or by the knife. When extravasation occurs behind the posterior layer of the ligament the urine finds its way to the perineum in the neighborhood of

the anus. When the rupture is in front of the anterior layer of the ligament the urine, directed by the deep layer of the superficial fascia, finds its way into the scrotum and up on the belly, but does not pass into the thighs. A contusion is distinguished from a rupture by the facts that in the former the perineal swelling is not very extensive and does not enlarge on attempting micturition, while in the latter it is extensive and does enlarge on attempting to pass water. Furthermore, contusion does not cause urethral hemorrhage, while rupture does. A contusion sometimes, but not often, prevents the passage of a catheter; a rupture almost always, but not invariably, does so. The mortality from severe rupture with extravasation is about 14 per cent. (Kaufman).

Treatment.—In some cases it is possible to suture the urethra, and this procedure should be carried out when possible. In order to suture, perform suprapubic cystotomy and also make a perineal section. Find the posterior end of the ruptured urethra by passing a catheter from the bladder into the urethra. Suture with silk. The sutures pass through all of the coats of the urethra. The roof of the canal is sutured first, then a steel sound is introduced from the meatus, and the urethra is sutured around the instrument. The sound is withdrawn and the bladder is drained by Cathcart's siphon as illustrated in Fig. 786. In recent cases of ruptured urethra the usual treatment is as follows: Immediately perform median perineal section and turn out the clot; trim off lacerated edges; find the proximal end of the urethra, pass a catheter from the meatus into the bladder, and leave it *in situ* until healing has begun around it. If the catheter cannot be passed from the meatus, open the bladder above the pubes and find the posterior urethra by retrograde catheterization. In retrograde catheterization we push an instrument from the bladder into the wound and use it to guide a catheter from the meatus into the bladder. When rupture occurs back of a stricture it is a good plan to excise the cicatricial tissue. In cases with extravasation make a median incision and numerous transverse cuts to secure drainage for areas of retained urine or pus. Then, at once perform suprapubic cystotomy. Drain suprapubically and from the perineum for about two weeks, by which time sloughing tissue will have separated. Then find the posterior urethra by retrograde catheterization and do a perineal operation to repair the damaged urethra. (See Eugene Fuller, in "N. Y. Med. Jour.," Nov. 23, 1901.) The wound is packed with iodoform gauze, and the bowels are tied up with opium for a few days. Many surgeons strongly disapprove of the custom of retaining the catheter, believing that the instrument does no real good, as urine is certain to get between the catheter and the walls of the urethra. In fact, it is quite enough to stuff the wound with gauze, the patient urinating through the wound for the first few days, after which time a catheter is used at regular intervals. Whatever method is employed, healing will require from six to eight weeks, and the patient must during the rest of his life, from time to time, introduce large-sized bougies.

Foreign Bodies in the Urethra.—These bodies may be calculi, bodies introduced by injury, as shot, bone, etc., bodies entering from a fistulous opening into the rectum, or bodies introduced from the meatus, as broken bits of catheters, straws, pins, etc.

The symptoms vary with the size and the times there are almost no symptoms, at other times pain, retention of urine, and hemorrhage. Examine carefully with a finger in the rectum and by sound, taking care not to push the body back, with water when the body becomes impacted, in close the lips with the fingers, and direct the urination, the surgeon opening the meatus when needed, the foreign body being often forced out. If the foreign body is impacted in the pendulous passage by at once tying a rubber tube around the body out, and, if unsuccessful, endeavor to catch it with a scoop, or with the long urethral forceps. If the body is large, cut it off, dividing any extension just back of the meatus incision of the meatus. If a hairpin is in the canal, the feet of the pin are inserted into the meatus, to prevent them catching on attempts to be squeezed to approximate the feet, and when a silver catheter is slipped over to retain them it can be extracted. If this fails, drag the pin out with a pair of forceps, touch the sharp ends of the pin out through the skin, and then withdraw the other. An ordinary catheter can be used in the same way, and when the head is too large to pass by way of the meatus. If a hard or sharp foreign body is in the prostatic urethra, do not catch it with an instrument, but push it forward. To do so will be apt to tear the membrane and push it into the bladder and remove it later by crushing (H. Hartmann, in "La Presse Méd.", 1891). If a trite loaded with fragments be caught in the urethra, perform a perineal section, to enable him to remove it. After the blades have been closed the instrument is removed.

Urethrorrhea is not urethral inflammation, but is due to irritability of the urethra and over-secretion of the urethra. It may be due to masturbation, sexual excess, and also, to withdrawal during sexual intercourse, and to ungratified sexual desire. One or two of transparent mucus is found at the urethra. A considerable amount may flow away while straining at stool or during an erection. This flow at stool is often called *urethrorrhea*. This discharge stains but does not irritate. The discharge contains mucus, mucous corpuscles, and spermatozooids, but no gonococci or pus organisms. It is well in all other respects, but in many cases it is associated with sexual weakness, or even impotence.

Treatment.—In an uncomplicated case it is cured by the abandonment of evil habits. If complicated, it may require treatment.

Urethritis, or Inflammation of the Urethra.—This can be divided into two classes. (1) *simple urethritis* is due alone to pyogenic cocci (particular

and the *staphylococcus pyogenes*), and (2) *specific*, in which the gonococcus is present.

Non-specific or simple urethritis may be due to several causes, such as traumatism; great acidity of the urine; chancre in the urethra; contact with menstrual fluid, leukorrheal discharge, the discharge from malignant disease of the uterus, ordinary pus, or acrid vaginal discharge; the passage of instruments; the administration of irritant diuretics; strong injections; worms in the rectum; a febrile malady; venereal excess and masturbation; the passage or impaction of foreign bodies, and papillomata of the urethra. A temporary and mild urethritis sometimes accompanies early syphilitic eruptions. Simple urethritis is less severe and prolonged than gonorrheal urethritis, though initially in the early stage the physician cannot invariably distinguish between the two forms. The diplococci of gonorrhea are never found in the discharge of simple urethritis, although there may be numerous other diplococci. In medico-legal cases testimony is not admitted as to the presence or absence of diplococci, as judges do not admit that their presence proves or their absence disproves gonorrhea. In the non-specific inflammation pus is not always present, many cases stopping short of pus-formation after a varying period of catarrh, but any catarrh may become purulent. A simple urethritis may be acute or may be prolonged for an indefinite period by the presence of large amounts of oxalate in the urine or the existence of the uric-acid diathesis (see Gouty Urethritis).

Treatment.—Seek for the cause and remove it. Correct any abnormal condition of the urine by means of suitable diet, drugs, and mode of life. Mild astringent injections are useful. It may be necessary to flush the urethra repeatedly with a solution of silver nitrate (1:8000).

Traumatic Urethritis. The onset pain in traumatic urethritis is coincident with the introduction of the foreign body. The discharge, which may be bloody, mucous, mucopurulent, or purulent, comes on within twenty-four hours.

Treatment.—If the inflammation is slight, prescribe diluent drinks, paregoric, a saline, or the following:

R. Tinct. belladonnæ	℥ss
Sodii bromid	℥iv
Tinct. opii camphorat	℥j
Syrupus zingib.	℥ss
Aqua destil	q. s. ad. ℥vj. M.

Sig.—A tablespoonful every six hours.

If the inflammation is severe, put the patient to bed, apply hot fomentations to the perineum, give diluent drinks, employ suppositories of opium and belladonna, and watch for fever and other complications.

Gouty Urethritis.—This condition first manifests itself in the posterior urethra, not in the anterior, as does clap. Its symptoms are great vesical irritability; pain on urination; discharge, usually scanty, associated with uric acid in the urine or other symptoms of gout. The *treatment* comprises dieting and the usual remedies for gout. Purgatives are given freely, and full doses of colchicum, piperazin, urotropin, or the alkalis; hot baths, low diet, diluent drinks, and diaphoretics are indicated. A chronic discharge from the prostatic region is apt to linger; for this there is nothing better than the usual

white in color and of variable length, and float in the urine. They are composed of pus-corpuscles and of epithelial cells which have undergone fatty degeneration. Many of these shreds form in the ducts of Cowper's glands, but the glands of the entire length of the urethra also furnish them.

Gonorrhea (Clap; Specific Urethritis; Tripper; Venereal Catarrh).—Gonorrhea is an acute inflammation of the genital mucous membrane, of venereal origin, due to the deposition and multiplication of gonococci in the cells of the membrane and a mixed infection with the cocci of suppuration. The disease is inaugurated by gonococci. After a few days or more secondary pyogenic infection develops and complications may result from the gonococci or from the bacteria causing the mixed infection. The disease attacks with the greatest ease surfaces covered with squamous epithelium. The gonococci enter into and multiply in the superficial epithelial and pass to between the deeper cells, where they lodge and multiply as the superficial cells are cast off. The pus from the urethra contains epithelial cells with gonococci inside of them, and also pus-cells with gonococci within them as a result of phagocytosis. Cultures are made with difficulty. Gonococci do not stain by Gram's method but stain best with a weak, watery solution of anillin dye. These bacteria are said not to be pathogenic to animals, although some observers deny this assertion. Gonorrhea is one of the most common and widely disseminated diseases. Probably one-half of all sterile women and many sterile men have been rendered sterile by this disease. It is responsible for not a few cases of abortion, for an enormous majority of female pelvic diseases, and it causes many cases of blindness from infection of children's eyes during delivery.

Gonorrhea in the Male.—In the male, clap begins within the meatus and fossa navicularis and extends backward throughout the length of the urethra. The mucous membrane swells and becomes hyperemic, and there is a discharge, first of mucus and serum, and then of pus. In severe cases the discharge is bloody (*back gonorrhea*). For a week or more the inflammation increases, then becomes stationary for a time, and then declines, the discharge growing less profuse and thinner, a watery discharge lasting for some little time. An ordinary case of genuine gonorrhea lasts from six to ten weeks, and even a case limited purely to the anterior urethra will rarely be cured within four or five weeks. During the acute stage the entire penis swells and the corpus spongiosum becomes infiltrated with inflammatory exudate. An interesting fact is that gonorrhea may induce mild septicemia without demonstrable complications, the condition causing, according to Thayer ("Am. Jour. Med. Sciences," Nov., 1905), a continued fever which, perhaps, lasts a number of weeks. In true gonorrheal septicemia the blood must contain gonococci. In the case recorded by Thayer and in the case recorded by Blumer and Hayes, cultures were obtained from the blood. Gonorrhea may produce grave septicemia and systemic complications. It tends particularly to attack serous membranes or other endothelial structures (joints, pericardium, endocardium, pleura, tendon-sheaths, intima of vessels, etc.). Among the complications are gonorrheal arthritis, myelitis, polyomyelitis, and multiple neuritis. There are 3 cases of gonorrheal myositis on record (Martin W. Ware, "Am. Jour. Med. Sciences," July, 1901). Phlebitis may arise. Mild endocarditis may arise or severe endocarditis may

occur, identical symptomatically with ulcer bacteria. In 6 reported cases of endocan cultures from the blood *intra vitam* (Thayer Nov., 1905). Cerebral embolism may occur (fluid obtained by lumbar puncture).

Gonorrheal rheumatism is discussed on p. 1341. It is rare. Infection of the peritoneum through majority of cases of gonorrheal peritonitis direct extension from the Fallopian tubes.

in the exudates of cases of pleuritis and peritonitis of gonorrheal origin. A child may contract gonorrhea and any person may develop it by getting gonorrhea.

Symptoms of Acute Inflammatory Gonorrhea

Onset of gonorrhea is from a few hours to two weeks to five days, when symptoms of the *prodromal* stage appear. The patient notices on arising a drop of thick mucus from the meatus together, and he feels some heat and itching in the meatus or in the navicular fossa. There may be some pain on micturition, and there is sure to be some discharge. The meatus is red and swollen, has a glazed appearance, and the lips are glued together by the mucus, and to squeeze out a drop or two. Even this is the case in the acute stage.

The urine appears clear, but on shaking, a turbid sediment of epithelial cells.

Within forty-eight hours the acute stage, or the stage of increase, begins. The meatus now red, swollen, and everted (fish-mouth) and the urethra red and swollen; if the prepuce is long, it is constricted, and in many cases very edematous. On the dorsum of the penis may be redness and pain. On micturition causes severe pain (ardor urinae) and the inflamed urethra and to stinging by the urine. The patient involuntarily relaxes the abdominal muscles, keeps the diaphragm elevated in order to diminish the force of the stream and lessen the size and force of the stream" (Taylor).

Because of the narrowing of the urethra, the stream is narrow, weak, twisted, forked, or is delivered in spurts. Emission may result from spasm of the muscles of the urethra. If fully developed, the entire urethra is inflamed. The triangular ligament; there is constant unquenchable itching of the penis and perineum, increased by walking or carelessly. Insomnia is common; chordee is common; the patient is warm in bed. By chordee we mean a permanent bend in which the penis is markedly bent. The spongiosum prevents it distending to accommodate the corpus cavernosa, and in consequence the stream is forced out in spurts, with tenesmus and a profuse discharge of mucus, greenish, or even bloody. The discharge is profuse and may crust upon the linen, the meatus, or

plications of this stage are *balanitis* (inflammation of the mucous membrane of the glans penis), *balanoposthitis* (inflammation of the surface of the glans and the mucous membrane of the prepuce), *phimosis* (thickening and contraction of the foreskin, so that the glans cannot be uncovered), and *paraphimosis* (catching and fixation of the retracted prepuce behind the corona glandis, with such swelling of the glans and prepuce that it is impossible to bring the prepuce forward over the glans). This is a dangerous condition and it should be reduced at once. In the *second or stationary stage*, which lasts from the end of the first to the end of the second week, the acute symptoms of the first stage continue. The most common complications of this stage are *peri-urethral abscess or phlegmon* (infection of a urethral gland or of submucous structures), *folliculitis* (inflammation of the follicles of Littre), hemorrhage, retention of urine (which is rare), gonorrheal arthritis, lymphangitis, and diminutive bubo on the dorsum of the penis (*bubonulus*), solitary and painful bubo of the groin, which may suppurate, *Cowperitis* (inflammation of Cowper's glands), inflammation of the prostate or of the bladder, gonorrheal ophthalmia, and *chordee* (painful erection with downward bending of the penis). In the *third or subsiding stage* the symptoms gradually abate, the discharge becoming scantier and thinner, and finally drying up. This stage is of uncertain duration, and in it there may occur *epididymitis*, or inflammation of the epididymis. Among possible complications we may mention peri-urethral abscess or phlegmon, Cowperitis, cystitis, prostatitis, bubonulus, folliculitis, gonorrheal arthritis (page 645), infective endocarditis, tenosynovitis, pyelitis, purulent ophthalmia, perichondritis, and peritonitis. Every urethral discharge should be examined for gonococci in order to make a positive diagnosis. This examination is made several times during the progress of the case, so as to determine when the organisms disappear. The examination can be easily made. Place a drop of discharge upon a cover glass, lay another cover-glass over this, and slide the glasses apart. Dry and fix the slides in the flame of an alcohol lamp. Bring the cover glasses in contact with a saturated solution of methylene-blue in 5 per cent. carbolic acid water. The staining-material is allowed to remain in contact with the slides for five or ten minutes, the glasses are washed with water, are then placed in a solution of 5 drops of acetic acid to 20 c.c. of water, and kept there "long enough to count one, two, three slowly," and again washed with water. Examination with the microscope shows the gonococci stained blue.* In doubtful cases, when the microscope fails to show gonococci, make cultures. Cultures should always be taken from a discharge in a child, from the fluid of an inflamed joint, from the discharge in gleet or purulent ophthalmia, and from the blood in obscure infections.

Subacute or catarrhal gonorrhea develops in men who have previously had gonorrhea, as a result of prolonged or repeated coition or of contact with menstrual fluid or leukorrheal discharge. There is profuse mucopurulent discharge, very little pain on micturition, but seldom chordee or marked irritability of the bladder.

Irritative or Abortive Gonorrhea. In this disease the symptoms, which are identical with those of beginning clap, do not increase, but are apt to disappear within ten days.

* Schütz's method, as set forth by R. W. Taylor in his work upon "Venereal Diseases."

Chronic Urethral Discharges.—Ch may follow gonorrhea, is characterized by t of clear, tenacious liquid. This discharge b of sexual excitement or the abuse of alcohol.

The persistence of a small amount of m zation of inflammation in one spot or the pre superficial ulcer, characterizes chronic gon on urination; erections produce aching pain; redness and swelling of the meatus. All t sexual excitement, by coitus, by violent exere

Gleet.—If a chronic urethritis lasts over gleet the lips of the meatus are stuck together them discloses a drop of opalescent mucopus discharge is rarely found. The discharge it stains the linen distinctly, and contains times gonococci. The urine is clear and c and coffee-shaped hooks. The discharge contains amyloid corpuscles. There are in the back, and dribbling of urine, and a large caliber, or at least will discover the inflammatory infiltration. A discharge may *titis*. In this condition there are frequ weight or dull pain in the perineum; diminis of urine; there is often a tendency to sexual sion. In prostatorrhea a milky discharge g and flows during muscular effort or while th is stained but slightly and the lips of the m waking. There is a history of masturbation is not aggravated particularly by alcohol or anterior urethritis there is a discharge fro gether of the lips in the morning. If there is no discharge of pus from the me made, it will be found that in a case of the first portion will be cloudy and show anterior urethritis of not very long standing, both the first containing clasp shreds, the last in chronic case neither sample will be cloudy, shreds. In gleet the rigidity of the ureth quantities of urine after each act of micturiti This retained urine decomposes and adds to alcohol, sexual excitement, or sexual interco

Treatment of Acute Gonorrhea. *Gena* touching the parts and dry them on an ind upon the face. Wear a suspensory bandag cially bicycle riding, and also wet. Moder patient must not only refrain from sexual it himself to indulge in sexual excitement, and malt, vinous, or spirituous, unless he is a hea case we should permit the moderate use of w

Some men become actually ill without their regular daily stimulants and such men should have them in moderation. Some surgeons permit the moderate use of claret to all patients. At least twice a day wash the penis for five minutes in a cup of warm water containing 3j of salt. Passing the urine while the penis is immersed in warm fluid lessens ardor urinæ. If the foreskin is long, catch the discharge on a bit of absorbent cotton caught under the prepuce and change it at each act of micturition. If the foreskin is short, cut a small opening in a square piece of old linen, slip the linen over the glans, catch it back of the corona, and bring the ends forward with the prepuce. Never permit the cotton or linen to stick fast and plug up the lips of the meatus. This may be prevented by applying sterile vaselin to the lips of the meatus. If the glans is completely naked, pin an old stocking foot upon the undershirt, put absorbent cotton in the toe, and place the penis within this bag. Never tie or fasten any material about the penis. The patient should drink freely of plain water or of water containing a little bicarbonate of sodium. He should obtain one bowel movement every day. I am accustomed to direct the patient, in accordance with Guitéras's rule (Begg, in "Phila. Med. Jour.," June 7, 1902), to avoid tea, much coffee, pickles, spices, condiments, rhubarb, tomatoes, and asparagus. Carbonated beverages, salt, preserved fish, and cheese are detrimental. Excessive smoking is forbidden.

Abortive treatment may be tried if the case is seen early. The use of strong solutions of powerful germicides has been abandoned because of the great pain they produce and the inevitable subsequent crippling of the urethra.

Abortive treatment is applicable only to specially selected cases and even then usually fails. It should never be used after the gonococci have invaded the submucosa, but only during the prodromal stage, when it is hoped that the germs are upon and not in the mucous membrane. This stage usually lasts but a few hours, usually not over forty eight. The patient generally presents himself after this period is passed. When the symptoms as described in the prodromal period prevail, the abortive treatment may be tried, after explaining to the patient that it will cause some pain and discomfort and in the end may fail or even aggravate the inflammation.

Germicides may be used and with some chance of killing the infection, for as yet the organisms are growing upon the superficial strata of epithelium much as a sod of grass upon soil. When the deeper structures have been invaded it is folly to attempt to abort.

The method advocated by White and Martin and which has proved successful in Prof. Orville Horwitz's clinic in a very limited number of selected cases is as follows: After urination four drops of a 4 per cent. solution of eucain is injected into the urethra; after which 1 or 2 drams of $\frac{1}{2}$ per cent. solution of protargol is instilled and retained for three minutes. The injections are repeated every two hours while awake.

Each time the bottle is half emptied it is replenished with sterile water to its full capacity, until the end of the third day. If successful, recovery is accomplished in about seven days. Should a mucoid discharge persist an antiseptic astringent injection is employed to complete the cure. During the treatment the patient must be kept at rest. The diet should be bland and light and the usual balsamic remedies are administered. If the symptoms become hyperacute, stop the treatment at once and give a sedative.

Another abortive method is the use of hot ir-
gimate solution (1:20,000), 2 pints being ri-
day. If in seventy-two hours the sympt-
abortive treatment should be abandoned. I
certain that there is no real abortive treat-
be efficient, would have to be carried out
the epithelial cells; in other words, would
distinct symptoms of the disease appear.

several minutes, when relaxation will usually occur; but if it does not do so, tell the patient to breathe slowly and deeply, and to make efforts at urination (Valentine). When the bladder is full the tube is withdrawn and the patient micturates. This procedure is practised once or twice a day for five or six days, or even longer, and the strength of the solution is gradually increased up to 1 : 1000. It has been claimed that after one or two weeks of this treatment gonococci permanently disappear in the majority of cases. Fig. 798 shows the irrigator devised by Ferd. C. Valentine. Valentine, of New York,* has constructed the following table, which is of use to a practitioner who wishes to employ irrigations with permanganate of potassium in the treatment of acute gonorrhea.

First day, first visit.	Anterior irrigation	1 : 3000
First day, 7 P. M.	Anterior "	1 : 4000

	Anterior "	1 : 500

For full directions regarding this method see Valentine's excellent book, "The Irrigation Treatment of Gonorrhea." If a stricture exists, it is not advisable to employ this treatment. Excellent results can be obtained by irrigations with fluid containing silver nitrate (1 : 12,000 to 1 : 8000).

When a patient is treated by irrigation, after the entire subsidence of acute symptoms, a thin, colorless discharge may persist. This can be cured by the use of astringents. Two or three times a day an astringent is injected by means of a half-ounce syringe. Dalton's formula is very useful: Zinc oxid and lead acetate, of each $\frac{1}{2}$ gr. to 3 gr.; tincture of catechu, from $\mathfrak{m}\text{x}$ to $\mathfrak{m}\text{xxx}$; glycerin, from \mathfrak{ss} to \mathfrak{ssj} ; and water to \mathfrak{ssj} .

Many writers oppose the irrigation treatment, claiming that it increases the liability to complications, especially prostatic infiltration, and enhances the danger of recurrence. I believe in the method. I do not think it shortens the duration of the disease, but do believe that it mitigates its intensity, makes the patient much more comfortable, and quickly causes the discharge to become mucopurulent. That it increases complications and the danger of reinfection is very doubtful. Much of the trouble which has followed its use has been due to raising the reservoir to too great a height.

* "The Irrigation Treatment of Gonorrhea."

Irritative gonorrhea will subside in a few days. The above directions should be followed, and the anterior urethra should be washed out several times daily with peroxid of hydrogen, or irrigated once a day with a hot solution of permanganate of potassium (1 : 4000). In *catarrhal gonorrhea*, at once order injections (1 grain to the ounce of sulphate of zinc, or zinc sulphate gr. viij, plumbi acetate gr. xv, water ℥viij; or gr. v of sulphocarbolate of zinc to ℥j of water; or White's prescription of ℥j each of acetate of zinc and tannic acid, ℥ij of boric acid, ℥vj of liq. hydrogen. peroxid.). For injecting use a blunt pointed hard rubber syringe of a capacity of three or four drams. Let the patient urinate and then sit on a chair, his buttocks hanging over the edge; throw a syringe-ful of the solution into the urethra and let it run out at once and throw in another syringe-ful and hold it in from three to five minutes.

In *ordinary acute gonorrhea* the old rule was to order balsams. The common custom is to give two capsules three times a day, each capsule containing 5 grains of salol, 5 grains of oleoresin of cubebs, 10 grains of balsam of copaiba, and 1 grain of pepsin. Clinical observation indicates that the balsams are of distinct value in gonorrhea. When used early, the discharge tends to become mucopurulent and the acute symptoms subside (S. Hermann, in "Dermatologisches Centralblatt," Berlin, Nov. and Dec., 1907). Many practitioners will not use balsams until the third week. Bacteriologic studies indicate that copaiba, when eliminated in the urine, has a certain amount of power in inhibiting the growth of gonococci, but that cubebs and sandal have not such power. Yet sandal is more useful than copaiba as a remedy. Salol is distinctly germicidal, hence it is given with the balsams. In a case treated with balsams an astringent injection is usually employed. The injection is used two or three times a day, immediately after micturition. As the inflammation subsides increase the strength of the injection. A good plan is to order an eight ounce bottle and eight half grain powders of sulphate of zinc. Direct the patient to fill the bottle with water, in which one powder is dissolved; when this is used dissolve two powders in a bottle-ful of water and so progressively increase the strength. When the discharge ceases stop the injections gradually. Whenever a syringe-ful is taken from the bottle a syringe-ful of water is put into the bottle, and thus pure water is soon obtained at which point injection is discontinued. If an astringent injection causes much pain, use a sedative injection—℥ij of boric acid, gr. viij of aqueous extract of opium, and ℥viij of liquor plumbi subacetatis dilutus. I have had as much success with the above simple method as with the most complicated of plans. Complication and complexity are not criterions of usefulness.

Argonin, which is a combination of albumin, silver, and an alkali, is highly recommended by some authors as a local remedy for gonorrhea (Schäfer-Guthrie). A solution of this material is non-irritant, the silver is not precipitated by chlorids, and the agent destroys gonococci. It is used by injection or irrigation. If used by irrigation employ a 1 : 500 solution twice a day. If used as an injection, employ a 1 : 200 solution six or eight times a day. When the discharge is found free from gonococci and remains free for three days, stop the argonin and use an astringent injection.

Protargol, metallic silver combined with a proteid, is a yellow powder soluble in water, the solution not being acted on by light. It is a non-irritant germicide. Neisser, after demonstrating the presence of the gonococci,

administers protargol by injection, the first injections being of a strength of 0.25 per cent., the strength being gradually increased to 0.5 per cent., and finally to 1 per cent. In the beginning he orders three injections a day, each injection being retained from fifteen to thirty minutes; after several days, when the symptoms improve he gives only one or two injections a day, and these are continued for ten days after gonococci disappear from the discharge. After protargol is abandoned an astringent injection should be used for a time. Some surgeons use a 1 : 1000 solution of protargol, and irrigate the anterior urethra and flush the bladder twice a day. The most powerful and useful of the silver salts is argyrol, or silver vitellin. This salt was discovered by A. C. Barnes and H. Hiller ("Med. Record," May 24, 1902). It is an extremely soluble preparation, contains 30 per cent. of silver, does not coagulate albumin, and is not precipitated by chlorids. When injected into the urethra it enters deeply into the mucous membrane and is powerful in destroying gonococci. (See "A Clinical Study of a New Silver Salt in the Treatment of Gonorrhea," by H. M. Christian, in "Med. Record," vol. lxii, 1902.) In most cases gonococci disappear within two weeks. The injection used at first may be of a strength of 2 per cent. The drug should be retained in the urethra four or five minutes, and three or four injections should be given each day. The strength of the injection can be gradually increased to 5 per cent. or even more. Picric acid has been highly commended as an injection. The strength of solution is 1 : 200, and it is to be retained in the urethra three or four minutes (de Brun's method).

Methylene-blue internally is occasionally of service in gonorrhea. A capsule containing gr. ij of the drug is given three times a day. It makes the urine greenish-blue and occasionally induces strangury. Urotropin renders the urine sterile. Salicylate of sodium may be of value late in the case.

Christian's plan of treating acute gonorrhea is very useful. It is as follows: Two solutions are used during the first ten days. Three times a day a solution of permanganate of potash is injected (gr. $\frac{1}{2}$ of permanganate of potash in 8 ounces of water), six syringefuls being used at each séance. After a washing with permanganate protargol is injected (gr. x of protargol to $\bar{\text{ss}}$ of water) and retained ten minutes. At the end of four days the strength of the protargol is increased to gr. xx in $\bar{\text{ss}}$ and the strength of the permanganate to 1 : 4000. During the third week abandon the above-mentioned solutions, put the patient on balsams, and use an astringent injection. Christian uses gr. x of sulphate of zinc, gr. ij of subcarbonate of bismuth, 2 ounces of solution of hydrastis, and 4 ounces of water. Cure is obtained in six or seven weeks.

In his clinic in Jefferson Hospital my colleague, Prof. Horwitz, employs the following plan of treatment: A capsule containing balsam of copaiba, salol, oil of sandalwood, and methylene-blue is given half an hour after each meal:

R. Methylene blue	gr. xxx
Balsam copaiba l	
Ole. sandal	aa (5iss. M.
Pone in capsulas No. xxx.	
Sig.—One after each meal.	

The patient begins at once, three times a day, the use by hand injection of a 10 per cent. solution of argyrol.

At each day injection the fluid is retained. At the bedtime injection the fluid is retained only about 3j is injected at a time, but as to fluid distention the amount is gradually given.

Argyrol is less irritant and, it is said, than other preparations, but it cannot penetrate deep value except in the period of onset or early in object to argyrol because it leaves a dark stain comes in contact, but this stain can be easily a 1:1000 solution of corrosive sublimate.

When the stage of decline begins (toward combined astringent and antiseptic treatment)

The capsules of methylene-blue, copaiba injections of argyrol are discontinued. A capsule oil of sandal, and balsam of copaiba is given but urotropin is given after each meal. An injection is given three times a day. This remedy is The strength is gradually increased until at the end of the fourth week the patient has received capsules of sandal and salol are substituted for and an astringent injection is ordered. The formula by J. Wm. White, is very satisfactory:

R. Hydrarg. chlor. corros.
Zinci sulphocarbolas
Acidi boraci
Acidi carbolic.
Boroglycerid (25 per cent.)
Aquæ destil.
Sig.—Inject. Dilute if it causes much pain

When the mucoid condition predominates useful:

R. Zinci sulph.
Plumbi acetati.
Glycerol tannin }
Hydrastin (Lloyd's) }
Mucil. acaciæ.
Aquæ destil.
Sig.—As injection.

The formula of the "injection Brue" is as

R. Plumbi acetat.
Zinci sulphat.
Ext. krameriz fl.
Tinct. opii
Aquæ destil.
Sig.—As injection.

When all symptoms have disappeared, the Whenever a syringe-ful of the fluid is taken

water is put in. When the fluid becomes pure water, the injection is discontinued. The capsules are stopped by gradual diminution in the number of daily doses. For three weeks after the entire disappearance of all symptoms alcohol is forbidden and sexual indulgence is prohibited. Should a relapse occur the patient is at once placed upon treatment as for the acute stage, and when the stage of decline again ensues he is placed on the previously mentioned antiseptics and astringents. Relapses are caused by a localized lesion or lesions in the anterior or posterior urethra, hence as soon as all acute symptoms subside an endoscopic examination is to be made and proper treatment is to be applied to the localized lesion. If during the treatment of gonorrhea a complication develops, local treatment of the urethra is at once discontinued and constitutional treatment suited to the new condition is prescribed.

If the onset of gonorrhea is marked by violent inflammatory symptoms (chordee, hemorrhage, severe pain, swelling, profuse purulent discharge), local treatment of the urethra is contraindicated.

If the invasion is hyperacute, no local treatment of the urethra is permissible until the disease assumes the character of ordinary gonorrhea.

Not unusually gonorrhea passes into a low grade of anteroposterior urethritis that proves most rebellious to treatment. This condition is especially common when a too stimulating treatment has been used. A mild astringent injection is used three times a day. Every second or third day an injection of nitrate of silver (1:4000) is given. If the silver salt sets up an acute inflammation the treatment used in the acute stage of gonorrhea is given until the symptoms abate.

A valuable plan in rebellious anteroposterior urethritis is daily irrigation of the anterior urethra with a warm solution of permanganate of potassium (1:6000), followed by the passage of a soft catheter and the filling of the bladder with a like solution. The patient empties his bladder after the catheter is withdrawn and thus flushes the entire urethra with the permanganate. The strength of the solution is gradually increased up to 1:2000.

Weiss uses corrosive sublimate (1:20,000) in the manner just described. It is particularly valuable in cases of bacterial contamination, the gonococci having disappeared.

Treatment of Complications.—*Ardor urinae* is relieved by urinating while the penis is immersed in hot water and by administering an alkaline diuretic. *Chardee* requires a bowel movement in the evening, and sleeping in a cool room, under light covers, and on a hard mattress; bromid is given several times daily, and a considerable dose is given at night; it may be necessary to use suppositories of opium and camphor or to give hyoscin. *Balanitis* requires frequent washing with warm water, drying with cotton, and dusting with borated talc or with boric acid and subnitrate of bismuth (1:6). *Balanoposthitis* requires soaking in hot water, and injections of black wash under the prepuce until edema of the foreskin sub-sides, and then cleanliness and the application of a drying powder. *Phimosis* requires soaking the penis in hot water, and injections of hot water beneath the foreskin, followed by black wash. If this fails, circumcision must be performed. If *paraphimosis* occurs, grasp the head of the penis with the left hand, squeeze the blood out, and try to push the head back, while with the right hand the penis is pulled upon as if

the surgeon intended to lift the individual by a collar on the dorsum with scissors; or, what is more sure, incise each side of the prepuce between the frenum. *Bubo* requires the application of rest, the use of a spica bandage, and rest. If the abscess is opened or aspirated. *Acute posterior urethritis* if symptoms are severe, by rest in bed. If the symptoms are given; if they do, they are withdrawn. *Urethritis* patient is placed upon a milk-diet with orders to abstain from Alkaline fluids do harm by favoring ammoniacal. Injections and irrigations are abandoned. If the symptoms are controlled by suppositories of opium and belladonna, have the patient urinate while in a hot bath. *Acute vesiculitis* is treated as is *acute urethritis*. *Acute vesiculitis* is treated as is *acute urethritis*. *Pyelitis* is treated by wet cupping of the loin, or milk-diet, the use of a small quantity of bland liquid, and the administration of opium. *Folliculitis* is treated by rest and the application of a hot fomentation (if that be the part involved). If the follicle opens into the urethra it may be cured by rest. *Peri-urethritis* is treated by rest and hot applications must be made. If the abscess is perianal, rest and hot fomentations may be used, but if it is a large one, make an external incision. *Cystitis* may be treated as *peri-urethritis*. *Gonorrheal rheumatism* is treated by rest and hot applications. *Acute prostatitis* and *cystitis* require confinement to bed, the use of diuretics, hot applications to the perineum, suppositories of opium, and belladonna or if the symptoms are severe, the discontinuance of balsams and injections of urotropin or salol. *Abscess of the prostate* is treated by rest and hot applications. *Retention of urine* the patient should try to pass urine; if this fails, a soft catheter is used. After relief is obtained, the patient should be put to bed and apply hot sand bags as for acute inflammation. *Chronic urethritis* requires cold hip-baths, cold water enemata, a milk-diet, avoidance of alcohol and over exertion, the use of opium, and the relief of stricture or phimosis by the use of a bougie derived from passing a soft bougie covered with a 1 per cent. ointment of protargol. If *epididymitis* is present, rest, abandon injections, shave the hair from the scrotum, elevate the testicles, and apply an ice bag. *Gonorrhea* is treated by suitable doses of bromid of potassium (gr. ʒss) and twice a day of 20 drops of guaiacol in ʒi of water. *Relief*. When swelling lingers, after treatment with adhesive plaster. A lingering case is treated by the use of iodid of potassium and the local application of a watch-crystal over the eye. *Ophthalmia* secure a watch-crystal over the eye, in a darkened room, rub the infected conjunctiva with a watch-crystal.

2 per cent. solution of silver nitrate, wash out the affected eye often with hot boric-acid solution, keep the pupil dilated with atropin, leech the temple, and give purgatives. Always send for an ophthalmologist.

When is Gonorrhea Cured?—When actual discharge ceases, a patient considers himself cured and yet he may have residuals of infection which are liable at any time to awaken into activity and produce anew an acute condition. Gonococci are frequently retained in the urethral glands and follicles or in areas surrounded by indurated mucous membrane. A man is considered to be well when shreds and pus disappear from the urine, when an examination of expressed mucus on three successive days fails to find gonococci, and when there has been no discharge for ten days. Furthermore, we must be sure that the prostate, Cowper's glands, and the seminal vesicles are free from disease.

Treatment of Chronic Gonorrhea and of Chronic Urethritis following Gonorrhea.—The first thing to do is to determine the *cause* of the prolongation of the discharge. Valentine's list of causes should be borne in

Fig. 799.—Bougie-à-boule.

mind ("Med Record," June 29, 1901). They are as follows: (1) Lack of treatment; (2) mis-directed treatment; (3) insufficient treatment; (4) over-treatment; (5) infraction of dietetic or hygienic regulations; (6) constitutional disturbances; (7) congenital or acquired deformities and complications; (8) involvement of the urethral adnexa; (9) marital reinfection. In a case in which a discharge persists or recurs, the symptoms and general condition must be closely studied, the discharge must be examined microscopically, the condition of the urine must be determined, and the urethra must be explored.

Exploration of the urethra is inaugurated by inspection and external palpation. Palpation detects induration, peri-urethritis, follicular abscess or inflammation, Cowperitis, etc. The prostate and seminal vesicles are examined by a finger in the rectum. The interior of the urethra is explored with a soft bougie à boule (Fig 799). On withdrawing this instrument the shoulder catches in any contracture. It is to be borne in mind that a large steel sound can often be introduced with ease when the bougie-à boule makes evident that a contracture exists. The emergence of the instrument is arrested by a patch of thickening, a granular area, a zone of epithelial proliferation,

a papilloma, or a stricture. In fact, anything of caliber interferes with the withdrawal of the b

obturator and insert the light. Turn on the light, mop the urethra with bits of cotton wrapped on a stick, and slowly withdraw the tube, examining the urethra as its walls fall together back of the retracting tube. After withdrawal of the tube irrigate the anterior urethra. To examine the deep urethra, carry the instrument through the prostatic urethra. After the examination give an intravesical irrigation.

When the cause of a discharge is once determined, rational treatment can be instituted, and to determine the cause the electric urethroscope is indispensable. An erosion of the mucous membrane or a granular patch requires touching from time to time with a solution of silver nitrate (1 or 2 per cent.). These applications are made through the tube of the urethroscope. A

Fig. 804.—Kellmann's anterior dilator

stricture or an infiltration is treated by gradual dilatation. This combines pressure and massage. If the caliber of the urethra is less than No. 21 of the French scale, conical steel sounds are used twice a week. If there is much hyperesthesia they are retained but a brief time; but as hyperesthesia diminishes the period of retention is lengthened, until an instrument can be kept in place without causing severe suffering for ten or fifteen minutes. It is not desirable to use cocaine, as it is distinctly dangerous, obtunds the sensibility so that undue violence may be used, and increases the post-operative inflammation. Before and after using an instrument the urethra must be cleansed as previously directed (page 1338).

When the urethra becomes tolerant to it is employed to act particularly on the area of treatment the caliber of the urethra is equal French scale, it is rarely necessary to precede with smaller sounds. Figs. 804, 805, 806, and 807 show the method of use. The instrument should be inserted in a sterile rubber cover.

Fig. 808.—Kollmann's gland syringe.

with lubrichondrin or synol soap. If a two-bladed dilator must be subsequently used, a four-bladed dilator must be subsequently used.

A dilator is cleansed by scrubbing its blades with alcohol, withdrawing, and burning the instrument.

The following rules are of the first importance (from "Med. Record," June 29, 1901):

1. The first dilatation must stop at that point where no further dilatation is felt by the operator when the blades are separated.
2. Dilatations, if done by a novice, must be repeated no oftener than every three or four days.
3. Each dilatation, in point of time, must be at least two minutes over that of the preceding session.
4. No dilatation must exceed one-half inch beyond that attained at the next prior séance, regardless of the degree of inflammation present.

As a rule, glandular and follicular infection must be treated by the dilator. If they are not, they must be treated by the urethroscope. The interior of a follicle may be treated by a wire or subjected to electrolysis, or touched with silver nitrate. A thickened crypt, or gland, may be slit with a knife. A polypoid growth may be removed by cautery, or special forceps. In a chronic case, in which the inflammation is superficial and limited, irrigations, urethral and intravesical, are of great value. (See Valentine's treatise on "The Irrigations of the Urinary System.")

In any lingering case of gonorrhea examination should be made for oxaluria, lithemia, or phosphaturia. Such morbid states of the urine are the result of a great prolongation of the inflammation. In such cases, treatment should be directed up by inflammation of the seminal vesicles (Fig. 809).

Gonorrhea of the anus and rectum.

occurs. It may result from pederasty, or in a woman from a flow of infectious material from the genitalia to the anus. It causes severe burning pain, aggravated by defecation. The parts are red, swollen, and tender. The discharge is profuse, being at first cream white, and then thicker and greenish. The diagnosis rests upon the history and the finding of gonococci in the discharge. The disease rarely extends above the anus.

Treatment.—If the anus only is involved, spray several times daily with peroxid of hydrogen, wash with salt solution, irrigate with permanganate of potash (1 : 4000), dust with talc powder, and interpose a piece of iodoform gauze between the inflamed surfaces. An ulcer, a fissure, or an excoriation is touched with lunar caustic. If the rectum becomes involved, secure a daily bowel movement and irrigate the rectum twice a day with boric-acid solution or permanganate of potash (1 : 4000).

Gonorrhea of the Mouth.—This is a very uncommon malady. It occurs in infants more often than in older people. Infection in infants may take place during birth if the mother has gonorrhea. The symptoms are those of violent stomatitis. The diagnosis is suggested by the condition of the mother and is proved by finding gonococci in the discharges from the mouth.

Treatment.—Wash the mouth frequently with boric acid and listerine (gr. xlvij to ℥viii), and swab the diseased areas at intervals with a 10 per cent. solution of argyrol.

Gonorrhea of the Nose.—It is alleged that this condition can arise, but an absolutely authentic case does not seem to be on record.

Gonorrhea in the Female.—There is much dispute as to the parts infected. Some observers maintain that the vaginal epithelium never contains gonococci and that gonococci found in a vaginal discharge have come from the cervix or uterine canal. Beyond a doubt, however, when young women who have not borne children contract gonorrhea the vulva and vagina usually suffer. In older women and in women who have borne children the vaginal tissues are altered and the cells are not nearly so prone to infection; hence in such subjects the vagina often or usually escapes. The initial infection is in many cases in the cervical canal, in some in the vulva or urethra. No matter what part was first attacked, other parts usually become quickly involved in the acute process. The urethra is involved in almost every case. Chronic gonorrhea is prone to linger in the urethra, in the glands of Bartholin, in the cervical canal, or within the uterus or in the Fallopian tubes. The great danger of gonorrhea in the female is in the development of ascending infection of the lining membrane of the uterus, which may reach the tubes, ovaries, and peritoneum.

When infection occurs during pregnancy or when pregnancy occurs during infection of the cervical or uterine canal, abortion may take place. Again, a pregnant woman may not abort but may go on to term and the child may receive a conjunctival infection during delivery and rapidly develop purulent ophthalmia.

In some cases when pregnancy occurs during the existence of gonorrhea, the disease seems to pass away and yet the child gets conjunctival infection during delivery or the mother subsequently develops pus tubes.

Treatment.—Place the patient in bed *at* ease, give hot hip-baths, keep the bowels *of* tives, insist on a fluid diet consisting chiefly *thra* by having the patient drink considerable external genital organs should be sprayed *a* two or three hours, and after spraying should and dusted with equal parts of starch and powdered stearate of zinc. Pads of cotton *f* used to catch the discharge. If urethritis *e* alkalis, balsams, and astringent urethral *inj*

When the acute symptoms have somewhat made to prevent ascending infection from the membrane of the canal may be cureted with bolic acid or nitrate of silver. A wiser plan daily with iodine or a 10 per cent. solution of portion of the cervix at the same time with irrigated twice a day with a warm solution (1 : 4000) and is lightly packed with iodoform particularly involved, treat that part by applying locally or paint the vulva with silver solution vaginal gland suppurates, open it.

If vaginitis exists and continues in spite of wash out the vagina every two hours, first bicarbonate of sodium, next with *Oj* of hot astringent solution (a teaspoonful of lead sulphate, a teaspoonful of alum, or four teaspoonfuls of boroglycerid in a pint of hot water) (White). As the attack subsides, containing gr. v of tannic acid. In some cases nitrate (1 : 200) or of argyrol (10 per cent.), (8 per cent.) moistened with boroglycerid (Le

In chronic cases of urethritis use strong irrigate the urethra and bladder with silver

For *uterine gonorrhea* observe the same wash out the uterus with tincture of iodine or nitrate of iodoform gauze.

Gonorrhea in Children.—Male Children common. When it affects children under ten abandoned and diseased female having had contact with her sexual organs. It may result from germs introduced into the penis. The symptoms are similar to those met with in an adult. The finding of the gonococcus is the legal proof of the existence of gonorrhea. It is to be remembered that boys may suffer from catarrhal urethritis, from balanoposthitis, or from overacidity of the urine, by the growth of the suspected micro-organisms.

The *treatment* consists of confinement to bed, bland drinks, light diet, etc. Circumcision is necessary in some cases. When the acute symptoms subside, injections are used as

Female Children.—Gonorrhea is more common in female children than in male children, and the vagina is involved as well as the vulva and urethra.

A female child may suffer from catarrhal inflammation of the vulva, as a result of the contact of foul urine, of feces, of the presence of seatworms, or of neglect of bathing. In such a case the vagina and urethra escape. Involvement of the vagina and urethra strongly suggests gonorrhea. A recently born child or a young infant may acquire gonorrhea directly from a diseased mother, or indirectly, by pus upon linen, the mother's fingers, etc. A diseased nurse may infect the baby. Older children who have ceased to nurse may get the disease from infected linen, bathtubs, etc., and may by these means infect child after child in an institution. Now and then the disease arises by a diseased man or woman deliberately bringing the child's private parts in contact with their own diseased organ.

The disease is acute: the urethra, vulva, and vagina are usually involved; the discharge is profuse, purulent, and often bloody. During the first day or two the discharge exhibits leukocytes but no gonococci, and the normal flora of the urethra disappear; later gonococci appear (Harmsen, "Zeits. f. Hyg. u. Infektionskr.," 1906, vol. iii). Microscopic examination of the discharge is absolutely necessary. Dry cover-slip preparations are made so as to obtain clasp shreds from the discharge. An attempt should be made to obtain cultures. The gonococcus is very difficult to maintain in culture; it must be frequently transferred, and it grows best in an incubator at a temperature of 36° C. No attempt is made to grow it upon ordinary culture-media. The finger may be sterilized and punctured, blood thus obtained being smeared upon ordinary agar. Upon this composite material growth can be obtained. Animal blood serum is not a good medium, but human blood serum is (Lehmann and Neumann). Human blood serum is obtained by opening a vein or from a fresh placenta.

Lehmann and Neumann ("Atlas and Principles of Bacteriology") find the following a satisfactory medium: Agar, containing 1 per cent. peptone and 5 per cent. glycerin, which has been liquefied and cooled to 50° C., is mixed "with one-half its volume of ascites fluid or the fluid from ovarian cysts." Plate cultures and streak cultures should be made. This excessive care in proving the presence of the gonococcus is imperatively necessary in female children because of the medico-legal questions which may arise in such a case and also because of the danger of infecting others.

Surgeons are apt to be doubtful about the diagnosis in many supposed cases of gonorrhea in female children. The clinical picture may simply be that of catarrhal vulvo-vaginitis, it may be that of gonorrhea. The finding of the gonococcus is regarded as conclusive from a clinical standpoint, but not from the legal point of view. Again, as Taylor points out, in some cases in which the clinical and microscopic evidence seems to prove the existence of gonorrhea no proof can be obtained that the condition is of venereal origin, and that in some cases in which everything indicates that the disease began as a catarrhal vulvo-vaginitis, a condition seemingly identical with gonorrhea has arisen. Obtaining a culture of gonococci is conclusive. The treatment consists in taking every care to prevent diffusion of the infection to others and

to the patient's own eyes. She is put to bed, upon milk, etc. Irrigations of bicarbonate of soda by protargol (1:5000, according to White) and injections are indicated.

Treatment of Gonorrheal Arthritis and End in the Journal A. M. A., Jan. 27, 1906, page 100. Torrey described the method of preparation of the treatment of gonorrheal arthritis. This serum, manufactured by a good chemical company, seems to be a valuable treatment of gonorrheal infections of joints, bursae, etc. Dr. Thomas W. Stellwagen, of the Jefferson Hospital, has used the material in a series of cases of gonorrheal arthritis with gratifying results.

Preparation of the Serum. To quote from the report: "Rabbits were at first used exclusively in the preparation of the serum. A very potent serum may be obtained from rabbits, but the serum itself is decidedly toxic for some of the animals, producing a rather alarming reaction. This matter will be discussed in detail. In order to obviate this serious objection, goats and sheep. Similar objectionable properties were found to be present in goat serum, but were entirely absent. Accordingly in later work sheep were used. They should be full grown, uncastrated animals. In the preparation of the serum it has been found advantageous to use a first inoculation may consist of the twenty-eight square inches of solid culture medium, emulsified in a sterile saline solution, and heated for one-half hour at 60°C.

In Stellwagen's studies and use of the serum, the results were obtained by giving the injections as often as possible and, further, to give them every day. The animals which had not noticed were now and then an eruption of white spots, slight headache and itching, with a trivial rise in temperature. In all cases generally showed marked improvement. The serum also seemed to be of use in other conditions, such as prostatitis, and epididymitis. Stellwagen maintains that the serum is a valuable adjunct in treatment, especially where the physician is unable to produce a result. Its great claim to popularity in the treatment of gonorrheal arthritis and other synovial infections, is well founded and valuable.

The serum must not be confused with the serum of the horse. In the clinic of the Jefferson Hospital, where it has been used, they did not produce the happy results which have been ascribed to them.

Stricture of the urethra, or narrowing of the urethra, is divided into inflammatory, spasmodic, and congenital. Inflammatory or congestive stricture is not a stricture of the urethra, but an inflammation of the mucous membrane.

Spasmodic stricture does not exist alone, but is usually associated with a hyperesthetic urethra, or an inflamed bladder.

Organic stricture is a fibrous narrowing of the urethra, due, as a rule, to chronic gonorrheal inflammation or to traumatism. True organic stricture is very rare in children, but can occur. Abbe reported a case of impassable stricture in the deep urethra of a male child two and one-half years of age, due to urethral gonorrhea. There were also two strictures of the anterior urethra. External urethrotomy was performed. Traumatic strictures occur in the bulbous or membranous urethra, and are due generally to force applied to the perineum, the urethra being squeezed between the subpubic ligament and the vulnerating body. Strictures resulting from gonorrheal inflammation occur in the penile, bulbous, or membranous urethra. Stricture never forms in the prostatic urethra except as a result of traumatism. Recent non-traumatic strictures are soft and are easily distended. Old strictures and traumatic strictures are very dense. A resilient stricture is one which contracts quickly after dilatation. The nearer a stricture is to the meatus, the more fibrous it is.

A *congenital* stricture is congenital narrowness of a portion of the urethra, usually the portion near the meatus. The more fibrous a stricture is, the more it narrows the urethra and the less dilatable it is. A stricture may be annular (forming a ring around the urethra), tubular (surrounding the urethra for a considerable distance), or bridle (when a band crosses the urethra from wall to wall). A stricture of large caliber will admit an instrument larger than a No. 15 French sound. A stricture of small caliber will not admit a No. 15 French sound. An impermeable stricture will not admit the passage of any instrument. Impermeable is more or less a relative term. A stricture may be impermeable when an anesthetic is not used, and permeable when the patient is anesthetized, or may be impermeable to one surgeon, but permeable to another. Impermeability is often a temporary condition due to inflammatory edema about an organic stricture.

Symptoms and Results of Stricture. There is usually a history of repeated attacks of urethritis. A chronic discharge may exist, the amount of which is variable. There is a feeling of weight in the perineum, soreness of the back, and frequency of micturition. Hypochondriacal tendencies are usual. In a deep stricture there is difficulty in starting the stream in micturition. In most cases the stream is small, twisted, and forked. There is often interruption or "stammering" of the stream, and it dribbles long after the conclusion of the act, so that the penis must be "milked" before it is returned within the clothing. The urethra back of the stricture dilates, a pouch forms, drops of urine collect and decompose, and a chronic inflammation results in the mucous membrane or the parts adjacent, which inflammation may go on to ulceration or to peri-urethral abscess. A urinary fistula results from the opening externally of a peri-urethral abscess. Retention of urine may occur, not from actual obliteration of the tube by the growth of the stricture, but by closure of the lumen of the urethra by muscular spasm and by edematous swelling in the neighborhood of the stricture. Edematous swelling may be due to cold, wet, venereal excitement, the use of alcohol, overexertion, etc. Spasm of the muscles results, and contact of the urine increases the spasm, and spasm plus edema of the mucous membrane closes the urethra. Spasm may exist in the urethra itself and in the muscles of the

neck of the bladder, but is only a temporary. The bladder is hypertrophied and often fastidiously. The diagnosis of stricture and of cystitis. The diagnosis of stricture and of cystitis.

of exploratory bougies.

follows to a great extent which is as follows: * H

two glasses. Examine the ur

in the first glass shows that urethral charge exists. Cloudiness in the second points to cystitis. The patient is placed recumbent with his shoulders elevated, urethra is washed out with warm salt or boracic acid. Bulbous sounds are begun with No. 15 French. If this with ease, take a larger size and note strictures are situated by the catch and drawal. If No. 15 does not pass, try a smaller size. Remember that the posterior layer of the triangular ligament catches the bulbous instrument on withdrawal. If the meatus is too small to permit of exploration, divide it with a curved bistoury, cutting within outward. After cutting the bleeding is arrested with styptic cotton. A piece of absorbent cotton is tucked into the cut. After each act of micturition the patient inserts a fresh bit of cotton, and at three days the urethral examination is succeeded with.

Treatment. A stricture of large size in the deep urethra requires gradual dilatation. A steel bougie is introduced every fifth day, the size being gradually increased. Never anoint a bougie with cosmoline. It may become a nucleus for a stone in the bladder; use oil, glycerin, synol or lubrichondrin. Before passing an instrument the patient urinates and his urethra is washed out with salt solution or acid solution. Glans, meatus, and urethra are cleansed as directed on page 1338. The sound is rendered sterile by boiling before using. Gradual dilatation can be effected by the use of the dilator or sizer, the tube being distended to the extent of 4 millimeters every fifth day. If after dilatation there is urethral spasm, pain, or very frequent micturition for a number of days and order each night a

Fig 1009
—Syme's
staff

* Med Record, Nov. 14

goric. In effecting gradual dilatation by sounds the instrument should be introduced every fifth day. During the treatment the patient should not use alcohol,

should refrain from sexual excitement, should avoid cold and damp, and should take internally capsules containing boric acid and salol. It is rarely necessary to dilate above No. 32 French. After the surgeon finishes treatment he teaches the patient to use an instrument and directs him to pass it once a month. Strictures in the pendulous urethra, if soft, are treated by gradual dilatation; if fibrous and contractile, by internal urethrotomy. In performing internal urethrotomy prepare the patient carefully; for several days before the operation give salol and boric acid by the mouth, and wash out the bladder repeatedly with boric-acid solution. Be thoroughly aseptic. Anesthetize the patient. Before cutting irrigate the urethra with warm normal salt solution, and after cutting irrigate again and tie in a rubber catheter. These precautions will prevent urethral fever. In cutting, insert Gross's urethrotome (Fig 812) back of the stricture, spring out the blade, cut the stricture on the roof of the urethra, close the blade, withdraw the instrument, and pass a full sized bougie.

Stricture of the meatus requires incision with a knife and the use of a meatus bougie until healing is complete. Strictures of small caliber in front of the membranous urethra require gradual dilatation and, if this fails, internal urethrotomy or division. Internal urethrotomy can be performed with the urethrotome of Maisonneuve (Fig 810). This instrument is shaped like a sound, has a groove upon its surface, and into this groove a shaft carrying a triangular knife

Fig. 811 —Gross's urethral dilator

can be inserted. The staff is screwed to a guide, the guide is carried into the bladder and the staff follows it. The point of the staff is carried to the prostatic urethra and the guide curls up in the bladder. The penis is held upon the stretch the blade is inserted and pushed down through the stricture. This instrument cuts the stricture, but not the healthy urethra. For *division* the patient is prepared as for internal urethrotomy. The divulsor of Gross, or of Sir Henry Thompson, or of Gouley (Figs. 811, 813, 814) is introduced, the blades are separated, the instrument is withdrawn, a large bougie is passed, and a catheter is tied in the bladder. Strictures of small caliber in the deep urethra require gradual dilatation; if this fails, employ external urethrotomy. In strictures of the deep urethra, if only a filiform bougie can be in-

Fig. 812 —
S. W. Gross's
exsperatory
urethrotome

roduced, the bougie may be left in place, and can be slipped in beside it, until in a few days it is permeable to a metal bougie. A tunnelled dilator, the filiform bougie, both be withdrawn, and a tunnelled and grooved staff can be carried in, and urethrotomy be performed. Thompson's dilator is filiform and the stricture be divulsed. Fort's dilator is to be of value, but I have had no personal ex-

Fig. 813—Thompson's divulsor.

pole of a galvanic battery and the positive pole. The guide carrying the blade is inserted, and the blade comes against the stricture the current is turned off and the instrument is carried onward until the blade is beyond the stricture, when the current is again turned on, and at a strength of 10 to 15 ma. The operation requires but little pain. After its performance

Fig. 814—Couley's divider.

of the French scale). The patient need not be operated on. By Fort's method we act purely on the impassable stricture of the deep urethra performed without a guide (the operation of Wheelhouse).

If a perineal fistula exists, dilate, divulse, and insert a catheter in the bladder for forty eight hours. Every few days with a metal instrument. Every morning drink urine with a soft catheter, introduce boric acid, remove the catheter, and let the man empty his bladder. Urine will flow from the fistula and a part from the urethra. The quantity which comes from the fistula lessens, and the fistula heals.

Urethral Fever.—Any operation upon the urethra, by a chill owing to shock (urethral shock), or a nervous fever. Urethral fever proper is a nervous operation. This condition is due to absorption of the

may be in the urine, may have been in the urethra, or may have been introduced from without. It usually follows the first urinary act after operation. It begins with a violent chill and presents the characteristics of a septic fever. It is accompanied by a marked tendency to urinary suppression, and may eventuate in septicemia or pyemia. Urethral fever can be prevented by rigid antisepsis. If this fever should arise, a catheter must be tied in the bladder, the bladder and urethra must be repeatedly irrigated with aseptic or antiseptic fluids, and the patient must be given urinary antiseptics and stimulants by the mouth.

Urinary Fever. Sir Benjamin Brodie pointed out that the withdrawal of residual urine in a case of enlarged prostate may be followed by very serious symptoms. The condition is spoken of as urinary fever, and is said by many to be due to the sudden and complete emptying of a bladder which has become accustomed to retaining permanently a considerable quantity of urine. Modern studies prove that urinary fever is due to infection of the bladder and kidneys, and not simply to the sudden withdrawal of all of the urine from the bladder, although such a procedure leads to vesical congestion and probably favors infection. The bacteria most often found are pyogenic cocci, colon bacilli, and micro-organisms which cause putrefaction and decomposition of urea.

The condition does not arise promptly, suddenly, and violently, as does urethral fever, but begins rather insidiously after several days. Mr. C. Mansell Moullin thus describes the condition: *

"So far as the broader features are concerned, the symptoms that present themselves in these cases are remarkably uniform. They do not begin at once. Nearly always some few days elapse before there is anything to excite suspicion. Then the urine becomes cloudy, though it may still retain its acid reaction. A small quantity of albumin, more than can be accounted for by the amount of pus that is present, makes its appearance. Under the microscope there are a few hyaline casts, perhaps a blood corpuscle or two, numerous pus-corpuscles, and myriads of bacteria. The specific gravity is lower than it ought to be, and is lower than it was before the catheter was used. The total amount passed in the twenty-four hours may either increase until it is as much as seven or eight pints, or diminish until it scarcely reaches twenty ounces. There is seldom any definite rigor, but there may be numerous slight chills. The pulse grows more rapid and feeble. The tongue becomes red and dry. There is complete anorexia. Delirium sets in at night, and in a considerable proportion of cases the symptoms rapidly grow worse and worse until, at the end of a few days, the patient sinks into a semi-comatose condition from which he seldom rallies. Post-mortem there are all the signs of recent acute cystitis and pyelonephritis. The mucous membrane lining the pelvis and calices of the kidneys, the ureters, and the bladder is swollen and stained by old and recent hemorrhages, and here and there a thin layer of pus is adherent to it. The pelvis and the ureters are dilated, the apices of the pyramids are eaten away, the cortex is shrunken and hard, the capsule is adherent, and in places between the tubules are minute collections of pus differing in shape and outline according to the anatomical arrangement."

* *Lancet*, Sept. 10, 1898.

Treatment.—Aseptic catheterization is urinary fever; and as the urethra contains the prepuce, glans, and meatus should be irrigated with boric acid or permanganate urethra be irrigated with boric-acid solution before the sterile catheter is introduced to drain.

If urinary fever arises, it may be possible gating the bladder with warm normal salt silver (1 : 8000), or boric acid solution, and diuretics, diaphoretics, saline cathartics, and perform suprapubic cystotomy for drainage.

Wheelhouse's Operation.—This operation of impermeable stricture. Wheelhouse's until it blocks on the stricture. The perineum and in front of the stricture. The edges of with forceps, the surgeon seeks for the opening a line probe through it, divides the stricture, and wound an instrument known as a probe to furnish a solid floor to facilitate the introduction in place a metal catheter is carried from the forger is removed and the catheter is tied in place catheter is removed and is then passed frequently.

of course, dressed antiseptically. Figs. 815 and 816 show the instruments for Wheelhouse's operation.

Cock's Operation. This operation opens the urethra back of the stricture and without a guide and relieves retention of urine. The surgeon introduces into the rectum the index-finger of the left hand, and the tip of the finger is rested upon the apex of the prostate gland. The surgeon incises the median line of the perineum, the back of the knife being toward the anus. When the point of the knife is felt to be near the finger the handle is lowered slightly, the blade is placed a little oblique, and the urethra is opened. A catheter is passed into the bladder from the wound and retained for a time, and the stricture is subsequently treated.

Epispadias is a congenital cleft in the corpora cavernosa, the roof of

Fig. 817. Beck's operation for hypospadias.

the urethra being completely or partly absent. In complete epispadias there are absence of the pubic arch and exstrophy of the bladder.

Partial epispadias may sometimes be remedied by a plastic operation.

Hypospadias is a congenital cleft on the floor of the urethra, the meatus opening on the floor at some point between the scrotum and the end of the glans penis, the channel in front of the meatus being a gutter and not a tube.

Hypospadias of the glans is the most common form. In this condition the urethra has no floor, as it passes beneath the glans, the site of the urethra is indicated by a groove, and the foreskin is absent below. Partial hypospadias requires no treatment except possibly dilatation or incision of the meatus. People who suffer from it are very prone to develop chronic urethral inflammation. In hypospadias of the penis the ill developed cord like corpus spongiosum draws the penis to the scrotum. In this variety of the deformity the penis is very short.

In complete hypospadias the opening of the urethra is back of the scrotum in the perineum, the penis is dwarfed and bound down, and looks not unlike a clitoris, the scrotum is divided into two portions, a gap existing between them, and in many cases the testicles have not descended. Such individuals are occasionally mistaken for females. In the penile complete forms of hypospadias a plastic operation should be performed between the eighth and tenth years of age. Such an operation unfortunately may fail. Hypospadias is rare in women, but it may occur. In such a case the urethra opens in the vagina. Fig. 817 shows the ingenious operation successfully practiced by Carl Beck for penile hypospadias.

Chancroid (soft chancre; the local venereal sore) is an ulcer, usually of venereal origin. The name chancroid was introduced by Clerc, who believed that a soft sore resulted from inoculating a person already syphilitic with the products of a hard sore. He further held that when a soft sore arose the syphilitic poison lost its infective properties, and "could be transmitted as a soft sore to a healthy person, and not cause general infection".* The chancroidal ulcer is not connected with the syphilitic poison, but is developed by inoculation with the bacterium of Ducrey. Until recently it was believed that a chancroid was not produced by a special poison, but arose after inoculation with inflammatory products or irritating secretions. It seems to have been proved, however, by Krefling and Colombini that the organism discovered by Ducrey in 1880 is the real cause. This organism is grown on a medium of fresh blood and bouillon or in "unmixed human blood" (See Lincoln Davis, "Observations on the Distribution and Culture of the Chancroid Bacillus." Report of Research Work, 1902-1903, the Division of Surgery of the Medical School of Harvard University.) As a rule, chancroids are of venereal origin, and result from contact with other chancroids, pus, mucopus, or areas of ulceration. A chancroid appears soon after intercourse, usually within five days, always within ten days. It is first manifested by a pustule which ruptures and discloses an ulcer. The ulcer has sharply defined and undermined margins, it looks "punched out"; the base is gray and sloughy, the discharge is profuse, purulent, foul, and auto-inoculable, and causes fresh chancroids by flowing over the parts. The area around a chancroid is red and inflamed, and considerable pain is apt to be complained of. The original chancroid spreads and new sores appear. The edge of a chancroid is rarely indurated unless caustics have been used or there is mixed infection with syphilis. Inflammatory induration passes gradually into the tissues, but the induration of a hard chancre is sharply defined. Fournier says that a chancroid may have a hard base if the sore is located in the sulcus back of the glans, on a lip of the meatus, or on the lower border of the prepuce of a man with phimosis, or when the ulcer is indurated. The surgeon should always ask if the sore has been cauterized and how it has been treated. When a chancroid after a time displays marked and sharply outlined induration it points to mixed infection of chancroid and syphilis. Chancroids are not followed by constitutional symptoms but are apt to be accompanied by painful inflammatory buboes which are prone to suppurate. In hospital practice about 20 per cent of patients develop buboes. The bubo may be one-sided or bilateral. The adenitis of chancroid

* "Syphilis," by Alfred Cooper.

is due in the majority of cases to the absorption of toxins and pus may be free from bacteria. Cases have been reported in which non-indurated sores were followed by syphilis. It is probable that a mixed infection existed, and that induration was overlooked, because a papular initial lesion was underneath the chancroidal ulcer. When inflammation in chancroids is high, a rapidly destructive ulceration known as *phagedena* may arise (Figs. 818 and 819), but this process is more common in syphilitic sores.

Treatment.—Ordinary cases of chancroid are treated by spraying with peroxid of hydrogen, drying with cotton, touching each sore first with pure carbolic acid and then with pure nitric acid, and dressing with black wash or dusting with iodoform or with calomel. Every few hours the patient soaks the penis in hot salt water (a teaspoonful of salt to a pint of water), sprays the sores with peroxid of hydrogen, dries with cotton, and dresses with black wash or dusts with iodoform or with calomel. As soon as granulation begins the sores should be dressed with 1 part of ointment of nitrate of mer-

Fig. 818.—Buttonhole perforation of the prepuce following phagedenic chancroid (Horwitz).

Fig. 819.—Buttonhole perforation of the prepuce following phagedenic chancroid (Horwitz).

cury to 7 parts of cosmolin. Mild cases do well without cauterizing, peroxid of hydrogen being frequently used and a drying powder being employed. In chancroids with phimosis slit up the foreskin, smear the raw edges of the wound with pure carbolic acid, and treat the ulcers by cauterization. A regular circumcision often fails because of infection of the stitch-holes. Phagedena requires the internal use of iron, quinin, and milk-punch, and the local use of powerful caustics (bromin or nitric acid or even the actual cautery). In some cases continuous antiseptic irrigation is valuable. When a bubo first begins, order rest, apply iodine or an ointment of belladonna or ichthyol, and make pressure by a spica bandage of the groin. Some surgeons advise the injection of 20-40 minims of a solution of carbolic acid (gr. x to the ounce), but I have never seen any benefit from it. Some inject a 1 per cent. solution of bichlorid of mercury, but the proceeding causes intense pain. Welander recommends the injection of a 1 per cent. solution of benzoate of mercury. I have had no experience with this method. If the

bubo persists, even though it does not suppurate, it should be excised. If pus forms, several methods of treatment are available: irrigation, injection with a solution of carbolic acid, or the application of an ointment of iodoform. After the opening with collodion (Scott Helms). Hayden, after removing the pus, washes out the cavity with peroxide of hydrogen, and then with corrosive sublimate solution. He then applies a warm iodoform ointment, and dresses with clean gauze. Fontain, Perry, and others commend this plan. Sometimes it succeeds. If the above plan fails, if it is not used, or if an ulcer or sinus forms, the glans is incised, curet, cauterized with pure carbolic acid, the hopelessly infiltrated skin, and pack the wound with iodoform gauze. In some cases it will be necessary to remove the gland.

Phimosis is a condition of the prepuce that makes the retraction of the glans impossible. It is usually congenital, but may be acquired. Congenital phimosis causes retention of smegma, which composes and lights up inflammation and thickens the skin of the glans. Congenital phimosis may induce retention of urine, prolapse of the rectum, and stricture of the urethra. The treatment is *circumcision*. Asepticize the

Fig. 821.—Cancer of penis (Horwitz)

glans occasionally during coition. The treatment consists of cauterization, arrest of bleeding, and occasionally incisions to relieve the pain.

Gangrene of the penis arises from phagedenic infection, from tight bands around the organ, from fracture with exposure of the organ, or from paraphimosis. If extensive, it requires amputation.

Cancer of the penis (Fig. 821) is common. It is usually a limited epithelioma of the foreskin, circumscribed, and

glands of the groin are removed; if cancer affects the glands, amputation of the penis and removal of the inguinal glands must be done.

Amputation of the Penis.—Ricord advised cutting off the organ with a single stroke of the knife, making four slits in the mucous membrane of the urethra, and stitching each of these flaps to the skin. Treves splits the skin of the scrotum along the raphé, separates the halves of the scrotum down to the corpus spongiosum, passes a metal catheter down to the triangular ligament, inserts a knife between the corpus spongiosum and the corpora cavernosa, withdraws the catheter, cuts the urethra across, detaches the urethra from the penis back to the triangular ligament, cuts around the root of the penis, divides the suspensory ligament, detaches each crus from the pubes, slits up the corpus spongiosum half an inch, stitches its edges to the rear end of the scrotal incision, introduces a drainage-tube, ligates the vessels, and sutures the wound.

Seminal Vesiculitis.—Inflammation of the seminal vesicles is due to the extension of a gonorrheal inflammation, to a pyogenic process, or to tuberculosis.

Acute inflammation is made evident by frequent and painful micturition, pains in the anus, rectum, and perineum, and possibly the hip-joint, back, and thigh. Defecation and micturition are excessively painful. Persistent erections may take place, and in some cases bloody ejaculations occur. Rectal examination detects the enlarged and tender vesicles external to the lateral lobes of the prostate and on a higher level.

Treatment.—Abandon local urethral treatment, and treat the patient as for acute prostatitis.

Chronic vesiculitis may result from the acute form or may develop insidiously in an individual with gonorrhea. It is one of the causes of chronic urethral discharge. The patient suffers from imperative and frequent demands to micturate, and he has a gleet discharge which becomes worse and better, but does not disappear. This chronic inflammation is believed to persist because of narrowing of the duct and consequent incomplete drainage of the vesicle. In chronic seminal vesiculitis there is usually sexual weakness, nocturnal emissions occur, and the semen may contain blood.

Treatment.—Treat the posterior urethritis by ordinary methods. Use hot rectal enemata. Milk the ducts by Fuller's method once every seven days. During massage the patient's bladder should be full. He leans over a chair-back, the knees being straight and the body at a right angle to the thighs. The surgeon covers his finger with a rubber stall and anoints it with oil or synol soap, and introduces it into the rectum, and makes pressure over the pubes with the fist of the other hand. The finger comes in contact with the lower half of the vesicle; it makes firm pressure for a moment, and is then drawn slowly toward the duct. This stroking is repeated several times. The other vesicle is treated in the same manner. This maneuver empties the vesicle and hastens the resolution of inflammation. After the completion of the stripping the patient should micturate, and the bladder and urethra should be irrigated.

Tuberculosis of the Seminal Vesicles.—Primary tuberculosis is very unusual. As a rule, there is antecedent tuberculosis of the testicle or prostate gland. About 50 per cent. of the cases occur in individuals under

forty years of age. The diseased vesicle is but later undergoes caseation and softens through the capsule and invades adjacent cases and found that in 34 of them the lungs.

Tuberculous vesiculitis may be unilateral tuberculous epididymitis the corresponding. In bilateral disease of the testicles both vesicles. Peritoneal tuberculosis may follow tuberculous cases spontaneous cure is obtained by fibrosis a tuberculous vesicle is found to contain slightly tender nodules.

Treatment.—If tuberculous epididymitis and vesiculitis, it is justifiable to remove the testicle, provided the prostate and other parts are free from disease and there is no distant metastasis. If testicles are removed, both vesicles can be removed. If vesicles suffer from primary tuberculosis, of course. Reported cases, however, do not seem to confirm this.

Kraske, Schede, and Rydygier have removed the vesicles by resection of the sacrum. Zuckerkandl, Dilke, and the perineal route. Villeneuve reached them by the rectal route. The curved perineal incision of Zuckerkandl is the best. H. H. Young makes a suprapubic incision, removes the bladder, and reaches the vesicles from behind by the retrocystic-extraperitoneal method (II. H. J. Nov., 1901).

Acute Prostatitis.—Acute inflammation of the prostate may be caused by inflammation in adjacent structures, by irritant applications in the deep urethra, by calculi, by calculus, various infectious diseases, a stricture, or by gonorrhea. The gland enlarges greatly, and is filled with blood and pus, and the gland-ducts may form distinct abscesses. The orifices of the ducts are distended and filled with pus, and the seminal vesicles also suffer. An abscess is liable to form in the prostate.

Symptoms.—A feeling of weight, fulness, and persistent pain at the neck of the bladder; tenderness; present and becoming most severe as the inflammation progresses; painful defecation; and bulging of the rectum. If a finger is introduced into the rectum, it can feel the enlarged and tender gland, unless the outline of the rectum in which case there will be felt a large, firm mass. Morris on "Injuries and Diseases of the Prostate." These symptoms are accompanied by difficulty of urination. The inflammation may abate without suppuration. If the temperature becomes characteristic, the pain becomes agony, the inflammatory mass is felt per rectum, and sometimes the swollen perineum becomes dusky and

certain to occur. The abscess may rupture into the urethra or the rectum, or may diffuse in the periprostatic cellular tissue and subsequently may open in the perineum. Spontaneous evacuation may be followed by recovery or by the development of annoying or dangerous complications.

Treatment.—Keep a hot-water bag on the perineum and three or four times a day use rectal injections of hot water. Place the patient on a milk-diet. Leech the perineum. Give suppositories of opium and belladonna, and also suppositories of ichthyol, and administer urotropin by the mouth. At the first sign of suppuration make a curved perineal incision. Retention of urine is relieved by a soft catheter.

Chronic Prostatitis.—May arise from stricture, venereal excess, chronic cystitis, or stone in the bladder, but gonorrhea is the common cause. The prostate is usually, but not always, enlarged, is somewhat softened, and the ducts contain pus and blood.

Symptoms.—There is usually a mucopurulent discharge or fluid can be obtained by massage of the prostate. There is a feeling of weight and fulness in the perineum, there is increased frequency of micturition, and the prostate is very sensitive to digital pressure. The patients are neurotic, frequently suffer from nocturnal emissions, and have but feeble power of erection. The prostatic urethra is extremely hyperesthetic. All the symptoms are aggravated by worry, sexual excitement, or violent exercise. An abscess may form and rupture into the urethra.

Treatment.—Tonics and nutritious food are essential. Intravesical irrigations with nitrate of silver solution (1:8000) do good. Massage of the prostate is useful. Some cases are benefited by touching the posterior urethra through a urethroscope tube with nitrate of silver (3 grains to the ounce) or by injecting by means of Ultzman's syringe a few drops of silver nitrate solution (5 grains to the ounce). Rectal suppositories of ichthyol may be ordered. Blistering the perineum at intervals may prove of service. At intervals of three or four days a full-sized cold steel sound should be gently introduced. If an abscess forms, open it through the perineum.

Prostatorrhea.—Just as overaction of the glands of the urethra constitutes urethrorrhea, so overaction of the glandular apparatus of the prostate gland constitutes prostatorrhea. Prostatorrhea is not inflammatory, although the prostate and posterior urethra are often congested, and the latter region is usually hyperesthetic. In some cases urethrorrhea exists with prostatorrhea. Prostatorrhea is produced by sexual excess, masturbation, ungratified sexual desire, and riding a bicycle with an improper seat. The condition is usually accompanied by marked neurasthenia, and may be associated with spermatorrhea and impotence.

The patient notices a milky or gray discharge after straining at stool (*defecation-spermatorrhea*), after violent exercise, sexual excitement, or a bicycle ride. The discharge also gathers in the urethra during sleep. Examination of the discharge shows it to be prostatic fluid, although spermatozooids are sometimes found. It is not purulent and contains amyloid corpuscles. The meatus is not glued up in the morning, and the linen is very slightly stained. The urine is clear and contains small comma-shaped hooks (Christian). Sexual excitement and alcohol do not appreciably aggravate the condition. The bladder is irritable, and there are frequency of micturition and

often some pain in the head of the penis at the nocturnal emissions may occur.

Treatment. The patient should correct his hyperesthesia or prostatic congestion, irrigate the day with a solution of silver nitrate (1 : 4000), introduce a cold sound. In some cases the irrigation of the prostatic urethra of a few drops of a 1 per cent. solution does good.

For the irritable bladder give hot hip-bath. A prescription is of service: gr. xv of bromid of potassium of hyoscyamus in $\frac{1}{2}$ ounce of cinnamon-water, three times a day are of service.

After the hyperesthesia of the urethra has ceased, the neurasthenia is treated by cold water and morning, the continued use, at intervals of a cold sound, irrigation every second or third day and the administration of strychnin and other.

Hypertrophy of the Prostate Gland. Morgagni that in old men difficulty of micturition is due to an enlarged prostate gland. Enlargement of the prostate is brought about by different forms of growth, senile change, occurring only after the age of sixty years.

It is not until after the attainment of sixty years of age that the prostate to cause symptoms long before the age of seventy. Sir Henry Thompson in his experience men over sixty have prostatic hypertrophy, but not the troublesome symptoms. According to Frey, men of fifty-five years of age present some enlargement of the prostate.

There are some that oppose the view that it is essentially a senile change. For instance, Dr. L. J. Hay (Am. J. Anatol. and Gen.-urin. Dis., March, 1901) says that it is not senile; that it really begins early in life, but is not manifest until during or after middle age. It begins during the third decade of life, but does not cause symptoms till beyond middle life. Socin and his associates, in postmortem examinations, reached the following conclusions: at the ages of thirty-six and forty the gland is hypertrophied between forty and fifty in 25 per cent., between fifty and sixty in 36 per cent., between sixty and seventy in 56 per cent., between seventy and eighty in 50 per cent., between eighty and ninety in 56 per cent. Enlargement begins long before it occasions symptoms, and the growth progresses very slowly. Some school maintain that hypertrophy of the prostate is due to arteriosclerosis, affecting not only the prostatic artery but the whole tract. The hypertrophy that ensues affects the whole tract as well as the prostate, because of distinct gross anatomical demonstration that Guyon's view is not correct. In many cases there is no sclerosis of the prostatic artery, and there are no sclerotic changes in other portions of

important point made by Caspar is that arteriosclerosis tends to cause degeneration, and not hypertrophy.

Some think that sexual excess is a cause of prostatic enlargement; some assert that antecedent gonorrhea is the cause, but it seems very improbable that either is causal. Belfield blames altered testicular secretion. Hawley believes the cause to be altered prostatic secretion and the "chemical action of pathologic proteids resulting from irregular metabolism or derived from disintegration of the secretion, or in the usual action of tissue enzymes" (G. W. Hawley, in "Annals of Surgery," Nov., 1903).

In the hypertrophied prostate there is an excessive production of fibrous tissue and of ill-formed glandular tissue, the mass constituting a fibro-adenoma. Fibro-adenoma is the common cause of enlargement (W. Bruce Clarke). Typical adenoma, according to Albarran and Hallé, is found in 14 per cent. of the cases ("Ann. des Mal. des Org. Gén.-Urin.," Feb. and March, 1900). Again, in not a few prostates there is no real enlargement, but there is an indurated fibrous mass producing obstruction. Albarran and Hallé ("Annales des Maladies des Organes Génito-Urinaires," 1898, vol. xvi) point out that in an enlargement of the prostate different elements may usually be recognized: soft hypertrophy of the gland; indurated enlargement of the glandular elements; fibrous enlargement; circumscribed tumor-masses; distinct fibromata or myomata; or adenofibromyomata. The real cause of the various forms of prostatic enlargement is not known. Nearly 10 per cent. of cases are cancerous (Oraison), and adenoma is apt to be transformed into cancer.

All the lobes may be enlarged equally; all may be enlarged unequally; the enlarged gland may surround the prostatic urethra like a horse-collar; or one lobe only may be enlarged. Symmetrical enlargement of the entire gland is not so apt to produce symptoms as is a non-symmetrical enlargement. In some cases the chief enlargement is into the bladder; in others, into the urethra. An enlarged prostate frequently shows a circular groove about it, due to the constriction exerted by the rectovesical fascia at the vesical neck.

The bridge of prostate which joins the two lateral lobes behind the urethra is known as the *lobe of Hodge* or the "*middle lobe*," and a comparatively trivial enlargement of the middle lobe may cause obstruction. Prostatic hypertrophy causes a narrowing and lengthening of the urethra, and gives this tube a tortuous course. The opening of the urethra into the bladder is usually pushed to a higher level, and there forms behind it a pouch in which urine collects. The urine that gathers in this pouch is known as *residual urine*. It cannot be voluntarily expelled. It may, therefore, collect in large quantity, and it is likely to decompose, producing cystitis. Residual urine strongly favors calculus formation. The mechanical resistance to the expelling of the urine causes congestion of the neck of the bladder and the posterior urethra and also hypertrophy of the muscles of the bladder. In consequence of the hypertrophy the bladder enlarges, thickens, and becomes fasciculated. When this takes place, micturition becomes very difficult and sometimes impossible. Enlargement of the middle lobe inevitably blocks the flow of urine and causes great distention of the bladder. In hypertrophy of the prostate gland the ureters and the renal pelves and calyces may distend and surgical kidney may develop.

It is useful to divide, as does Horwitz, per into three groups: (1) those in whom there is urinary symptoms are very trivial; (2) those in and disturbances of urinary function, who relief, but who do very well by this method; a plete breakdown during the period in which (Orville Horwitz, in "Phila. Med. Jour.," N

Treatment.—There is no known method trophy. Many cases of enlargement are treated if this is conducted with careful cleanliness, if hygienic rules, he may be kept comfortable for has formulated several sound rules as to whe treatment. He says, if the patient is intelligen severe, if the amount of residual urine is not

great, if the bladder retains considerable expulsive power, and if catheterization is easy and painless, we are justified in relying upon this simple plan of treatment. Prevent cystitis by emptying the bladder each evening with a coudé catheter. If there is trouble in passing the catheter, strengthen the instrument by inserting a filiform bougie as a stylet (Brinton). It is very seldom that a metal instrument is used, but if it is required, a catheter with a large curve is employed. If a soft semisolid instrument can be passed, teach the patient how to clean it, how to use it, and how to keep it, but never permit the patient to use a metal instrument himself. A dirty instrument may cause fatal infection. It is true that some people use dirty instruments for long periods without trouble, but in most cases there will be trouble if it is attempted. It is absolutely necessary to use only perfectly aseptic instruments. Metal instruments are sterilized by boiling in water. Rubber catheters can be cleansed by washing with soap and running water and boiling. Woven instruments can be placed in a glass cylinder, the bottom of which is like a sieve. This jar is placed for twenty-four hours in a vessel which contains formalin. The vapor of formalin is an excellent germicide, and does not injure the catheter. After sterilization the instruments are kept ready for use in a glass cylinder which contains calcium chlorid.* Guyon scrubs the catheters with soap and water, dries them outside and inside, and places them in a sealed jar, and exposes them to the vapor of sulphurous acid for forty-eight hours. If there are three ounces of residual urine, use the catheter only at night. If there are six ounces, use it night and morning. If there are more than six ounces of residual urine, add one more catheterization a day for every additional two ounces present until the catheter is used six times in the twenty-four hours. It should never be used oftener than this. Gradual dilatation with steel sounds is of benefit, but forcible dilatation is not advisable. The sound may be passed once a week. Tell the patient to avoid violent exercise, cold, damp, sexual excitement, and the use of alcoholic liquors; prevent constipation and indigestion, and direct him to drink milk and plenty of water. A hot hip-bath at night adds to his comfort. Hot enemata are of value. If a large quantity of residual urine exists, or if cystitis begins, wash out the bladder daily with boric-acid solution, or normal salt solution, or nitrate of silver (from 1 : 10,000 to 1 : 2000), and give urotropin or salol and boric acid by the mouth (Cystitis, page 1319). In some severe cases, if a large-sized rubber catheter be tied in the bladder for a few days, great relief is obtained. Retention of urine can be relieved by the introduction of a coudé catheter strengthened with a whalebone. In exceptional cases a silver instrument with a prostatic curve must be employed or aspiration must be practised. Many cases occurring among well-to-do people can be kept comfortable by catheterization. Some surgeons still think that only when this fails should an operation be performed. Unfortunately, sooner or later the regular use of the catheter will cause cystitis. A poor man cannot give the necessary time and attention to make catheter life safe and operation must be thought of in him sooner than in others. If the symptoms grow constantly worse, if the suffering becomes severe, if the patient cannot urinate without the use of an instrument, if catheterization is painful or impossible, if the patient is too careless or ignorant to trust with a catheter, if only a catheter of very

* R. W. Frank, in *Berliner klin. Woch.* No. 44, 1895

small size can be introduced, if attacks of persistent or recurring cystitis or hematuria, infection of the kidney, if the residual urine of the bladder should be opened. Do not postpone until the patient becomes really ill. Give palliative measures, but if they fail, operate. Before determining upon an operation, make a careful examination. This is particularly valuable before a perineal operation. It shows us the nature, size, and situation of the enlargement and a calculus if one exists. This examination is of great value in determining the advisability of operation desirable. Prostatectomy is an affair certain to result in cure. It is a grave operation, which may be attended by death, which unfortunate consequences may arise from that—"It is altogether too grave an operation to be undertaken for every enlarged prostate, and only in selected cases." The operation is contraindicated in disease of the kidneys, and if it is performed, a cure is to be expected. Age is not in itself a contraindication. If the cardiovascular system are sound. An occurrence of incontinence of urine due to injury of the neck of the bladder or of the part. A usual sequel is impotence.

In the majority of cases in which palliative treatment is to remove an obstructing mass and depress the bladder into the prostatic urethra, the operation is abolished and the bladder can be thoroughly emptied between prostaticotomy and prostatectomy. The operation may be performed by the galvanocautery (Bottini's operation) or by the pubic or perineal, and the latter may be performed by the sight (as in the operations of Nicoll and Young) or by the touch (as in Young's operation). No one route is best for that individual case. The surgeon should study the case and the operation. The surgeon should study the case and the operation. The surgeon should study the case and the operation. It was formerly believed that any operation on the prostate necessarily produce impotence. This we now know is not true. The suprapubic operation is probably less likely to produce impotence than the perineal, as it usually spares the ejaculatory ducts. Deschi's operation certainly produces sterility and may, but does not necessarily produce impotence. Willy Meyer ("Med. Record," Oct. 1901) has shown that impotence may also be caused by damaging important structures passing through the perineum, and also by the removal of the verumontanum and prostatic urethra, and thus the erection.

The perineal operation is as safe as the suprapubic, and is rapidly performed. It is the desirable route of approach per rectum and does not mount high up within the rectum in the stages of soft hypertrophy (Willy Meyer, in

and when prolonged drainage is required. According to Francis S. Watson ("Annals of Surgery," June, 1904), the mortality in 203 cases was only 2.9 per cent. In 563 cases of removal through the perineum by dissection, the mortality was 5.5 per cent. Young's cases in this group number 150 and his mortality was 4.6 per cent., the mortality of Hartman's was 9 per cent., of Albarran, 4 per cent., and of Murphy, 3.9 per cent. (Schachner, in "Annals of Surgery," August, 1908). In 190 cases of blind enucleation through the perineum the mortality was 4.7 per cent. (Schachner, *Ibid.*).

After the performance of the perineal operation the drainage is at the lowest part of the bladder. In a perineal operation every effort should be made to do as little damage as possible to the urethra. If we destroy the entire prostatic urethra, the operation becomes easy and rapid and nature rapidly repairs it, but a traumatic stricture may follow and may make the patient's condition worse than at first. As Moore says, we must destroy a portion of the floor of the urethra, but we can preserve the roof and the side walls. Another point in the perineal operation is to avoid injuring the rectum. A tear may enter the rectum, or, even if the gut was not torn, sloughing of the rectum resulting in recto-urethral fistula may occur. The rectum may be opened because the surgeon fails to stick close to the urethra in his dissection, and sloughing may be due to an injudicious use of the retractors. If the rectum is opened, it should be at once sutured with catgut. In most cases it takes about three weeks for the wound in the perineum to heal, and in some few cases a perineal urinary fistula is established. Urinary incontinence may follow this operation. By simply incising the prostate gland the floor of the urethra may be lowered to the level of the floor of the bladder. Simple incision of the prostate in this manner, or by Bottini's method, is known as *prostatotomy*. The mortality is small and the relief is often great. Prostatotomy is performed on old and exhausted patients with damaged kidneys. A large tube should be worn during the healing of the wound.

The suprapubic operation is easier than the perineal; it is less safe; it gives excellent results if temporary drainage only is needed. According to Watson ("Annals of Surgery," June, 1904), the mortality in 69 cases was 8.6 per cent. Freyer reports 600 cases varying in age from forty-eight to eighty-nine years. There were 47 between the ages of eighty and eighty-nine, and 7 were seventy-nine; most of the cases had been entirely dependent on the catheter for periods up to twenty-four years. "Nearly all were in broken health and many apparently dying before operation." "Few were free from one or more grave complications, such as cystitis, stone in the bladder, pyelitis, kidney disease, diabetes, heart disease, chronic bronchitis, paralysis, hernia; and in a few instances there was malignant disease of some other organ than the prostate" (P. J. Freyer, in "Archives Internationales de Chirurgie," vol. iv, Fascic. 4, 1909). In these 600 cases there were 37 deaths in periods from six hours to thirty-seven days after operation, a mortality of 6.15 per cent. It is indicated in rather young subjects in whom we greatly fear impotence; in cases in which the gland is placed high; in cases in which the gland is not palpable per rectum, but is causing serious symptoms, and in which the hypertrophy is recognized by the cystoscope (Meyer), this condition exists if there is a middle lobe; in cases in which cancer exists; or in which calculus complicates the case. It is the most useful operation when the hypertrophy is very large

and intravesical. It is not a suitable method if the belly-walls are very thick. If as it is sure to be in cases with advanced cystitis in the perineal operation. If when a suprapubic it is found that prolonged drainage is indicated is used. If permanent drainage is required it is the best. After a suprapubic cystotomy the opening may be kept permanently patent by McGuire's operation. It is only in very advanced permanent suprapubic drainage is employed incision the floor of the urethra cannot be brought level only by the performance of prostatectomy the strictures divided are less improved and the drainage is better than in the perineal cystotomy inflicts injury upon the bladder, it ruptures the bladder, and is often followed by infection. Murphy, "Jour. Amer. Med. Assoc.," March 1908, "control is less common than after the perineal operation may be seriously torn, and if such a wound is sutured with catgut. In this operation, if the surgeon must exercise great care to avoid the ureters may be damaged and subsequently become atonic. If death occurs after prostatectomy it is usually postoperative complications, usually pulmonary embolism," August, 1908) uses Watson's figures for each operation. The table is as follows.

	Per cent.

Perineal operations	17.8	
Suprapubic	22.0	

Freyer's Method of Suprapubic Prostatectomy. The bladder is washed out through a catheter with warm water. The prostate is filled with the solution. The nozzle of a catheter is inserted into the end of the catheter. This catheter is running out and enables the surgeon to quickly remove the prostate on occasion shall arise. The bladder is opened. The prostate is free from veins. The incision is vertical, is made in the middle of the prostate. It is about 1 inch in length (it can be enlarged if necessary). If the prostate is found they are at once removed. A finger is inserted up the prostate and keep it steady. The finger

into the bladder, and by means of the finger nail the mucous membrane is scratched through over "the most prominent portion of one lateral lobe, or over the so-called middle lobe, if there be but one prominence" (Freyer, in "Archiv. Internat. de Chir." Fascic. 4, 1909). This portion of the gland is only covered with mucous membrane, and when this is scratched through, the true prostatic capsule is reached. The finger is kept in close contact with the true capsule and enucleates the gland by passing first posterior, next outside, and finally in front of one lateral lobe.

"The finger is then swept in a circular fashion from without inward, in front of and to the inner side of the lobe, detaching this from the urethra, which is felt covering the catheter, and pushed forward toward the symphysis between the lateral lobes, which will, as a rule, have separated along their anterior commissure in the course of the manipulations. The other lobe is attacked and treated in the same manner. The finger is next pushed well downward behind the prostate and the inferior surface of the gland is peeled off the triangular ligament. When the prostate is felt free within its sheath and separated from the urethra, with the finger in the rectum, aided by that in the bladder, it is pushed into the bladder through the opening in the mucous membrane, which, during the manipulations, will have become considerably enlarged" (Freyer, *Ibid.*). The prostate is removed from the bladder by forceps. If the lobes come away separately, Freyer believes that the ejaculatory ducts are uninjured and remain attached to the urethra. There has been an active controversy as to whether Freyer's operation does or does not destroy the prostatic urethra. It seems certain that even if it is left it must slough for want of blood-supply. In my operations by this method it has come away with the prostate.

In Freyer's earlier operations he sought to leave the urethra and accompanying structures behind, but he is now convinced that the prostatic urethra may be torn or removed without ill results.

McGill's Operation: The bladder is opened by a suprapubic incision, the edges of the cut bladder are sutured to the abdominal wound with catgut, and the interior of the viscus is carefully explored with the finger and by sight, an electric light being used for illumination. If a sessile growth exists, the mucous membrane is incised and the growth enucleated with finger or a curet. A pedunculated growth is cut away with sharp-edged forceps. If a mass projects into the bladder, an incision is made to divide it into two portions and each half is enucleated. Hemorrhage is arrested by irrigation with hot salt solution and by compression with gauze pads. In some cases a tampon must be inserted. The bladder is drained for several days or a number of days by a siphon (Fig. 786). As a matter of fact, a dense fibrous prostate cannot be enucleated and can be removed only by scissors or cutting forceps.

Fuller's Operation: Open the bladder above the pubes; have an assistant push the gland up by means of a fist in the perineum. The gland can be lifted by two fingers in the rectum (Guit  ras). The surgeon makes a small incision through the mucous membrane over the prostate, enucleates the gland by means of the finger, and drains through an incision in the membranous urethra, as well as through the suprapubic opening.

Belfield's Operation: Belfield performs suprapubic cystotomy, makes a perineal cut to enable the finger to approach the prostate, pushes the prostate up toward the belly, and enucleates it from within the bladder.

Perineal Prostatectomy.—Perineal prostatectomy is less bloody than suprapubic prostatectomy. The sphincter of the bladder is not damaged, the entire prostate can be brought into view and removed, and perfect drainage is obtainable after operation.

Nicoll's Operation: Perform suprapubic cystotomy. Then incise the perineum down to the prostate, split the capsule of the prostate, insert the

Fig. 822.

Fig. 823.

fingers of the left hand into the bladder, and push the prostate into the perineum so as to bring it within reach. Enucleate the gland from the perineal wound without damaging the mucous membrane of the floor of the bladder.

Alexander's Operation: Alexander makes a suprapubic incision and uses it for the same purpose as does Nicoll, but he also opens the membranous urethra on a grooved staff. After enucleating the gland he inserts a drainage tube through the incision in the membranous urethra. In a very thin subject it may not be necessary to perform suprapubic cystotomy. Alexander has brought the gland into an accessible position in the perineal wound by separating the prostate, and Gunter has done so by making an incision in the rectum and inserting two fingers into the prevesical space. Syms advocates exposing into the peritoneal cavity, inserting the hand, and pressing the prostate into the perineum without opening the bladder above the pubes.

Bryson's Operation: This is a satisfactory method in some cases. The bladder is irrigated and filled with warm salt solution. A grooved staff is intro-

duced and a median perineal section is made to open the urethra just in front of the apex of the prostate gland. The knife is pushed back in the groove of the staff sufficiently far to incise the ring at the apex of the prostate; the forefinger is passed into the prostatic urethra and the staff is withdrawn. Then a short tear is made by means of a blunt instrument into the mass of the left lobe and the finger is introduced and enucleates the lobe. The same procedure is carried out on the right lobe, and, finally, if necessary, on the middle lobe. If the middle lobe requires removal, but cannot be reached, a suprapubic cut is made into the cave of Retzius, two fingers are inserted, and the lobe is pushed within reach of the finger below. A large perineal tube is introduced for drainage and bleeding is arrested by packing. Horwitz also introduces a catheter and ties it in place.

Young's Operation: This surgeon frequently operates under spinal anesthesia. He places the patient in an exaggerated lithotomy position and introduces a sound. In thin subjects the incision is in the raphé and is carried close to the anus; in short individuals the incision is an inverted V. He incises the recto-urethralis muscle transversely, exposes the membranous urethra, opens it, and inserts his tractor into the opening in the urethra (Fig. 828). The tractor is turned 180°, the blades are opened, and traction is made. The capsule is incised on each side of the ejaculatory ducts and the gland is removed by blunt dissection, the forceps grasping each lobe during enucleation (Fig. 829). Every effort is made to save the urethra. After removing the lateral lobes the tractor is used to bring a middle lobe, if one exists, into the wound, and it is also enucleated. The bladder is drained for about one week.

Bottini's Galvanocaustic Prostatotomy.—Bottini, of Padua, in 1874 suggested cauterizing the prostate by means of a special instrument. He sought to burn away a portion of the gland in hope that the contraction of the scar would cause the remainder of the gland to shrink. The instrument of Bottini is shaped like a catheter, and carries a platinum blade which is heated by an electric current. Bottini's early instrument was not satisfactory and the operation never became popular until Freudenberg improved the tools in 1897 (Fig. 824).

Bottini's galvanocaustic operation is performed as follows: The bladder should be emptied, irrigated, and distended with air, and the posterior urethra must be anesthetized by instillation of cocaine or eucain. The current is tried to see how many seconds it requires to heat the blade sufficiently. The current is broken, the instrument is introduced, the cooling current is set in motion, and one assistant watches this and nothing else. Turn on the current. Wait the required number of seconds for the blade to become red hot (twelve to fifteen seconds), turn the screw at the handle, and burn a groove in the prostate. A groove should be burned toward the rectum, one to the side, and, if it is thought desirable, one to the opposite side. No groove should be burned toward the pubes. When a groove has been burned, return the blade into its sheath, increasing the current while doing so in order to keep the blade from adhering to the tissue, then shut off the current. After withdrawing the instrument it is not necessary to introduce and retain a catheter. The patient is confined to bed only twenty-four hours, there is rarely bleeding or fever, and the results are good. The scars contract and the gland atrophies. During the period of healing a steel sound should be passed from time to

time (Bangs). It is alleged that fibrous stri may follow in some cases.*

the ordinary operation fails entirely; but, as Young shows (Figs. 825, 827), if an oblique cut is made on each side across the base, this lobe will drop out of the way and quickly atrophy.

Fig. 827. —Incising the middle lobe (Young).

Much of this shrinking may be due to diminution of congestion and edema, but true atrophy undoubtedly occurs in the glandular elements. Very remarkable results have been recorded. In some cases the patients become absolutely comfortable and dispense entirely with the catheter. Cystitis ceases, and desire to urinate frequently becomes less marked. Unilateral orchidectomy has been employed, but it is not satisfactory. In 1894 Mears suggested ligation of the spermatic cord. In 1895 Lauenstein suggested division of the spermatic cord. In 1896 Tilden Brown suggested ligation of the vas. Reginald Harrison in 1896 advised section of the vas. Lennander in 1897 proposed excision of the vas deferens (*vasectomy*). It is slower in its results, but just as certain as castration. In spite of the great simplicity of orchidectomy the mortality has been considerable (from 11 to 18 per cent., according to some authors. Socin and Burkhardt say 16.2 per cent.). In several instances mental disturbance has followed the operation. Castration is now very seldom performed, as vasectomy is just as useful and is safer. Vasectomy is valueless in cases of fibroid prostate, does some good in adenoma, but is most valuable when the prostate is generally hypertrophied and prone to great congestion, causing violent symptoms. The testicle does not atrophy after vasectomy, mental disturbance does not occur because the internal secretion of the testicle is still

Castration and Vasectomy —In 1886 Sanitzin demonstrated clinically the shrinking of a large prostate after double castration (Hawley, in "Annals of Surgery," Nov., 1903). In 1893 Ramm, of Norway, performed double castration in order to cause shrinking of an enlarged prostate. In 1893, after a long series of careful experiments, J. William White recommended the operation of bilateral orchidectomy for the treatment of prostatic hypertrophy. He proved that removal of the testicles causes a rapid shrinking in an enlarged prostate.

furnished to the organism, and impotence must.

Other Methods.—Among other operations (ligation of the vascular elements of the cord; ligation of the vas and its artery and vein; Albarran in 1897); parenchymatous injections; ligation of both internal iliac arteries. Angi 5.5 per cent. (Socin and Burekhardt).

Results.—The relative merits of these various are in dispute. It is certain that many can be kept comfortable by aseptic catheter; for other reasons must be abandoned, or if the a careful study of the case should be made before. The Bottini operation has come into somewhat apply it to almost any sort of case, and claim free from danger. Meyer uses it for any case but if the prostate is very large, ligates the vas and cauterizing the prostate, in order to lessen the

ally enlarged prostate. It may do great good, urine is extremely foul, some operation permitted adenomatous prostate in which enucleation is a method. In other cases in which it is probable cases of uncertain diagnosis, in cases in which cases in which the middle lobe is at fault, do a sometimes a perineal incision may be made, and to bring the floor of the urethra level with the tr

In old men with great obstruction and with and involvement of the kidneys, and in individuals permanent suprapubic drainage is sometimes the

The mortality from Bottini's operation is over 5 per cent. Horwitz collected 888 operations: 84.3 per cent. were cured or improved, 10 per cent. were not improved; and 5.7 per cent. died ("Phila. Med. Jour.," Nov. 16, 1901). Young had 3 deaths in 41 operations.

Vasectomy done early gives a mortality of from 3 to 5 per cent. If performed later, the mortality is 10 to 15 per cent. Socin and Burckhardt estimate the mortality of bilateral vasectomy as 8.3 per cent. The mortality of bilateral orchidectomy is 16.2 per cent.

The mortality of prostatectomy is variously estimated. Freudenberg collected 753 cases: 622 were cured, 44 died, and 87 were not improved.

Guitéras collected 152 cases done by various methods ("Jour. Amer. Med. Assoc.," Nov. 2, 1901). Twenty-five died. Bangs believes that the mortality from prostatectomy should not be above 8 per cent., but statistics indicate that it is from 10 to 15 per cent. in most hands. W. Bruce Clarke reports a mortality of 9 per cent. The mortality of the suprapubic operation is higher than that of the perineal operation. Belfield estimates the former at 16 per cent. and the latter at 9 per cent. Watson estimates the mortality of the former as 8.6 per cent. and of the latter as 2.9 per cent.

The earlier the operation is performed, the safer it is. (See "The Choice of Method in Operating Upon the Hypertrophied Prostate," by Willy Meyer, in "Med. Record," Oct. 7, 1905; "A Critical Review of the Technic of Perineal Prostatectomy," by Charles Greene Cumston, in "American Medicine," August, 1906; "The Operative Treatment of the Hypertrophied Prostate," by Francis S. Watson, "Annals of Surgery," June, 1904.)

Malignant Disease of the Prostate Gland.—Primary malignant growths of the prostate are not infrequently encountered, but secondary growths are much more rare than are primary growths. When malignant disease does occur, it is almost always cancerous. Secondary cancer of the prostate finds its most usual antecedent in cancer of the rectum. Epithelioma does not occur. Scirrhous occasionally occurs; but the most frequent form is encephaloid. Round-celled, spindle-celled, or mixed-celled sarcoma may develop. Powers says there have been but 31 authenticated cases of primary sarcoma reported ("Annals of Surgery" Jan., 1908). Sarcoma is most frequent in childhood. It grows rapidly, is usually soft, and causes pain in the rectum and perineum or pubic region, but early in the case, at least, there is seldom residual urine (Powers, in "Annals of Surgery" Jan., 1908). No real cure of sarcoma has yet been reported.

Carcinoma of the prostate may occur at an earlier age than ordinary hypertrophy of the prostate. The latter does not become evident until after the age of fifty; but carcinoma of the prostate may begin at any time after the age of forty, and sarcoma of the prostate may commence in early youth.

At first the carcinomatous growth enlarges slowly; but it soon begins to grow with rapidity. It breaks through the capsule and fungates into the bladder or into the urethra. The pelvic, the inguinal, and the femoral glands become involved early in the course of the disease. It is not usual to find great obstruction to urination or to the passage of a catheter at an early period, but later both these conditions are noted. Early in the case there is pain only when obstruction to urination occurs; later, the pain in the neck of the bladder may be severe, and there may also be pain in the loin and in the sciatic

nerves. Hemorrhage usually occurs. In the trivial and intermittent, but when fungation usually take place. The blood is usually mixed with a large hemorrhage unassociated with pus, likely to contain pus or any large quantity of pus involved in the growth.

When the prostate gland is felt by means of the rectum it is found to be of stony hardness and to be enlarged. Reginald Harrison points out that an ordinary hypertrophied prostate is not anchored as a carcinomatous gland; that the tumor is firm to the touch; and that, although it is firm to the touch, it is not anchored. The patient with carcinoma of the prostate has a distinct cachexia, and metastatic deposits are found in the column, in the kidneys, and in other organs.

In making a diagnosis Harrison insists upon the fact that in cancer one does not find a smooth projection, but that what projection there is is uneven and firm. In a hypertrophied prostate, on the contrary, the surface is smooth and projects into the bladder.

Treatment. Radical operation is out of the question. Permanent suprapubic drainage is made in the case of the patient great relief. (See "Remarks on the Treatment of Prostatic Cancer," by Reginald Harrison, in "Brit. Med. Jour." of 1891.)

Tuberculosis of the Prostate Gland. Tuberculosis of the prostate is rarely primary. It is usually secondary to tuberculosis of the lungs or of the epididymis. In the majority of cases the lungs are involved in a tuberculous process, and the disease is first seen by the surgeon. The disease appears between twenty and thirty years, but it may attack at any age. It begins by the formation of a number of tubercles in the immediate neighborhood of the prostatic tubules. These tubercles, together, forming cavities and, eventually, the disease is prone to rupture into the urethra. In very advanced cases the abscess ruptures through the perineum into the peritoneum.

The disease occasionally undergoes spontaneous resolution, or tissue formation or calcification. The tubercles may extend to the seminal vesicles, the bladder, the ureters, and in some cases it inaugurates thrombophlebitis.

Symptoms. The patient suffers with frequent micturition; and from time to time attacks of cystitis take place, and weakness and a loss of energy are attendant. The disease is not commensurate with any ordinary inflammation. The disease alone is said not to cause marked hectic fever. When the disease becomes advanced, the temperature attains a characteristic level. When the disease has advanced, the patient loses continence, on account of the involvement of the neck of the bladder. Commonly, the discharge is purulent or mucopurulent matter may be obtained by

matter may contain tubercle bacilli, and in some cases the urine also contains these bacilli. Early in the course of the case rectal examination detects some enlargement of the gland, many nodules, and tenderness; later in the disease it finds marked enlargement and areas of softening.

Treatment.—Early in the case Senn recommends parenchymatous injections of iodoform emulsion, the punctures being made through the perineum. If these fail, operation must be considered. When one takes into account how rare primary tuberculosis of the prostate is, one is impressed with the infrequency with which a radical operation should be attempted. If there is absolutely no evidence that any adjacent organ is involved or that any distant focus of disease exists, it is justifiable to perform perineal prostatectomy. As a rule, however, the only surgical operation performed consists in making a curvilinear incision in front of the rectum, which exposes the prostate, and permits the surgeon to open and curet caseous foci. If an abscess forms, it should be evacuated by means of a perineal incision and cavities should be curetted and packed with iodoform gauze.

If it is determined that no operation is advisable, antituberculous treatment is employed. One should look to the patient's general health, administer urotropin, and avoid using instruments as much as possible; because, as Sir Henry Thompson has shown, instrumentation irritates the prostate, causes a great deal of pain, and makes the disease worse in every case.

Retained and Malplaced Testicle.—In 1 person of 1000 there is undescended or ectopic testis. The testicle may be arrested in its passage to the scrotum (*cryptorchism*, single or double); it may remain in the lumbar region; it may reach the internal abdominal ring; it may lodge in the inguinal canal; it may emerge from the external ring, but fail to enter the scrotum; or it may pass into an unnatural position, as into the perineum or the crural canal (*ectopia of the testis*). The failure of descent may be unilateral or bilateral, but when bilateral the degree of descent is seldom the same on the two sides. The gland may be, but seldom is, functionally active. When retained in the abdomen it never has the power of spermatogenesis. Before puberty the testicle is usually normal, but after puberty there is practically always more or less atrophy. In about 1 case out of 5 there is spermatogenesis. A retained testicle is liable to attacks of orchitis and may become tuberculous or sarcomatous. In most cases there is neither pain nor tenderness, and the patient presents himself for treatment because a lump has appeared in the groin. In some cases there are sudden attacks of violent pain, accompanied by nausea (Rawling, on Incompletely Descended Testicle, in "Practitioner," August, 1908). A testicle in the inguinal or crural canal or in the perineum is far more apt to become sarcomatous than is one retained within the abdomen. Over 10 per cent. of cases of sarcoma of the testicle are in undescended glands. In 80 per cent. of individuals the testicles have descended at birth; most often it is the right testicle which fails to descend. Sometimes a testicle descends after being retained for months or even years. In Keyes' case it descended in the thirtieth year. Late descent usually causes hernia, and in 90 per cent. of all cases hernia exists. In double cryptorchism, in which the testicular function has been abolished, there is delayed union of the bony epiphyses and epiphyseal fractures are common, and there may be excessive growth of long bones. The same liability is noted in those subjected to castration in infancy. When such a

subject reaches manhood, he may develop son is usually seen only in children (Gross and Set 1905). In operating on these cases we usually naculum and a vaginal tunic extending well

Treatment.—If one testicle is undescended, and before puberty, if it lies in the canal, and the former should be removed if it is found in the scrotum. Both testicles should not be removed and be placed within the abdomen. I would do this, but it may not enter and remain in the masculine groove, and be missible in an adult, because he has definitely a masculine line, and undescended or ectopic testicles in an adult are functionally useless and menaces. If a testicle is found it should not be operated upon unless it causes trouble. A retained gland into the scrotum before the age of puberty, it will be almost certain to be found after puberty, it will be almost certain to be found. A testicle should be restored to the scrotum if possible. Even when operation is performed to replace the testicle. In Rawling's 29 cases only 4 were permanent, but, however, claim better results. For instance, from one to six years, and in 31 of them the results were good. The method I employ is that advocated by Bevan, through the aponeurosis, separation of the cord (usually in the posterior sac wall); removal of the cord and fibrous adhesions around the cord; the removal of the fingers, closure of the canal as in hernia; suturing the external ring, as advocated by Dowd. This method Bevan operates for a testicle within the canal, and vaginal process, removing all the coverings of the testicle, suspended by the vas and spermatic vessels of the testicle a very wide range of mobility. A procedure means of the finger, the testicle is placed in the scrotum without suturing. The canal is now sutured as in cord transplantation. There is a certain improvement in the testicle after Bevan's operation. I believe this method is employed in the more severe cases. If there is no improvement performed until between the eighth and twelfth

Orchitis is inflammation of the testicle. It may be cold, wet, traumatism or epididymitis, gout, mumps, fever. The testicle is round, swollen, tender, red, is red and swollen, the tunica vaginalis is filled with fluid. Chronic orchitis results from the acute form, and is almost always combined with

The **treatment** of the acute form consists in rest, as for epididymitis (page 1391). The chronic form consists in the causative lesion, if possible, the wearing of the testicle, applications of ichthyol or mercurial ointment, and of potassium by the mouth. Strapping with rubber does good. Castration may be required.

Tuberculosis of the testicle may perhaps be primary, but in the vast majority of cases is secondary to tuberculosis of the prostate, bladder, or seminal vesicles. I have never seen a case I was certain was primary. As Keyes says ("Annals of Surgery" June, 1907), careful examination will show one of three conditions—tubercle bacilli in urine, indurations in the prostate, and vesicles or "a distinct haze in the urine due to prostatic catarrh." These patients are nearly always sterile. The disease may be preceded by pulmonary tuberculosis, peritoneal tuberculosis, anal fistula, renal tuberculosis, or tuberculous disease of bones or joints; and primary tuberculosis of the testicle may be followed by near or distant tuberculous lesions. In some cases involvement of the prostate exists, but cannot be detected (*latent tuberculosis of the prostate*); in other cases the prostate is in a state of subacute inflammation. The epididymis is always involved before the testicle and early chronic lesions are localized there for some time. In most cases the bacilli reach the prostate and vesicles by way of the blood, and reach the epididymis by way of the vas deferens, the lesions of the prostate and vesicles developing first or remaining latent. In some cases tuberculosis of the kidney or bladder is followed by tuberculosis of the testicle. The spread from the prostate, vas, or bladder is by epithelial infection. There is no evidence confirmatory of the idea of ascending infection from the urethra. In a child with an open vaginal process, tuberculous peritonitis may directly cause tuberculous epididymitis. The disease begins in one testicle, but in the vast majority of cases the other testicle becomes involved after a few weeks or months. If the other testicle remains free for three years, its chance of remaining free is good. If but one epididymis is involved, the testicle may not be affected for weeks or months. Von Bruns says that in 18 per cent. of such cases the testicle is not involved for six months; in 40 per cent., for over two months ("Archiv. f. klin. Chir.," Bd. 63, H. 4). It usually comes on gradually, but it may begin acutely, as I have seen in two instances during the progress of tuberculous peritonitis. An acute onset or an acute exacerbation of a chronic case usually means a mixed infection. The disease may follow a slight injury or inflammation, and is most common in young men, but may arise at any age. The causal influence of antecedent or existing gonorrhea is doubtful. Some maintain that sexual excess predisposes. There is often a family history of tuberculosis. A chronic case begins by swelling of the epididymis. Palpation detects one or two or several rounded nodules, or a diffuse hardening. In the latter case the epididymis is much enlarged, and there is usually a slight hydrocele. Rectal examination commonly detects nodules in the prostate and vesicles. In a few cases there are frequency of micturition, tenesmus, hematuria, and seropurulent fluid can be massaged from the vesicles and prostate and milked from the urethra. In some cases bacilli are found in the urine. In others the urine is hazy. Sooner or later nodules appear in the testicle. The vas is always swollen and may or may not be palpable. In an acute case one testicle is involved. The testicle is very painful and the epididymis is greatly swollen and smooth. The testicle quickly swells, there is always a hydrocele, and the scrotal skin becomes reddened. In a few days the acuteness of the symptoms subsides, but suppuration shortly occurs. In any case of tuberculosis of the testicle nodules tend to soften and run together

After a time the skin may become red and a caseous breaking down epididymis or testicle mixed infection, but in many cases where softer there is mixed infection. The duration of 5 cent. of the 100 cases carefully studied by Ke years after the beginning of the trouble, and 4 operated upon) seemed free from tuberculous of the cases that supplicated were apparently 1 of Surgery" June, 1907). Except in the acute if at all, painful, and tenderness is trivial. In

Fig. 830. Obstructive hyperemia for the testicles. by the patient, crossed. A piece of tape is placed behind and Schimieden).

hydrocele forms. In a questionable case employed. If a hydrocele exists, the fluid should and cultures be made from it.

Treatment. Before attempting any operation patient is placed recumbent, the diseased testis is bathed in a solution of 10 per cent. of potassium permanganate. A tube of a caliber of 25 F. is wound twice around the scrotum and secured with a clamp. If both testicles are diseased, both are embraced by the tube with the required treatment is applied for two or three hours a day. The patient should be recumbent during the application. If the patient is very painful and gets about. During the use of Bier's treatment is required (page 245). If a cold abscess is present, it should be treated antiseptically. If Bier's treatment fails, consider

An acute case requires unilateral castration. If, in a chronic case the disease is limited to the epididymis or to the epididymis and vas, resect the epididymis (*epididymectomy*) and the vas deferens. If the testicle is diseased, *orchidectomy* is performed. It was long believed that orchidectomy was useless if the vesicles and prostate were involved, but Koenig and others maintain that vesicular and prostatic tuberculosis improves after removing the diseased testicle or epididymis. If the epididymis of each testicle is involved, bilateral epididymectomy should be performed. When both testicles are diseased and other organs and structures are not extensively involved, bilateral orchidectomy is performed or, better, the testicle which is most diseased is removed and the diseased portion of the other is extirpated. Cumston points out that the testicle may be diseased and yet even when exposed the disease not be detectable. Hence in doing epididymectomy he splits open the testicle to see if it is diseased. If it is not diseased he sutures it with catgut and removes the epididymis. If it is diseased, he considers the advisability of unilateral orchidectomy (Charles Greene Cumston, in "Annals of Surgery" June, 1909).

In association with and after operation employ antituberculous remedies, order a nourishing diet, send the patient to a good climate, and insist on an open-air life. A very large percentage of unilateral cases are cured by operation (over 40 per cent.). Some few bilateral cases are cured.

Orchidectomy, or Castration (*Excision of a Testicle*).—Bilateral castration should never be performed without deliberate consideration. It often produces grave mental disorder. This is in part the result of the depression attendant on knowing that the glands are gone and in part in the loss to the organism of the internal secretion of the testicle. A boy castrated before puberty never becomes potent. A man may retain potency for a considerable time. I removed a tuberculous kidney from a man who had been castrated by my colleague, Dr. Horwitz, two years before, yet he was still able to have intercourse. Unilateral orchidectomy does not make a man either sterile or impotent and does not produce mental disturbance. In orchidectomy an incision is made over the cord, commencing just outside the external ring and running down over the base of the tumor. Clamp the cord and divide it near to the ring, remove the testicle, ligate the spermatic artery alone, and then ligate the entire thickness of the cord. The cord is ligated with chromic gut. The skin is sutured with silkworm gut. Drainage is not required. It is often advisable to remove a considerable amount of scrotal skin.

Epididymitis, or inflammation of the epididymis, is usually due to inflammation of the urethra. It is apt to occur in the stage of decline of a gonorrhea, and is announced by a complete cessation of the discharge. It may result from the passage of a urethral instrument, the voiding of urine which contains fragments of calculi, or as a complication of prostatic hypertrophy. *Acute epididymitis* is characterized by swelling about the testicle, pain in the groin, and tenderness over the posterior part of the testicle. The pain becomes acute, swelling rapidly increases, and the constitution sympathizes. The swelling is due partly to engorgement of the epididymis and partly to fluid in the tunica vaginalis (*acute hydrocele*). *Chronic epididymitis* is usually linked with orchitis, and it follows an acute attack or a chronic urethral inflammation.

Treatment by septic puncture with a needle will relieve tension and pain. Leeching over the use of an ice-bag, elevation, application of laxatives and opium constitute the usual treat

Fig. 841.—Hydrocele of tunica vaginalis (Horwitz).

In nearly one-half of the cases the testicle is descended. In every case there is a long mesos normally placed, torsion of the cord will hardly nals of Surgery," Aug., 1901). The twisting m the left. The symptoms arise suddenly, and us cases a hernia also exists. When the rotat hemorrhages take place into it, and gangrene undescended or partially descended testicle (are noted in the abdomen or the groin. If th tuny, the gland feels nodular and the epidid tumors are sudden pain, vomiting, moderate sh or a swollen testicle in the scrotum. The s roughing. The symptoms resemble those of less violent, and the bowels are not obstructed.

Treatment. An incision should be made and the testicle is not gangrenous, untwist and l by a catgut stitch. If the testicle is gangren us that in 88 per cent. of cases the testicle is cording to Scudder, there are 32 cases on reco 1 was not, but all recovered; in 3 the testicle ("Annals of Surgery," Aug., 1901).

Vaginal hydrocele—*chronic hydrocele* llection of fluid in the tunica vaginalis testis may cause it, but in most instances the cau inflammation exist. The fluid is albuminous, taneously, it is thin, straw-colored, and may The testicle is at the lower and back part of ductuates, is translucent, grows from below u

of an exploring-needle permits the yellow fluid to flow out. Sometimes a hydrocele has an hour-glass shape. This is the *hydrocele "en bissac"* of the French. In this condition (Fig. 832) two cavities exist, usually but not invariably communicating. The constriction between the cavities is due to inflammatory thickening.

Fig. 832.—Hydrocele "en bissac." This hydrocele extends up the cord into the inguinal canal and to the internal abdominal ring (Horwitz)

Treatment.—Simply tapping the sac with a trocar is only palliative; air must run in as fluid runs out, and suppuration may occur, which will be dangerous without drainage. Never tap a rigid sac. The injection of irritants should be abandoned, as it exposes the patient to serious danger because

Fig. 833. Varieties of hydrocele. a, Congenital; b, infantile; c, fuscular; d, encysted; e, vaginal.

of inflammation occurring without provision for drainage. Hearn incises the sac, dries its anterior with bits of gauze, swabs it out with pure carbolic acid, packs it with iodoform gauze, and dresses it antiseptically. The packing is removed in twenty-four hours and the wound is allowed to close. In most cases I prefer this method. If the sac is rigid and will not collapse, either stitch it to the skin and pack it or excise a large portion of its parietal layer and insert a drainage-tube (*Volkman's operation*). It has recently been

proposed to tap the sac with a trocar and place as a drain for some days, and to dress as

Longuet's operation is easy and successful *position of the testicle*. It was introduced (*Méd.*, Sept. 21, 1901). A local anesthetic inches in length is made. The testicle is lifted and all the other coats except the skin fall together for the cord. One catgut suture will hold it made for the testicle beneath the inner edge of the fingers. The testicle is rotated on its long axis. The testicle rests against the scrotal septum, the cord covered with tunica. The skin is sutured.

Congenital hydrocele (Fig. 833, *a*) is a funicular process into the tunica vaginalis. It runs back into the peritoneal cavity, from which the **treatment** is the application of a truss to obliterate it.

Infantile hydrocele (Fig. 833, *b*) is a process and the tunica vaginalis, the funicular process but not below. The **treatment** is to puncture the wall with a needle.

Encysted Hydrocele of the Cord (Fig. 833, *c*).—The funicular process is obliterated above and below these two points and fluid collects. The **treatment** is the same as for infantile hydrocele. If this fails, incise and puncture below.

Funicular Hydrocele (Fig. 833, *c*).—The funicular process is open below, but is open above. Raising the pelvis into the peritoneal cavity. The **treatment** is the same as for infantile hydrocele.

Encysted hydroceles of the testicles and epididymis. **Diffused hydrocele** of the cord is simply edema. **Hernia** is the distention of a hernial sac with fluid.

Hematocele (Fig. 834). *Vaginal hematocele* is the result of traumatism, a tumor, or the rupture of a pyriform tumor, which fluctuates, but which the scrotum is livid, and the testicle is below and to the side. **Encysted hematocele of the cord** is a form of hematocele of the cord in which a hemorrhage has occurred. The **diffused form** is due to effusion of blood into the cellular substance of the cord. **Encysted hematocele** is due to effusion of blood into an encysted space. **Chymatous hematocele** is extravasation of blood into the cellular substance of the cord.

The **treatment** of a recent case of vaginal hematocele is to bed, support the scrotum, and apply an elastic bandage. If swelling does not soon abate, incise, irrigate, and suture.

Varicocele is varicose enlargement of the spermatic cord. The veins are thickened and convoluted. The assigned causes are strain, occupation requiring prolonged standing, and sexual desire is a cause. Hereditary predisposition is a cause. Left-sided than right-sided varicoceles, because the left testis empties into the vena cava at an angle.

vein has no valves (Brinton) and empties into the left renal vein at a right angle. Varicocele is a very common condition. The elder Senn found it in 21 per cent. of 10,000 recruits. An irregular swelling exists in the scrotum and extends up the cord. This swelling feels like "a bag of earth-worms"; it exhibits a slight impulse on coughing; the scrotal skin and cremaster muscle are attenuated; the testicle lies at the bottom of the swelling and is softer and smaller than normal; the swelling diminishes on lying down and increases on standing or on making pressure over the external ring. The scrotum is pendulous and the scrotal skin frequently contains varicose veins. The testicle may be soft and shrunken. There is usually some discomfort, aching,

Fig. 834. - Acute hematocoele of tunica vaginalis the result of traumatism (Horwitz).

or dragging in the testicle and the groin, and even neuralgic pain in the cord. There may be no discomfort of any sort. A large varicocele may be free from discomfort and a small varicocele may produce much annoyance, or *vice versa*. There are sometimes mental depression and hypochondriasis. As a man reaches middle age a varicocele usually ceases to give trouble.

Treatment. In treating varicocele, reassure the patient: tell him there is no real danger of impotence; order cold shower-baths, correct constipation and indigestion, give occasional tonics, and order the patient to wear a suspensory bandage. If the testicle becomes much atrophied, if the pain and the dragging are annoying, or if the mind is much depressed, operate (page 462).

XXXVII. AMPUT.

AN amputation is the cutting off of a limb or a portion of a limb at a joint. Amputation may be necessary because of gangrene, of tumors, of intractable disease which will not heal, of traumatic aneurysm, etc. because of the existence of a defect or disease.

Classification.—Amputations are classified by the time of operation after the injury: a *primary* amputation is performed as soon after the occurrence of the accident—as soon as possible and before he develops fever; a *secondary* amputation is performed some time after the accident, suppuration having

Fig. 835.—Esmarch's elastic bandage.

F

intermediate amputation is performed during the development of suppuration. (2) As to the division of the limb, it is divided according to which joint is cut and the situation of the flap.

In performing an amputation maintain the hopelessly damaged portion; sacrifice as little as possible; prevent hemorrhage during the amputation; have enough sound tissue in the operation; have enough sound tissue in the operation; have enough skin to cover the muscles; and secure the wound.

Hemorrhage may be prevented by the use of Esmarch's elastic bandage (Fig. 835). Ordinarily we can apply this bandage around the line of the prospective incision, encircle the limb (the thin tube shown in the cut), and remove the band, aseptically before using, and apply the band, aseptically before using. After the band has

not freely or forcibly be moved, because of the danger of tearing muscles which are firmly fixed by the compressing band. When elastic compression is used in an operation the surgeon should be very careful to tie *every visible vessel*. The paralysis of the small vessels induced by pressure often prevents bleeding, and unless their mouths be found and the vessels be tied reactionary hemorrhage will occur. Reactionary hemorrhage is the great danger after the use of the Esmarch bandage, and paralysis or sloughing may also follow

Fig. 837.—Petit's spiral tourniquet

Fig. 838.—Charrrière's tourniquet.

its employment. If there be an area of suppuration or of gangrene or an extra osseous malignant growth, do not apply the bandage as directed above. One bandage can be applied from the periphery to near the lower border of the area of growth or infection, and another, from near the upper border of this area, up the limb. If the bandages are applied in this manner the contents of the diseased area (tumor cells and fluid or septic products) are not squeezed into the circulation. In cases like the above many surgeons

Fig. 839.—Carlini's knife, and saws for amputation

hold the extremity in a vertical position for five minutes, lightly stroking it toward the body with the hand, and at once apply the constricting band. As a matter of fact, this plan satisfactorily empties the limb of blood, and it is not necessary in any case to force the blood out by elastic compression. Some surgeons prefer the tourniquet. Figs. 837 and 838 show two forms of tourniquet. To apply Petit's tourniquet, place the plates in contact, apply a small, firm compress over the artery and a broad thick compress over the outer surface of the limb, buckle the tapes around the limb so that the plate

is over the broad pad, and tighten the tourniquet with the screw (Fig. 836). When a tourniquet during transportation, bandage the limb, sew and place the plates of the instrument over the tourniquet may be used upon the brachial artery joint disarticulations Wyeth's pins are passed of blood the band is fastened above them, from slipping.

The instruments and appliances required are: apparatus or tourniquet, amputating knives and saws (Fig. 839), a lion jawed forceps, bone

Fig. 840.—Amputation of arm by the circular method (Drault).

elevator, retract static, and tool aneurysm-needle tures, sutures of ages, and solution the thigh and at forearm: it is eight inches with cutting tails on

Methods of Amputating.—Transverse and 841).—This is the oldest method of amputation. The incision is at a right angle to the axis of the limb. Kocher considers also as a circular incision an oblique cut around the limb if the line of the incision "continues in one direction" (Kocher's "Text-Book of Operative Surgery," translated by Harold J. Stiles). This method is called the *oblique circular amputation*. A *racket incision* is formed by adding a longitudinal cut to a transverse circular cut. If the edges are rounded, the *lanceolate incision* is formed. *Rectangular flaps* are formed when two longitudinal incisions are added to a transverse circular cut. If the corners of a rectangular flap are trimmed, *rounded flaps* are formed. The three last-mentioned plans are considered under the head of the Modified Circular Amputation (page 1399).

The surgeon should stand to the right of the limb and use a long

Fig. 841.—The

from heel to point (Fig. 840). After an assistant has retracted the skin the operator divides the soft parts by a series of circular cuts. He does not cut at once to the bone, but divides the skin and subcutaneous tissues. At the retracted edge of the first cut the superficial muscles are divided, and after these muscles retract the deep muscles are divided. The periosteum is incised with a bone knife and pushed up with an elevator, and after the application of the retractors the bone is then sawed, the saw starting from heel to point. A periosteal flap can be made to cover the end of the

Fig. 842.—Circular amputation; dissecting up the skin-flap (Esmarch).

bone, but it is unnecessary. In this amputation is formed a cone whose apex is the bone and whose base is the skin-edge. Figure 841, from Kocher, shows the steps of the operation and the shape of the resulting stump. In one form of circular amputation (*amputation à la manchette*) the retracted skin is cut by a circular sweep of the knife, a cuff of skin and subcutaneous tissue is freed and turned up, and the muscles are cut circularly at the edge of the turned-up cut (Fig. 842). The pure circular amputation is performed on the arm and the thigh; the *amputation à la manchette* is performed chiefly through the wrist and the lower forearm.

Fig. 843.—Modified circular amputation, skin-flaps and circular cut through muscles (Esmarch).

If there is more sound skin upon one side of the extremity than upon the other, the transverse circular incision sacrifices more of the limb than is necessary and the oblique circular is preferable. An objection to the transverse circular incision is that the cicatrix lies directly at the end of the stump and is liable to cause pain when subjected to pressure.

Modified Circular Method.—In this operation the circular skin cut may be modified by making a vertical incision to join the first wound, the

muscles being cut by a circular sweep (rather than by vertical skin incisions (rectangular flaps). The method is known as the "mixed method." The modification of Liston's modification consists in dissecting the muscles into elementary flaps and in dividing the muscles into elementary flaps known as the "mixed method." The modification of the thigh, the leg, the arm, and the forearm.

Oblique Circular Method (Elliptical Method)—The lower ends of the incision as shown in Fig.

Fig. 844.—The early steps of an oblique circular amputation (Kocher).

bone (Fig. 854, a, b) extends from the point of the bone is called the "racket" amputation. If the bone is cut, the operation is known as a T-amputation. The operation is performed at the metacarpophalangeal and shoulder-joints; the T operation may be performed at the elbow-joint.

Flap Method.—A flap may be composed of skin and muscle, but the skin flap must always be present, for the latter will be covered by it. A flap may be made badly, but the best flap has a moderate amount of skin and muscle.

cover the muscle and enough muscle to cover the bone). Flaps may be *single* or *double*. Double flaps may be *lateral* or *antero posterior*, *square* or *U shaped*, *equal* or *unequal*, and they may be cut by *transfixion* (Fig. 845), by cutting from without inward, by dissection, or by cutting the skin from without inward and the muscles by transfixion.

Fig. 845.—Amputation of the thigh by transfixion (Gross)

Completion of an Amputation.—

When an amputation is completed, tie the main vessels, pull down the nerves and cut them high up, smooth the flaps, take off the constricting band, and after arresting hemorrhage apply sutures. In some cases the deep parts are stitched with a continuous catgut

suture and the superficial parts are closed with silkworm gut; in other cases the deep parts are not stitched at all, the skin alone being sutured with silkworm-gut. Drainage-tubes should be used except in amputations of the fingers and toes.

SPECIAL AMPUTATIONS.

Fingers and Hand.—In amputating the thumb and index-finger save every possible scrap of tissue. In either of the fingers, if it be necessary to amputate above the middle of the middle phalanx, the attachment of the flexor tendons will be cut off and the finger will be liable to project directly backward, so that it is better with these fingers either to disarticulate at the metacarpal joints or to stitch the flexor tendons to the periosteum. The flexor tendons have fibrous sheaths extending from the proximal end of the distal phalanx

Fig. 846.—Amputation of the finger

Fig. 847.—The line of the joints in the flexed position of the finger: a, Extensor longus digitorum; b, Interosseus and lumbricals; c, Extensor longus digitorum and interosseus; d, Interosseus and lumbricals; e, flexor sublimis; f, flexor profundus (Kocher)

to the metacarpophalangeal articulations, these sheaths being thin and collapsible opposite the joints, but being thick and rigid opposite the shafts of the bone. The fibrous sheath is known as the *theca*, and when it is cut in an amputation it should be closed, otherwise it may carry infection to the palm of the hand. The theca does not exist over the distal phalanx, and it is not distinctly visible over the joint between the distal and middle phalanges. To effect closure over the shaft of a bone, strip up the periosteum and pass catgut sutures vertically through the theca and the periosteum (Treves). In amputation of the fingers and the thumb an Esmarch bandage is unnecessary, though pressure may be made upon the arteries at the wrist. Only two or three ligatures are necessary. Close with a very few sutures, so as to favor drainage between the threads.

The distal phalanx is best removed by a long palmar flap (Fig. 846, N).

The palmar flap (a) is marked out by cutting through the skin and subcutaneous tissue. The incisions are next carried to the bone, the flap is dissected from the bone, the finger is strongly flexed, a transverse incision (b) is carried across the dorsum on a level with the base of the third phalanx, the soft parts are pushed back, the joint is opened, the lateral ligaments are cut from within outward, the third phalanx is forcibly extended, and the remaining structures are cut from below upward. Fig. 847 shows the lines of the joints when the finger is flexed. The middle phalanx can be removed by the same method (c, Fig. 846). The proximal phalanx can be removed by a long palmar flap or by a long palmar and a short dorsal flap (d, e, Fig. 846).

Disarticulation at a metacarpophalangeal joint is best performed by the oval method. The incision upon the dorsum (A) is begun just above the head of the metacarpal bone, is carried down to beyond the base of the phalanx, and involves the skin only (Figs. 848 and 849). One

Fig. 848.—A. Disarticulation of a metacarpophalangeal joint. B. Amputation of a finger with the metacarpal bone.

Fig. 849. Disarticulation of the little finger and index finger. Disarticulation of the middle finger with its metacarpal bone. Disarticulation of the thumb with its metacarpal bone (Kocher).

incision sweeps around the finger at the level of the web, going only through the skin (B); the finger is extended and the palmar cut is carried to the bone; each lateral incision is carried to the bone while the finger is bent in the opposite direction, the flaps are dissected back to the joint, the finger is strongly extended, the joint is opened from the palmar side, and disarticulation is effected. Cutting off the head of the metacarpal bone improves the appearance of the stump but weakens the hand, hence in a workman it must not be done unnecessarily. If it is necessary to remove a metacarpal bone, the incision (C) is made from the carpometacarpal joint.

Amputation of the thumb through its distal or proximal phalanx is performed identically as is an amputation of a finger. Amputation of the thumb, with a portion or the whole of its metacarpal bone, is performed by the oval or racket incision (Fig. 849).

Disarticulation at the wrist-joint can be done by the oblique circular method (Fig. 851) or by a double flap. In the double-flap amputation a dorsal flap is made by carrying a semilunar skin incision between the styloid processes; the skin is lifted, the wrist is forcibly flexed, the joint is opened

by a transverse cut, and a long semilunar palmar flap which includes only the skin and fascia is made by dissection. Kocher prefers to amputate by an oblique incision. The lower end of this incision is about the middle of the palm and the upper end is in the line of the wrist-joint (Fig. 851). The hand is strongly flexed, the extensor tendons are divided, the posterior

Fig. 850.—Modified circular amputation of the forearm (Bryant).

ligament of the joint is incised, and incisions below the styloid processes divide the lateral ligaments and certain tendons. The flexor tendons are separated from the bone and are divided so as to remain in the palmar flap.

Amputation through the forearm may be effected by the circular method (Fig. 851), the modified circular, or the flap operation. The modified circular is an excellent plan. A semilunar dorsal skin-flap and a semilunar skin-flap on the flexor surface are made. The flaps are raised, the muscles are

Fig. 851.—Disarticulation of the middle finger. Disarticulation at the wrist-joint. Amputation through the forearm by the oblique circular method (Kocher).

cut circularly (Fig. 850), the interosseous space is cleared with the knife, a three-tailed retractor is applied, the periosteum is pushed up, and the bones are sawn half an inch above the flap. In sawing the bones, start the saw upon the radius, draw it from heel to point, make a furrow on the radius and

Fig. 852.—Disarticulation of the elbow-joint by the oblique circular method (Kocher).

ulna, and saw both bones at the same time. After sawing, cut away any irregular edge with bone pliers. In the lower third Teale's amputation may

be done, the dorsal flap being the long one. In Teale's amputation rectangular flaps are made. The long flap is equal in width and length to one-half the circumference of the limb at the point where it is to be sawn. The short flap is equal in width to the long flap, but is only one-fourth its length. The two longitudinal cuts are at first taken only through the skin, but the two transverse cuts go at once to the bone. The flaps are dissected up from the interosseous membrane and the bone. In the middle or the upper third of a fleshy arm two semilunar skin-flaps can be cut from without inward, and the muscle can be cut by transfixion.

Disarticulation at the elbow-joint can be done by the elliptical method or by a long anterior and short posterior flap. In Kocher's oblique operation the incision begins anteriorly over the joint-line and ends posteriorly a hand's breadth below the summit of the olecranon (Fig. 852). A posterior flap which contains the integument, insertion of the triceps, the anconeus, and periosteum is dissected up until the posterior surface of the humerus is reached. The joint is opened anteriorly by a transverse incision,

Fig. 853.—Use of Wyeth's pins in amputation at the shoulder-joint. The acromion is marked by a black line (Keen).

and the radiohumeral articulation is opened from without inward (Kocher). In the double flap operation the forearm is partly flexed and a skin cut marks out a long anterior flap, the knife being entered opposite the external condyle and being withdrawn one inch below the internal condyle. The muscles, which are bunched forward, are cut by transfixion. A posterior semilunar flap is made, which separates the attachments of the radius, the ulna is cleared, and the triceps is cut at its insertion (Bell). Gross advocated sawing through the olecranon and the inner trochlear surface.

Amputation of the arm is best performed by marking out with a knife two equal semilunar anteroposterior flaps, the first cut being carried through the skin alone, the muscles being then transfixed with a long knife. Teale's method is shown in Figs. 380 and 381. The circular or the modified circular amputation may be performed.

Disarticulation at the Shoulder-joint.—In this operation some surgeons use Wyeth's pins to hold the Esmarch band in place. The anterior pin is entered at the middle of the lower margin of the anterior axillary

fold, and emerges one inch within the tip of the acromion. The posterior pin is entered at a corresponding point on the posterior axillary fold, and emerges more posteriorly than the first pin and an inch within the tip of the acromion. After the extremity has been drained of blood by the Esmarch bandage or by stroking and a vertical position, the Esmarch band is applied above the pins (Fig. 853). With a competent assistant, however, the pins are not necessary, the surgeon divides his main vessels as the last step of the operation, and the assistant controls them before they are cut and until they are tied, with his thumbs slipped back of the bone.

Fig. 854.—Amputation at the shoulder joint: *a, b, c, d*, Larrey's operation; *f, g*, Dupuytren's operation.

Larrey's Operation.—In this method of shoulder-joint disarticulation the limb is held from the side and an incision is made down to the bone, the incision beginning just below and in front of the acromion and running vertically for four inches down the outer surface of the arm (Fig. 854, *a b*). From the center of this incision an oval incision (*c d, c e*) is carried around the arm, the inner aspect of the oval reaching as low as the lower end of the vertical cut. The oval incision at first involves only the skin and subcutaneous tissues. The anterior structures are divided close to the bone, and the posterior structures are next cut. To disarticulate, cut the capsule transversely upon the head of the bone; while the arm is rotated outward cut the subscapularis, and while the arm is rotated inward cut the supraspinatus and infraspinatus and the teres minor. Cut away any

Fig. 855. Disarticulation at the shoulder-joint by Kocher's method (Kocher).

Fig. 856.—Removal of the entire upper extremity (Kocher).

tissue holding the humerus to the body, hanging nerves, capsule-fragments, and tissue-shreds, insert a tube, and sew up the wound vertically. Bell advises an oval incision with a racket handle. Spence used an anterior racket incision.

Kocher's Operation.—Kocher makes an anterior lanceolate incision (Fig. 855). The incision begins over the clavicle just external to the coracoid process of the scapula, and is carried downward, dividing, as it advances, the anterior fibers of the deltoid muscle. "Bleeding vessels and the cephalic vein are ligatured. In the upper part of the wound the acromial branches of the

acromiothoracic artery are also ligatured. The bone at the edge of the deltoid (only the upper divided). The capsule is divided over the lesser groove. The periosteum, the insertions of the major, latissimus dorsi, and teres major are detached. The capsule, along with the insertions of the and teres minor muscles, is also detached from and from the great tuberosity. The head of the humerus is extruded from the wound. In cutting down on the chest it is necessary to ligature the circumflex arteries; they must be tied. The racket incision is now cut circularly at the level of the axillary folds. The vessels are easily isolated, the former being ligatured and the latter cut. "Text-book of Operative Surgery," translated by J. B. DeBorja, cautions us to avoid the circumflex nerve when the deltoid is the muscle of the stump.

Dupuytren's Operation.—In Dupuytren's operation a U-shaped flap is marked out by a skin-incision. If the amputation is to be at the right shoulder, the arm is raised and the knife is entered at the root of the acromion, forced under the skin, and is withdrawn at the coracoid process, then the flap is pulled off from the chest. If the left shoulder is the site, the procedure is reversed (Treves). The knife is then used to raise a flap composed of this muscle, the disarticulation is effected as in Larrey's method, the back of the bone and a short internal flap is cut out.

Lisfranc's amputation is by transfixion with a wire and a posterior flap, and can be performed very easily.

Amputation of the Entire Upper Limb.—*The Interscapulo-thoracic Amputation.*—This is an amputation above the shoulder joint, when the scapula and the humerus are removed.

Fig. 7. Removal of the whole upper extremity.

By it are removed the scapula and the humerus, or the entire upper limb. It is employed in cases of malignant tumor of the shoulder joint. The operation is performed by making a large incision on the right side of the chest, and as a preliminary measure the axillary artery should be ligated. According to the necessity, the scapula is divided by the outer and middle thirds of the bone; ligates are then used to cut the anterior flap, and the posterior flap is marked out by dividing the skin by dividing the skin with the scalpel blade to the chest. The operation is very bloody. Fig. 8 shows the operation. Fig. 9 shows the result.

The usual procedure of tying the axillary artery as a preliminary measure possesses

artery is very deeply situated at this point, is in close relation with the pleura, and is covered to a considerable extent by the vein; and the phrenic nerve is very near. Le Conte resects the entire clavicle before tying the vessels. He maintains that then one of two courses may be taken: The veins may be severed first, and afterward the artery may be exposed and tied. When this is done, the amount of blood remaining in the arm is lost. The procedure that he selects as the best, however, is to expose the axillary artery as high up as possible, and place a temporary ligature around it; then elevate the arm, empty it of blood, place a permanent ligature around the third part of the subclavian artery, and divide the artery in this portion of its course (Robert G. Le Conte, "Annals of Surgery," Oct., 1902). If the scapula is involved in the tumor, the mortality is something over 23 per cent. (Berger, "Revue de Chir.," Aug., 1905).

Amputation of the Toes and the Foot.—Only through the great toe is *partial* amputation performed, and it is effected by the formation of a long plantar flap, just as a long palmar flap is formed from the finger. Amputation at the metatarso-phalangeal joints is performed by an oval or racket incision (Fig. 858, c). Amputation of a toe with removal of its metatarsal bone is shown in Fig. 858, *a b* and *d e*.

Disarticulation at the Tarsometatarsal Articulation.—**Lisfranc's Operation** (after Treves).—In order to amputate the right foot by

(after Treves).—In order to amputate the right foot by this method begin an incision on the outer border of the foot, behind the tubercle of the fifth metatarsal bone; carry the incision forward one inch and sweep it across the foot half an inch below the tarsometatarsal articulations; bring the incision to the inner edge of the foot, half an inch in front of the articulation of the tarsus with the first metatarsal bone, and carry the cut straight back along the inner margin of the foot until it reaches a point three-fourths of an inch above the articulation of the metatarsal bone of the great toe. A very short semilunar dorsal skin-flap is thus formed. Fig. 864 shows the flaps as cut by Kocher. After the skin-flap has been dissected back for a quarter of an inch the tendons are divided, and the flap, which now contains all the soft parts, is dissected back to *above* the joint. A long plantar flap is cut, reaching from the origin of the first flap to the necks of the metatarsal bones; the skin-flap is dissected up until the hollow behind the heads of the metatarsals is reached, when, with the toes in extension, the tendons of the plantar muscles are divided. The plantar flap composed of all the soft parts is dissected up to above the joint. Figs. 865 and 864 show the line of Lisfranc at the articulation. The joint is opened from the outer side according to the rule: in separating the fifth metatarsal direct the edge of the knife toward the middle of the first metatarsal; in separating the fourth metatarsal direct the edge of the knife toward the distal end of the first metatarsal; in separating the third metatarsal direct the edge of the knife toward the middle of the first metatarsal; in separating the second metatarsal direct the edge of the knife toward the distal end of the first metatarsal; in separating the first metatarsal carry the knife almost directly across. The separation is completed by bending down the front of the foot, and at the same time the peroneus brevis and tertius are divided. Open

Fig 450 - Lines in amputations of the foot (Guinea).

Fig. 85b Amputation of the toes with and without the metatarsal bones.

surfaces. The greatest difficulty is met with at the inner side in clearing the projecting sustentaculum tali" (Kocher's "Text Book of Operative Surgery," translated by Harold J. Stiles).

Disarticulation at the Ankle-joint. —Syme's Method.—The foot is held at a right angle to the leg, and a skin incision is carried, from just below the external malleolus, straight across or a little backward across the sole to a corresponding point on the opposite side. Do not take this incision near to the inner malleolus, as to do so will endanger the posterior tibial artery. The incision is carried to the bone, the flap being pushed back and separated from the bone by means of a strong knife and the thumb nail until the tuberosity of the os calcis has been reached. The foot is now extended and a transverse cut is made across the dorsum, joining the two ends of the first incision; the ankle-joint is opened, the lateral ligaments are cut, disarticulation is effected, and the foot is finally completely removed by severing the tendo Achillis. A thin piece of bone including both malleoli is sawn from the tibia and fibula. The flap is perforated posteriorly to secure drainage (Fig. 381).

Pirogoff's Method.—Flex the foot to a right angle with the leg. "Make an incision from the tip of the internal malleolus across the sole a little in front of the long axis of the tibia, to a point in front of the apex of the external malleolus down upon the bone."* Dissect the flap backward from the calcaneum for a quarter of an inch, but do

Fig. 868. Lines of section of the os calcis and the bones of the leg in Pirogoff's amputation.

not dissect the flap from the posterior portion of the os calcis. Join the extremities of the first incision by another at which reaches to the bone, and which is "an inch in front of the lower extremity of the tibia" (Bryant), but saw off this bony projection obliquely and leave it adherent to the tissues. The saw is used after disarticulation of the ankle joint; it is passed behind the astragalus, cutting downward and forward, sawing the os calcis obliquely and leaving a considerable portion in place in the flap. The lower ends of the tibia and fibula are well exposed by raising the anterior flap slightly. The sawing is begun anteriorly just above the articular surface, and is completed half an inch above the articular surface posteriorly. The lines a and b (Fig. 868) show the sections made by the saw. The sawn surface of the os calcis is brought into contact with the sawn surfaces of the tibia and fibula, and the flaps are sutured.

Amputations of the Leg.—The so-called "point of election" is at the

*"Operative Surgery," by Joseph D. Bryant.

upper part of the middle third of the leg. Seventy years ago Liston advised surgeons not to amputate in the lower third of the leg because of the scantiness of the soft parts, because the stump is apt to ulcerate, and because it is uncomfortable in an artificial leg. These views have been much modified. The amputation near the ankle is safer than the amputation near the knee, and artificial legs are now made which may be worn with comfort. In amputations of the leg by the *long anterior flap*, cut through the skin, dissect up the anterior muscles with the flap, and cut all the posterior tissues

Fig. 869. — Diagrammatic representation of amputation of the leg after the method of Bier.

with a single transverse sweep. Amputation by the *rectangular flap*, Teale's method, is very useful (see page 1404). The long flap is anterior, and is in length and breadth equal to one-half the circumference of the limb. The short flap is one fourth the length of the long flap. The flaps are dissected up, the bones are sawn, the long flap is turned upon itself, and its edges are sutured to the edges of the short flap.

Bier suggests a plan (Fig. 869) to increase the supporting power of the stump after a leg-amputation. After the wound has healed, a wedge-shaped piece of bone is removed above the level of the stump. The lower extremity is turned forward and upward through an arc of 90 degrees, and unites in this position (Zuckerkandl's "Operative Surgery"). Thus the medullary cavity is closed and the skin which must bear pressure is healthy and free from cicatrices; and as the muscles are still attached to the bone, they do not undergo atrophy.

Sédillot's leg-amputation (Fig. 870) is by a long external flap. A longitudinal incision is made along the inner edge of the tibia, the tissues are drawn toward the fibula, a knife is introduced and passed to the outer edge of the tibia, just touching the fibula, and is brought out posteriorly, thus transfixing the calf muscles and cutting an external flap. A convex incision is made on the inner side, the bones are cleared and are sawn one inch above the flaps, half an inch more being taken from the fibula than from the tibia, and the tibia being bevelled anteriorly.

Fig. 870. Sédillot's amputation of the leg (Wyeth).

Modified Circular Amputation of the Leg.—Cut semi-lunar skin flaps, lay them back, and cut circularly to the bone at the edge of the turned up flap. Another method of modified circular amputation is by adding to the circular cut a vertical incision down the front of the leg. In sawing the bones of the leg the surgeon, who stands to the outer side of the right leg or to the inner side of the left leg divides the fibula first, and at a higher level than the tibia, and bevels the anterior surface of the tibia. In sawing the left fibula the saw points to the floor, in sawing the right fibula it points to the ceiling.

Amputation of the Leg by a Long Posterior and a Short Anterior

Flap.—In this operation a posterior U-shaped flap is made equal in length and breadth to the diameter of the limb. The skin-incision is begun one inch below the point where the bone is to be sawn, and behind the inner edge of the tibia, and is carried to a point posterior to the peronei muscles. The

Fig. 871.—Amputation of the leg by a long posterior flap (Gross)

gastrocnemius muscle is divided transversely at the level of the flap, the soft parts on either side in the line of the flap being cut to the bone. Through these vertical cuts the muscles are lifted from the bones and are divided through their lower part by cutting from within outward. The anterior flap is formed by making a semilunar skin-flap and by cutting the muscles across at its retracted edge (Fig. 871).

Amputation of the leg by lateral flaps is not a popular operation, as it offers too much encouragement to subsequent protrusion of the bone.

Amputation just below the Knee.—The seat of election is one inch below the tuberosities. No muscle is needed in the flap. Cut two flaps of skin equal in size and semilunar in shape, these flaps beginning anteriorly two inches below the tuberosity of the tibia. One flap is antero-external and the other is postero-internal. The flaps are pulled up, the anterior muscles are cut as high up as possible, and the posterior muscles are cut through the middle of the portion exposed (Bell). The bone is sawn one inch below the tuberosity.

Disarticulation of the Knee. In disarticulation by the long anterior flap, make a long anterior skin flap, incise the ligament of the patella, turn up a flap containing the patella, open the joint, and complete the disarticulation by cutting from within outward and downward. The knee may be disarticulated by means of a long anterior and a short posterior flap. Kocher prefers the oblique incision (Fig. 872). This secures an anterior flap. The leg is

Fig. 872.—Kocher's oblique incision for disarticulation at the knee-joint (Kocher)

held that it makes an angle with the thigh of 135 degrees and "the incision falls in the continuation of the long axis of the thigh" (Kocher's "Text-book of Operative Surgery," translated by Harold J. Stiles). The posterior part of the incision is opposite the line of the joint and the anterior part of the incision ends four finger breadths below the tibial tubercle.

Amputation through the Femoral Condyles.—Syme's Method by a

Long Posterior Flap.—Carry a skin-incision, with a very slight downward curve from one condyle to the other, across the middle of the patella. Cut down to the bone, retract the flap, and cut the quadriceps above the patella. Insert a long knife at one angle of the wound, pass it back of the femur, and make it emerge at the opposite angle, cutting a posterior flap eight inches long. Retract the posterior flap, clear for sawing, and section the condyles horizontally. Carden made a curved section of the condyles at their widest part. In children Buchanan showed that we can easily separate the lower

Fig. 873. —Diagrammatic representation of Gritti's operation.

Fig. 874. Diagrammatic representation of Sabanejeff's operation.

femoral epiphysis. In *Gritti's supracondylar amputation* an oblique incision is made. The upper end of the incision is posterior and just above the condyles. Its lower end is anterior and two finger-breadths below the patella (Kocher). The ligament of the patella is cut, the flap is turned up, the femur is sawn at the base of the condyles, the articular face of the patella is sawn off, and the sawn patella is fastened to the sawn femur and the flaps are sutured (Fig. 873). Sabanejeff makes an anterior flap, opens the knee-joint from behind, saws the condyles at their broadest part, takes a bone flap from the anterior portion of the tibia and fastens it to the femur (Fig. 874).

Amputation of the Thigh. —

In high amputation in the *lower third* either a flap or a circular operation may be performed. In a double flap operation a semilunar skin incision should be made from without inward, and the muscles should be cut by transfixion (Fig. 875). In the lower third Teale's flap or the long anterior flap may be employed. The amputation by a long anterior flap consists in making a lengthy skin-flap, reflecting it, cutting the anterior structures to the bone, again

Fig. 875. —Amputation of the thigh. Bryant

entering the long knife at one angle of the incision, pushing it back of the femur, bringing it out at the outer angle, and cutting the structures behind the bone directly backward. Bell amputates by a long anterior semilunar

flap and a short posterior flap. In amputations in the *upper two-thirds* of

Fig. 876. —Pancoast's aorta tourniquet.

the thigh the best plan is to mark out equal anterior and posterior semilunar skin-flaps, divide the skin with a scalpel, enter the long knife at one angle of the anterior flap, bring it out at the other angle, and cut the muscles by transfixion. Cut the posterior flap in the same manner. Some surgeons prefer a long anterior semilunar flap and a short posterior semilunar flap. The pure circular amputation is not adapted to the thigh.

Disarticulation at the Hip-joint.

—Various methods have been employed to prevent or limit hemorrhage during this formidable operation. Abernethy used digital compression of the external iliac artery or of the femoral artery. This is an extremely tiresome procedure; the finger is liable

to slip; and, in any case, compression so situated fails to intercept the blood-current in a number of large vessels.

Various other methods have been employed. It was formerly the custom to compress the aorta by means of an abdominal compressor (Figs. 876, 878). A tourniquet is very likely to be displaced during the operation. The intention is to compress the artery against the spine, but in effecting this the circulation in a portion of the intestine may be impaired. In any case, as Senn says, the circulation is cut off from half the body, and the patient is exposed to grave danger from "sudden vascular engorgement of important internal organs" (Senn). Again, an abdominal compressor of this sort does not arrest venous bleeding. A number of years ago Davy suggested that a suitable cylindrical piece of wood, about 25 inches long, and shaped like a cone at the end, might be introduced into the rectum and used to compress the common iliac artery upon the pelvic brim. This appliance is known as *Davy's lever*. It is apt to slip, and may do serious damage to the rectum.

Some surgeons have practised preliminary ligation of the common femoral artery or of the external iliac artery, and others have tied the vessels while making the flaps. I followed this

Fig. 877. —Posterior flap on subject of unusual case requiring hip-joint amputation. *a* δ The posterior incision. *c*, *d* the external iliac artery and the beginning of the posterior cut.

plan with perfect satisfaction in a recent case of sarcoma of the femur with involvement of the iliac glands. If any form of compression is used, that recommended by Macewen, of Glasgow, is the most successful and satisfactory (Fig. 879). The weight of the assistant's body is thrown upon the patient's aorta by the right fist, placed slightly to the left of the umbilicus. McBurney has suggested the prevention of bleeding by making a small abdominal incision and having an assistant make direct digital pressure upon the iliac artery. I employed McBurney's method in a recent case and found it most satisfactory. In this case a sarcoma of the thigh reached up so far that no band could be applied above it and I was obliged to make the posterior flap shown in Fig. 877. If the constricting band of Esmarch is applied by the

Fig. 878. - Von Eschmarch's aorta tourniquet.

Fig. 879. - Macewen's method for compression of the abdominal aorta ("American Text-Book of Surgery").

ordinary method, it is certain to slip. It may remain in place if applied as a figure of eight of the thigh and the pelvis, but even then it is uncertain.

The most satisfactory method in the great majority of cases, is Wyeth's, in which the constrictor is held in place by the preliminary passage of two steel pins. Trendelenburg's method consisted in passing one pin and winding an elastic tube about it. Wyeth applied the principle and greatly improved the method. The outer pin is inserted an inch and a half below and a little internal to the anterior superior spine of the ilium, and is brought out just back of the great trochanter.

The inner pin is entered one inch below the level of the crotch and internal to the saphenous opening, and it emerges an inch and a half in front of the tuberosity of the ischium. A sterile cork is pushed on the end of each pin, to save the surgeon from wounding himself upon the sharp points. After the limb has been emptied of blood by

holding it in a vertical position for five minutes and stroking it from the periphery toward the body, the constricting band is fastened about the limb above the pins.

Fig. 880. — Amputation at the hip-joint—Wyeth's bloodless method

In the *bloodless method of Wyeth* (Figs. 880, 881), after the passage of the pins and the application of the band of the Esmarch apparatus, the amputation is proceeded with. The hip is brought well over the edge

Fig. 881.—Wyeth's bloodless amputation at the hip-joint. Cuff of skin and calotaneous is turned back; muscles divided at level of small trochanter; bone partly stripped and large vessels exposed for deligation.

of the table, a circular incision is made down to the deep fascia, six inches below the constricting band, and is joined by a longitudinal skin-cut reaching from the band to the level of the circular incision, and the cuff is

Fig. 882. —Senn's method of performing bloodless amputation at the hip-joint. Dislocation of head of femur and upper portion of shaft through straight external incision. Elastic constrictors in place, the anterior one tied (Senn).

Fig. 883. —Elastic constriction completed by constricting the posterior segment of the thigh. Flaps formed including all the tissues down to the muscles (Senn).

reflected to the level of the lesser trochanter. A circular sweep at the level of the retracted skin is opened freely, the cotyloid ligament is bent upward, forward, and inward to dislocate, and, using the thigh as a handle, the round ligament is removed. After ligating the vessels and introducing the stump, the wound is sewn together vertically. The old transverse scar is extinct. A *T-amputation* may be employed. A straight incision down to the bone, starting on the outer side of the limb, and a circular incision below the constricting band, the muscles being reflected to the level of the retracted skin. This method is applicable to the hip joint, and is an advance on the older method of prevention of dislocation by a straight length of the axis of the bone. This is an inch or more great, and the great insertion of the bone, strong and forward, is aided in the while of the operation. Then, and the

Fig. 884.—Keen and DaCosta's case of interilio-abdominal amputation. The shaded portion of the bone was removed ("International Clinics," vol. iv, 19th series).

this cannot be accomplished, the head of the bone is removed from the dorsum of the ilium. After dislocating, the part of the femoral shaft are cleared. The straight line with the body, the thigh is slight of forceps is inserted into the wound behind the normal situation of the lesser trochanter, downward and inward, two inches below the behind the adductor muscles. As soon as the an incision two inches in length is made upon through the opening. The tunnel in the tissue is made with the forceps. A piece of rubber tubing three-quarters of four feet in length is caught about the middle

drawn. The rubber tube is cut in two at about the point at which the forceps have held it, and half of the tube is used to constrict the anterior segment of the thigh (Fig. 882) and the other half to constrict the remaining portion of the thigh (Fig. 883). Before the constricting bands are tied the limb is held vertically for a sufficient length of time to make it practically bloodless; the amputation is then completed (Senn's "Practical Surgery").

Other Methods.—John G. Sheldon ("Amer. Med.," April 19, 1902) has modified Senn's method as follows: He disarticulates the head of the femur and frees the upper part of the femur from its attachments. He then introduces a pair of long, stout artery-forceps behind the femur and clamps the femoral vessels. He forms the flap, removes the limb, and ligates the vessels. In this operation the surgeon can work rapidly and can make a flap of any size or shape, and is not hindered by a constriction apparatus; but this method does not cut off the bleeding from the obturator and the sciatic arteries.

Larrey amputated by lateral flaps, and Liston by anteroposterior flaps. Forneaux Jordan's method consists in dividing the soft parts low down, tying the blood-vessels on the face of the stump, shelling out the femur from the soft parts, and disarticulating.

Interilio-abdominal Amputation.—This very formidable operation is occasionally performed for sarcoma of the ilium. The operation was first performed by Billroth in 1891, and the patient died. Dr. Keen and I collected 19 cases, including 1 of our own. Five of these cases recovered (W. W. Keen and J. Chalmers DaCosta, in "International Clinics," vol. iv, 13th series). Our patient perished in thirty-three hours from suppression of urine and with gangrene of the parts supplied by the internal iliac artery. In some cases the entire innominate bone has been removed, in others portions of it have been left. In our case we made the flap shown in Fig. 884, tied the internal iliac artery after rolling up the peritoneum, but spared the external iliac, kept the femoral in the flap, and sawed through the bones as indicated in Fig. 884), leaving in place the portions shown in white.

Fig. 885. Keen and DaCosta's method of interilio-abdominal amputation ("International Clinics," vol. iv, 13th series).

XXXVIII. DISEASES OF THE MAMMARY GLAND.

Hypertrophy of the Breast (Fig. 886).—This is a rare condition. It may affect one breast or both. It is most apt to appear at the age of puberty, but it may appear in childhood, adult life, or old age. The breast may attain enormous size. In Porter's case the breasts of a woman of thirty-seven were so very large that they were carried hung upon a frame ("Boston Med. and Surg. Jour.," March 3, 1892).

These very large breasts are not composed of true gland tissue, but rather of fat and connective tissue (Sheild). Hypertrophy may also occur in the male breast. In some cases hypertrophy occurs so rapidly as to merit the name acute. Such cases may perhaps be sarcomatous.

Treatment.—Be sure it is hypertrophy and not sarcoma, adenoma, or lipoma. Try recumbent posture, dry diet, pressure, and iodid of potash (Sheild). If these means fail, amputation is the only resource.

Mammillitis and Fissure.—The nipple may inflame as a result of injury, but the condition is rarely encountered except in a woman who is nursing a baby. It is most common after a first pregnancy, when the nipple is deformed or when the skin is delicate. The nipple is slightly injured during nursing, and the epithelium is macerated by the milk and saliva. If the inflammation is not arrested, a spot excoriates or an irritable ulcer forms (a fissure). A fissure is often surrounded by an area of acute inflammation, and nursing causes intense agony. Because of the pain the mother is apt to

extend the intervals between nursing, and as a consequence the breasts become swollen with retained milk. The ulcer not unusually bleeds when the breast is taken by the child. Besides the facts that a fissure causes pain to the mother, it often leads to grave trouble. It is a suppurating area, and as such may lead to abscess of the mother's breast, or may impair the health of the nursing child.

Prevention of Fissure.

—During pregnancy the nipples should be carefully attended to. They should be washed often in sterile water and bathed in alcohol, and if retracted, ought to be drawn out repeatedly. During the period of lactation the nipples are washed in sterile water, dried, and dusted with borated talc powder as soon as

Fig. 886.—Hypertrophy of Breast (Horwitz)

an act of nursing is completed. Washing the nipples regularly with the following solution tends to prevent the formation of a fissure: iodid of mercury, gr. ij; alcohol, 3iss; glycerin and distilled water, ññ a pint (Lepage). If a small abrasion appears, order the woman to wear a nipple-shield during nursing, and after each act of nursing to wash the part with hot sterile water, dry, and dust borated talc over the surface. If a fissure forms, wean the child at once, and dry up the milk in both breasts. It is useless to try and dry it up in one breast. Milk may be dried up by applying ointment of belladonna locally, and administering iodid of potassium internally; by strapping the breasts with adhesive plaster (Parker); or by applying to the nipples six times a day a 5 per cent. solution of cocain in equal parts of glycerin and water (Joise). The fissure is not treated by ointment.

These preparations are septic, prevent drainage, and aggravate maceration. Wash the fissure twice a day with peroxid of hydrogen, dress it with gauze wet in boric-acid solution (gr. x to 5j of water), and cover the dressing with waxed paper. If the fissure resists treatment, touch it with lunar caustic.

Acute Mastitis and Abscess.—Acute inflammation of the breast, as a result of injury of the breast or nipple, may occur in either sex at any time of life. Very commonly in both sexes a few days after birth the breast becomes distended with a material which in reality is milk. The fluid is usually small in quantity. The process is physiological, and, as a rule, ceases spontaneously (Guelliot). If it lingers, the application of belladonna ointment will stop secretion. If the nurse meddles with and tries to squeeze out the fluid, acute mastitis is apt to arise in one gland, or occasionally in both. The skin of the breast reddens, the gland swells and becomes tender and painful, the child loses its appetite and becomes feverish, restless, and sleepless. Such a condition is treated by the local use of lead-water and laudanum. If pus forms, the local signs and constitutional symptoms are aggravated. Evacuate the pus, dress with hot antiseptic fomentations, and be sure that the child is well nourished. Tonics and stimulants are indicated.

A condition identical with the secretory activity of the glands of the newborn may occur in either sex at puberty. The methods of treatment are the same in both cases. As a matter of fact, rarely more than one lobule at this period inflames, and suppuration is most unusual.

Mastitis is most usually met with in a woman who is nursing a child, and is due to bacterial infection. Primipara are particularly liable to develop mastitis. So are women with deformed nipples. In many cases an abrasion of the nipple exists, and through this breach of continuity bacteria gain entrance to the breast-tissue. The abrasion may be so slight that it can only be detected when the nipple is examined through a magnifying-glass (Marmaduke Shield). Streptococcal infections are very generally due to inoculation of a fissure of the nipple. Bacteria may pass up the milk ducts, coagulating the milk and penetrating through the walls of the acini. Staphylococci not unusually pursue this route in reaching the breast-tissue. Occasionally causative bacteria reach the breast through the arteries (in septicemia and in septic wounds of the genital organs).

Symptoms.—There are pain, swelling, and tenderness in the breast, and in most cases a fissure or abrasion exists. There is a febrile condition. Occasionally a chill ushers in the attack.

Treatment.—Order the patient to suspend nursing. The physician endeavors to arrest the secretion of milk. Treat the nipple as advised on page 1420. Support the breast and apply ichthyol ointment or lead water and laudanum.

Mastitis may undergo resolution; it may terminate in organization and induration; it may eventuate in suppuration.

Acute abscess of the breast follows acute mastitis. There may be but one area of suppuration, or multiple foci may exist, which eventually fuse. The symptoms of mastitis, local and constitutional, are greatly aggravated. After a time the skin becomes dusky and edematous. The axillary and superficial cervical glands enlarge. The abscess will eventually open spontaneously at one or more points, leaving branching fistulae. A super-

ficial abscess is situated just beneath the nipple, and pus may flow from the nipple.

An intramammary abscess is in the depths of the gland. There are often multiple foci of suppuration. Nodules are felt in the gland, pus may run from the nipple, but cutaneous redness is late in appearing.

Retromammary abscess is a rather rare condition. It may occur alone or be associated and connected with an area of inframammary suppuration. It may result from metastasis or from caries of a rib. The breast is lifted up by the fluid beneath it.

Treatment.—Open a superficial abscess by an incision radiating from the nipple. Treat as any other acute abscess. An intramammary abscess should be opened by a radiating incision, and pockets of pus should be broken into with the finger. An examination is made to determine if a retromammary abscess also exists. If this is found to be the case, an incision is made at the point of junction of the thorax and mammary gland, and at the lower border of the gland. The gland is raised from the chest wall, the pus evacuated, a drainage-tube is inserted, and a few sutures are introduced. If retromammary abscess exists alone, make the last named incision in the first place.

Chronic Mastitis.—This condition may be present in only a portion of the breast, or may attack many lobules (lobular mastitis). The ordinary form may arise after weaning a child, or may be due to a blow, to the pressure of corsets, or to numerous slight traumatisms. It may occur in the young, the middle aged, or the old. The patient has slight pain at times in the gland. Examination detects a firm, elastic area, which is somewhat tender and does not possess distinct margins. The skin is not adherent to the mass unless suppuration occurs. If the mass is pressed against the chest by the surgeon's fingers, it becomes evident that no real tumor exists.

Treatment. Remove any cause of irritation. Support the breast in a sling. Apply ichthyol ointment. During the night employ a hot water bag. If pus forms, treat as before directed.

Chronic lobular mastitis is a condition in which numerous lobules become indurated. The real cause of this condition is unknown. It may occur at any age after puberty, and often attacks both breasts. Such a breast is apt to be painful, especially at the menstrual periods, it feels unnatural, solid, and careful examination detects numerous indurated areas each of which is of small size. At the menstrual period the breast enlarges and new nodules may be detected. In some of these cases violent neuralgic pains are present in the gland (mastodynia). Chronic lobular mastitis tends to lead to cyst-formation. When cysts form fluid may occasionally discharge from the nipple.

Treatment.—Support the breast and apply ichthyol ointment or bella donna ointment. Examine the generative organs and correct any existing abnormality. Improve the general health by good food, tonics, and open air life. In cases where multiple cysts are known to exist the question of treatment is uncertain. There seems to be little doubt that such cases tend in some instances to eventuate in cancer. I believe that the proper treatment when multiple cysts exist is extirpation of the breast.

Tuberculosis of the Mammary Gland.—Sir Astley Cooper, in 1820, wrote on "scrofulous swellings" of the breast, and Velpeau also referred to

them. Nevertheless, Virchow in his treatise on tumors, stated that the mammary gland was not subject to tuberculosis. Durbar first proved the existence of the condition by histologic or bacteriologic observations. Primary tuberculosis of the breast is a rare condition. If we are to judge from English and American literature, it is a very rare condition, and only about 40 cases confirmed by bacteriologic findings and histologic study have been reported. It is seldom that both glands are involved. Tuberculosis of the breast may be secondary to tuberculosis of the skin, of related glands, of the rib, etc. It may result from some distant tuberculous lesion of bone, of joint, of lung, etc. It may be a part of general miliary tuberculosis. We consider here primary or, as Grissler named it, solitary tuberculosis, tuberculosis apparently limited to the breast in an individual free from evidences of antecedent tuberculosis, and of tuberculosis elsewhere. It occurs usually in those of excellent general health. The route of infection may be by the blood, by the lymph-ducts, and perhaps by the lymphatics from the skin or nipple. E. M. Von Eberts (in "Am. Jour. Med. Sciences," July, 1909) states that there is no reported case before the age of puberty, that the most advanced case reported was fifty three years of age, that maturity of the gland and lactation predispose, and that the reported cases show the proportion of the married to the unmarried as 4 to 1. It is vastly more common in women than in men. In many cases there is a history of antecedent inflammation or abscess during lactation. In some cases there is a history of traumatism. There are two forms of the condition, and in each form, sooner or later, degeneration occurs, and fistula from a cold abscess arises (page 178); these forms are *nodular* and *confluent* (Von Eberts, *Ibid.*). In the *nodular* form a nodule, several nodules, or many nodules arise in the glandular tissue. There is little or no pain. If nodules are under the nipple retraction may occur. The condition is very slow in progress and a year or several years may elapse before degeneration occurs. Degeneration results in cold abscess (page 155) or fistula formation. Schley has pointed out that cold abscess is a termination more common in the confluent than in the nodular type ("Annals of Surgery," 1903). In the confluent form the condition develops much more rapidly, is associated with pain, is most apt to arise during lactation, is particularly prone to abscess and fistula formation, and is liable to acute exacerbation from secondary pyogenic infection. The axillary glands are found enlarged in three fourths of all cases of primary tuberculosis. Cases have been reported of carcinoma and adenoma associated with tuberculosis.

Treatment. In a very slowly developing nodular case, in which it is certain lactation will not arise, it may be considered proper to treat the condition with tuberculin, etc. (see chapter on Tuberculosis). In the confluent form and in cases of the nodular form in which tuberculin treatment has failed, or in which we cannot exclude the possibility of pregnancy, the breast should be removed and the glands and fat should be removed from the axilla. Most of the cases recover permanently after radical operation (see Braendle, of Tübingen, in *Beit. Z. klin. Chir.*, 1906, Bd. 1).

Cysts and Tumors of the Nipple.—Tumors are rare in the nipple, but do sometimes occur. The following growths are occasionally seen: fibroma, angioma, papilloma, myxoma, myoma, and epithelioma. Sebaceous cysts of the nipple and areola are not very unusual. A cancer of the nipple may be a primary growth, or may be secondary to gland cancer.

Primary epithelioma of the nipple presents as an epithelioma in any other region. It begins as a sore or an excoriation of the nipple. Ulceration follows, circular in outline, has hard edges, and furnishes a purulent discharge. The mammary gland becomes indurated. The subclavian glands enlarge, and later growth must not be confounded with a chancre.

Treatment of Tumors of the Nipple. In the early stage the nipple and the breast need not be removed.

Epithelioma of the nipple requires the removal of the nipple and also the clearing out of the lymphatic cords in the axilla and of the subclavian triangle.

Paget's Disease of the Nipple (Mammary Paget's Disease) is a chronic inflammation of the epithelium of the areola occurring in women beyond middle life. It is often associated with epithelioma of the nipple and of duct cancer. It is not associated with the usual cutaneous eczema, it is not associated with the usual cancer, either local or constitutional, and is not cured by the ordinary disease.

The diseased area is raw and red, and furnishes a yellow discharge. In some cases Paget's disease is due to auto-infection of the nipple having been effected by the ducts. Investigations have shown the presence of Paget's disease.

Treatment consists in removal of the nipple and the axilla.

Tumors and Cysts of the Mammary Gland may be innocent or malignant. Tumors may be of the following kinds (sarcoma, fibro-adenoma). Malignant tumors are about twenty-five.

Innocent Tumors of the Mammary Gland are. *Periductal fibroma, fibrocystadenoma, adenoma, periductal fibromyxoma, myxoma, and* etc. It is maintained by most authorities that an innocent tumor may and often does become malignant.

Periductal Fibroma, Fibro-adenoma. This is a state of great confusion. The term is used by Cornil and Ranvier to the same sort of growth called a fibroma, Billroth an adenofibroma, and others a mammary tumor. It is doubtful if a pure fibro-adenoma is a gland. A fibro-adenoma consists of acini and connective tissue. Each of these structures proliferates, but the fibrous tissue proliferates more rapidly than the glandular. Bloodgood says (Feb., 1908) "the fibro-adenoma microscopic section shows a circumscribed area of normal breast tissue, in which the glandular stage of the tumor, is greater in amount than the fibrous. The parenchyma undergoes pressure atrophy and is replaced by fibrous tissue." A growth of this character is surrounded by a capsule. It is firm, elastic, lobulated, superficially situated.

unassociated with retracted nipple, glandular enlargement, adhesion to the skin, or cachexia, and may occur at any age up to fifty, but is most common between twenty and thirty (J. Bland Sutton). Such a tumor is rarely very painful, but it may be tender on rough handling and may be painful at the menstrual period. As a rule, there is but one of these tumors in a mammary gland, but the tumors may be multiple in one gland, or one may exist in each gland. It is not very common for sarcoma or carcinoma to arise.

Periductal Fibromyxoma.—It is most common in young women. It may be multiple in one breast or both. It is an encapsuled, lobulated, and elastic growth, which is seldom painful, usually small, and often remains quiescent indefinitely or even disappears. It may enlarge and even attain a large size. When it enlarges it is apt to become cystic and sarcomatous.

Treatment of Periductal Fibroma or Fibro-adenoma—Extirpation of the tumor. A tumor known to be innocent may be removed through an incision made along the junction of the mammary gland and breast, at the lower margin of the gland, as Thomas proposed, or, better, at the edge of the outer hemisphere, as advocated by Warren ("Annals of Surgery," June, 1907). The incision exposes the fibers of the great pectoral muscle, the gland is raised from the muscle, and its posterior surface exposed. Any growth is exposed by an incision from center to periphery and this incision is exploratory. Warren removes an innocent tumor, a cyst, or cysts by a V-shaped incision, the apex of the V being at the center of the gland, and he wisely insists that the tumor is not to be dissected out. Several radiating incisions may be necessary to explore a cystic breast. The V-shaped space from which the tumor or cyst was removed is closed by a double row of catgut sutures. Incisions for exploration seldom need to be closed with suture. The gland is sutured to the outer edge of the pectoral fascia, and a row of sutures is inserted through the deep layer of the superficial fascia. Warren calls this operation "*plastic resection of the breast*." It leaves the patient free from deformity.

Fibrocystadenoma or **cystic adenoma** (**adenocoele**) is a rare form of slowly growing tumor, which is apt to attain a large size, which is nodular in outline, hard to the touch, and firmly attached to the mammary gland, but mobile upon the chest. A cystic adenoma has a distinct capsule. This form of tumor is painless, and is most apt to occur in women between thirty and forty who have borne children. The growth is adherent to the skin, but the cutaneous surface is not discolored, the cutaneous veins are not distended, the axillary glands are not enlarged, and the nipple is not retracted. From the walls of the dilated acini papillomatous growths are apt to arise (intracystic vegetations).

Treatment.—Extirpation.

Papillary Cystadenoma.—This condition is often called villous papilloma or duct papilloma. There is much more epithelial proliferation than in the fibrocystadenoma, and the warty masses project into the cyst cavities. These growths are firm, grow slowly and painlessly, and seldom fluctuate. They do not adhere to the skin, attain a large size, or cause glandular enlargement. They are situated near or under the nipple, and occur particularly in middle life. Discharge of bloody fluid from the nipple is a common symptom.

Treatment.—Extirpation.

Simple Adenoma. This is a very rare tumor. It occurs in young and

middle-aged women. It is soft, nodular, and freely movable. It does not adhere to the skin and does not cause lymphatic involvement. It consists of glandular acini and a very delicate stroma of connective tissue. It tends to become cancerous.

Treatment.—Extirpation.

Myxoma is a rare tumor, and only occurs in a person of middle age. The growth is solitary, is soft, may be round or lobulated, and occasionally fungates. The nipple is not retracted, the superficial veins are not distended and the axillary glands are not enlarged.

Treatment.—Removal of the mammary gland.

Angioma.—This form of tumor is very rare. It may arise secondarily to a nevus of the skin (Sutton). The diagnosis of angioma of the skin is readily made. In a cavernous angioma of the breast it will be found that the tumor can be lessened in size by pressure, and will be increased in size by coughing, laughing, and holding the breath. Pulsation may be detected and a bruit may be audible.

Treatment.—For treatment of nevus see page 361. If a cavernous angioma exists in the mammary gland, it will be necessary to extirpate the gland.

Lipoma and enchondroma occasionally occur in the breast.

Cysts of the Mammary Gland. **Involution cysts** (cystic degeneration of the mamma) occur in women who are approaching the menopause. They occur earlier in those who are sterile than in those who have borne children, and may arise after chronic mastitis. The parenchyma of the gland undergoes atrophic change, but the ducts remain become blocked and dilated. Numerous small cysts form, and both glands, as a rule, suffer. Adipose growths may arise in the walls of the ducts. In some cases there is much white fibrous tissue between the cysts (cystic fibroma).

The subjects of this disease are often nervous, hysterical, and despondent. One or more ill defined indurations are detected. Frequently there is a history of discharge from the nipple and of attacks of lancinating pain in the breast. Cystic breasts are dangerous, because the intracystic vegetations are liable to eventuate in duct cancer.

Treatment.—In such cases, after confirming the diagnosis by an exploratory incision, remove the entire breast (Snow).

Lacteal cyst (galactocoele) is an accumulation of milk brought about by blocking of some of the milk-ducts. It arises soon after the delivery of the child, and grows rapidly. A large quantity of milk may collect and rupture of the cyst-walls can occur, the fluid passing into the glandular connective tissue.

A galactocoele is rounded, fluctuates distinctly, and increases in size during nursing. There is little or no pain. In some cases the contents of the cyst coagulate and a solid mass is formed.

Treatment.—Incision and drainage.

Hydatid cysts are rare, but do occasionally occur. There are no positive cases on record (Le Conte, in "Amer. Jour. Med. Sciences," Sept. 1880). A small, hard, movable, and painless mass appears in the mammary gland. Usually it gradually increases in size, but it may grow rapidly for a time and then remain apparently almost stationary for a period. If rapid growth takes place there is always pain, and pain is usual in any case when the cyst

attains considerable size. Fluctuation is often absent and crepitation is never obtained (Le Conte). Suppuration is apt to occur and sinuses may form.

Treatment.—A small and recent cyst may be extirpated. If the cyst is not recent, but is fairly large and adherent, incise, evacuate, and pack with gauze. If the cyst is large and adherent, but is surrounded by considerable breast-tissue, partially amputate the breast (Le Conte). If the cyst is large and the breast practically destroyed, or if the nipple adheres to the cyst, remove the mammary gland (Le Conte).

Malignant tumors of the mammary gland are ten times more common than innocent tumors. We should regard every palpable tumor in the gland as malignant until it is proved to be innocent. In other words, we reverse the rule of jurisprudence. We regard every tumor as guilty of malignancy until its innocence is proved. If the mistake is made of regarding an innocent tumor as malignant, the woman loses her breast. If a malignant tumor is regarded as innocent the woman loses her life.

Sarcoma.—Sarcoma of the mammary gland is a very rare growth (not over 3 per cent. of breast tumors). It may occur at any age from puberty to old age. It was long thought to be most common from twenty to thirty-five years of age, but Rodman's investigations show that one half the cases occur in the fifth decade of life (Rodman on "Diseases of the Breast"). The growth may be composed of round cells or spindle cells; both varieties may be present, and myeloid cells may be found. Circumscribed sarcoma arises usually between the ages of twenty and thirty; it is firm to the touch, as it contains much fibrous tissue, is painless, does not grow very rapidly, glands are not involved, and there is no cachexia. The nipple is not retracted. The growth may adhere to the skin. It is composed of giant cells or spindle cells, and rarely returns after extirpation of the breast.

Diffused sarcoma is composed of small round cells, arises in the center of the breast, and grows with great rapidity. It is most commonly met with about the age of thirty-five, and a history of injury can often be elicited. The tumor is soft, some parts being softer than others because of cyst formation. It is usually mobile upon the thorax, though it soon becomes adherent to the skin. The tumor reaches a very great size, and soon fungates through the skin. There is little or no pain. The cutaneous veins over the tumor are distended, the nipple is not retracted, and the axillary glands are not often enlarged. Diffuse sarcoma is apt to recur after removal.

Treatment.—Remove the breast, and if the muscles of the chest-wall are infiltrated, remove them. The axillary glands should be removed whether or not they are enlarged. Operation will not cure when metastases exist. If the case is inoperable, we can try the use of Coley's fluid. If the toxins of erysipelas fail to arrest the progress of the disease, keep the patient as comfortable as possible by the administration of cocaine and morphin.

Endothelioma.—This is a very rare tumor. I have had one case of it. The diagnosis cannot be made from carcinoma.

Treatment.—As for cancer.

Carcinoma or Cancer of the Mammary Gland of the Female (Fig. 837).

—The great majority of mammary tumors belong to the genus carcinoma. Cancer is due to proliferation of the epithelium of the acini (acinous cancer) or of the ducts (duct cancer).

Acinous cancer is vastly more common than is much connective tissue and but little parenchyma (encephaloid or medullary cancer). In some cases there is little connective tissue (encephaloid or medullary cancer). In some cases parenchyma or stroma occurs, the growth is

Scirrhus, the common form of acinous cancer. On section it is concave, and Sutton says "the tumor is without a capsule, and the epithelium is of fibrous tissue. Portions of tissue, even

Fig. 887.—Scirrhus carcinoma (J. C.)

tumor, contain foci of proliferating embryos or withering scirrhus the fibrous stroma contains fatty degeneration (Senn)

Halsted in 1898 described *adenocarcinoma* in the direction of unrestrained epithelial proliferation. The tumor shows the formation of tubular acini and resembles adenoma. Adenocarcinoma is not cancer. In the common forms the proliferati

blance to glandular structure, but multiplies irregularly in connective-tissue spaces or lymph-spaces.

Causes and Symptoms.—*Scirrhus* is more common among women who have borne children than among those who have not. Heredity is manifest in only about 10 per cent. of cases. The younger Gross found it in 1 case out of 9. Trauma has no apparent influence in producing cancer. The disease is rare before the age of thirty-five, and is most common between forty-five and fifty. The author operated for scirrhus of the breast on a woman only twenty-seven years of age. Henry saw a woman of twenty-one with cancer. It is frequently met with in the aged. These tumors are rare

Fig. 888. Carcinoma of right breast. Lesion first noticed six months before photograph was made.

in the negro race. A hard nodule is found in the breast, usually under the nipple, but possibly far away from it. The growth is nodular, and is immobile from the beginning. In a large, fat breast there is often a deceptive sense of mobility, because some of the breast tissue moves with the tumor. The cancer may have been present for a considerable time before being discovered. Sometimes wide-spread lesions develop from a small or an undiscovered breast cancer (pleural effusion, enlarged glands of the neck, disease of the spinal cord, bones of skull and brain). In obscure lesions of bones and viscera examine the mammary glands, because the trouble might be due to metastasis from an undiscovered carcinoma of the breast. What Osler calls *mastitis carcinomata* is a wide-spread regional metastasis, affecting one or both breasts and beyond them, and which attains a considerable size in a very few months. The breast soon becomes enormous and brawny, the skin is infiltrated, there are no nodules, the glands above the clavicle usually enlarge, and the arm may swell. Metastases may occur within the chest, either by lymph regurgitation from the axillary and subclavian glands, or directly through the chest walls to pleura and lung or to mediastinal glands. Retrac-

tion of the nipple is present in over one-half of the cases. It occurs when the growth is near the nipple, and is due to the contracting fibrous tissues of the tumor pulling on the milk-ducts. If the growth is far away from the nipple a dimple is apt to form on the skin of the breast because of the pulling upon the suspensory fibers.

Glandular enlargement in the axilla soon follows the appearance of a scirrhus; the glands become very hard and adherent. In over 60 per cent of persons the glands of the axilla are felt to be enlarged when the patient first comes for treatment. Because the surgeon cannot feel enlarged glands is no proof that there are none. As a matter of fact, the glands are usually involved within two months of the beginning of the disease, but the involvement can rarely be detected externally until months later. Enlargement of

Fig. 889.—Recurrent carcinoma. Cancer en cuirasse.

the axillary glands is followed by enlargement of the glands in the posterior cervical triangle and in the mediastinum. Herbert Snow has shown that the blocking of the axillary glands often leads to regurgitation of lymph containing cancer-cells, the cells being thus deposited in the head of the humerus and the thymus gland. Cells in the thymus, after a time, cause a projection of the sternum (the *sternal symptom*). When the axillary lymphatics are extensively involved, the arm swells from obstruction to the lymph-flow (lymphoedema) or pressure upon the vein. The tumor usually grows rather slowly unless lactation is established; then it grows rapidly. As it grows it infiltrates adjacent structures (the pectoral fascia, pectoral muscles, subcutaneous cellular tissue, and skin). When the skin is destroyed, an ulcer forms, and around this ulcer the skin becomes red and filled with cancerous nodules, which feel

like shot in the skin. Metastases are apt to occur into the bones, liver, brain, pleura, spine, thymus gland, and rarely the eye.

Pain is usually present in scirrhus carcinoma. It is lancinating and neuralgic in character, and not brought on or increased by handling. It

Fig. 890.—Recurrent carcinoma of the breast.

ceases if colloid degeneration begins. The general health is usually unimpaired until ulceration takes place, when cachexia arises. The *cancer en cuirasse* of Velpeau is a condition in which the lymphatic vessels of the skin are extensively invaded, the growth itself being adherent to the wall of the

Fig. 891.—Ulcerating scirrhus carcinoma.

thorax. In this condition the chest-wall is fixed, respiration is difficult, and the temperature is commonly somewhat elevated.

In *atrophic* or *withering scirrhus* the contraction is so great that it seems as though the mammary gland had been removed. The duration of scirrhus, when left to run its course, varies, but the disease generally produces death

within two and a half years. Occasionally it causes death within a year. In atrophic scirrhus the patient may live for many years.

Duct cancer is not a common growth. It arises from the duct-walls in conditions of cystic degeneration of the mammary gland. The tumor is softer than the acinous growth and is not nodular. There is no pain, no retraction of the nipple, no skin dimple. Serous or bloody fluid may often be squeezed from the nipple. A duct cancer grows and infiltrates less rapidly, and involves adjacent glands later than does an acinous growth.

Cancer of the Male Breast. This condition is seldom met with, though I believe it to be more common than is generally supposed. I have seen 3 cases within the last ten years. Each patient was in the early forties; neither complained of pain. In one, the breast had been extremely large from early years. In each case the growth was indurated, but in neither was there any retraction of the nipple. The condition in each patient was scirrhus carcinoma. Warfield has collected 32 cases from literature and has added 5 others ("Bull. of Johns Hopkins Hosp.," Oct., 1901). The patients were between forty and seventy years of age; 8 gave a history of injury; in 9 cases there was pain, and in 12 the nipple was retracted. Palermo has collected 752 cases of tumor of the male breast ("Semaine Médicale," May 20, 1908) and 649 of them were cancerous.

Treatment of Carcinoma of the Mammary Gland.—The treatment is early and thorough operation; the earlier and the more thorough, the better. The older surgeons operated simply to prolong life a few months, the modern surgeon operates with the hope of curing the patient. The mortality of the operation is surprisingly small. It is certainly under 2 per cent. Rodman's statistics (2133 operations performed since 1893 by twenty-one American surgeons) show a mortality of less than 1 per cent. I have personally lost 4 patients in over 200 operations. In 1878 Billroth's statistics showed only 8 cures in 143 cases. In 1896 W. Watson Cheyne reported 12 cures out of 21 cases (57 per cent.). His cases now show 54.8 per cent. alive and well from six to thirteen years after operation. Depage's statistics show that 48 per cent. of cases passed the three-year limit ("Presse Médicale," Oct. 21, 1908). Greenough, Simmons, and Burney consider 320 cases operated upon radically ("Annals of Surgery," July, 1907); 88 cases passed the three-year limit. Bloodgood ("Am. Jour. Med. Sciences," Feb., 1908) sets forth Halsted's statistics:

"The statistics in Halsted's clinic up to the present time show that among 210 cases, in which three years or more have passed since the operation, 4.1 per cent. are apparently well. If we consider the cases in which the axillary glands, studied microscopically, showed no evidence of metastasis, 61 cases, or 85 per cent., are well. In cases in which the axillary glands showed metastasis (110), 30 per cent. remained free from recurrence for three years. When the glands in the neck showed metastasis (40 cases), only 10 per cent. remained well for three years. In all of these groups metastasis has been observed after an interval of three years of apparent cure. Such late metastasis may take place up to eight years after operation. Excluding these cases of late recurrence, the definitely cured in these three groups is reduced to 75, 24, and 7 per cent. respectively, or, for all cases together, 35 per cent. I have not time to give the facts, but there is evidence to indicate that when the microscope fails to

demonstrate metastatic cancer cells in the lymphatic glands in the axilla, this is not a positive proof that metastasis has not taken place, and for this reason and others, which space prevents me from stating, there should be no restriction in the complete operation for carcinoma of the breast." It will be observed that of these 40 cases, with involvement of neck and axilla, only 4 passed the three-year limit. If they had not been operated upon, statistics would have been bettered. The surgeon who would not operate on such cases would have a higher percentage of cures for his statistics, but he would have sacrificed to statistical glory these 4 cases. If there is the *slightest* doubt of the diagnosis, make an exploratory incision before making the incisions for the removal of the breast (see Dawbarn's remarks on the deceptive signs given by thick-walled abscesses in the "Annals of Surgery," March, 1908). If the mass proves to be cancer, I always pack in a piece of gauze just wrung out of boiling water and go on at once with the removal of the breast. As Dawbarn shows, this method seals up the open mouths of lymphatics. A radical operation should remove the breast and much of the skin above it, the pectoral fascia, the pectoral muscles, the fat and glands of the axilla, and the fascia over the serratus magnus. As Cheyne says, remove all the glands along the axillary vein and lift up the vein at the apex of the axilla and remove the glands and fat behind it. The sheath of the vein should always be removed. Cheyne points out that the line of spread must be traced upward along the vessels and nerves and downward along the external respiratory nerve of Bell ("Lancet," March 12, 1904). If three years after an operation there has been no return, we regard the case as cured (Volkmann's limit). As a matter of fact, recurrences are noted after five years, and this limit should be used instead of three years. It is true that 80 per cent. of those passing the three year limit remain free from recurrence. Over 90 per cent. of those passing the five-year limit remain free. Coley reported 65 cases of recurrence—15 per cent. recurred after three years and 6 per cent. after fourteen years. Karsenhoff collected 10 cases of recurrence during the seventh and eighth years, 2 each after the ninth, tenth, eleventh, twelfth, and fifteenth years, and 1 each after, at various intervals, from fifteen to twenty five years. Martin suggests that these later so-called recurrences are really new growths in persons predisposed to cancer ("Annals of Surgery," Oct., 1908). Certain cases are unsuited for a radical operation: cases in which metastases exist; cases of *cancer en cuirasse*; cases where axillary involvement is very great. Cheyne would also rule out cases where large glands may be felt above the clavicle, believing that in such cases the mediastinal glands must be cancerous.*

Halsted's Operation. Halsted performs a very radical operation. He removes suspected tissue *in one piece*, and thus prevents carcinoma cells falling into the wound, for it is well known that if such cells should fall into the wound they may grow just as may a graft of healthy epithelium. The neck, shoulder, the arm to the elbow, the entire surface of the chest down to the waist, both breasts, the axilla, the side and the back of the diseased side must be sterilized. It is necessary to have, besides scalpels and the ordinary instruments for an operation, a great number of hemostatic forceps (80 to 100). Place the patient recumbent, with a sand-pillow under the shoulder of the affected side. The shoulder is right at the edge of the bed, and a nurse holds

*See "Objects and Limits of Operation for Cancer," by W. Watson Cheyne.

the arm from the side. Halsted describes his operation as follows:† The skin-incision is made as shown in Fig. 892, and is carried at once through the fat. The triangular skin-flap (*a, b, c*) is turned down. The costal insertions of the great pectoral muscle and the muscle are split between the clavicle and

Fig. 892.—Halsted's operation for carcinoma of the breast, the first incision.

costal portions and up to a point opposite to the scalene tubercle, and at this point the clavicular portion of the muscle and the tissue overlying it are cut through close to the clavicle, and the apex of the axilla is at once exposed. The cellular tissue under the clavicular portion of the muscle is dissected from the muscle, and the splitting of the muscle is continued on to the humerus.

Fig. 893.—Halsted's operation for carcinoma of the breast, the mass turned down.

The part of the muscle to be removed is cut through close to its humeral insertion. The whole mass circumscribed by the first incision (skin, breast, areolar tissue, and fat) is raised with considerable force in order to put the submuscular fascia on the stretch as it is stripped from the thorax close to the

† Johns Hopkins Hosp. Reports, vol. iv, *Annals of Surgery*, Nov. 1894.

ribs. It is well to include the delicate sheath of the pectoralis minor muscle. The lower and outer boundary of the lesser pectoral having been passed and exposed, the muscle is cut at a right angle to its fibers and a little below the middle. The tissue over the pectoralis minor muscle near its coracoid insertion is divided as far out as possible, and is then reflected inward to prepare for the reflection upward of this part of the minor muscle. The upper portion of the minor muscle is retracted upward. Some surgeons do not remove the lesser pectoral muscle. I believe it should be removed, because the axilla can then be more easily and rapidly cleared. The removal of the muscle does not impair arm movements, and its retention leads to the formation, when healing is complete, of a cord-like band in front of the axilla. (See Douglas Drew, in "Brit. Med. Jour.," May 17, 1902.) The small blood-vessels under the minor muscle are carefully separated from it, are dissected out very clear, and are ligated close to the axillary vessels. Having exposed the subclavian vein at the highest possible point below the clavicle, the contents of the axilla are dissected away with a sharp knife and the vein and its branches are stripped absolutely clean. The loose tissue about the artery and the nerves should also be removed. When the vessels are cleared, the axillary contents are rapidly stripped from the inner walls of the axilla and the lateral wall of the thorax (Fig. 893). The fascia which binds the mass to the chest is cut close to the ribs and the serratus magnus muscle. Just before reaching the junction of the posterior and lateral walls of the axilla an assistant draws the triangular flap of skin outward in order to spread out the tissue which lies upon the subscapularis, teres major, and latissimus dorsi muscles. The operator cleans the posterior wall of the axilla from within outward. The subscapular vessels are clearly exposed, and are caught before they are cut. In some cases the subscapular nerves are removed, in others they are permitted to remain. Having passed these nerves, the mass is turned back into its normal position and severed from the body of the patient by a stroke of the knife from *b* to *c*, repeating the first cut through the skin. Every bleeding point, however small, is tied with fine silk. From 60 to 100 ligatures or even more may be required.

After the completion of the operation the wound into the axilla is closed with a subcuticular stitch of silver wire; if a cut has been carried above the clavicle, it is closed in the same manner, and the edges of the elliptical opening are brought nearer together by a purse string subcuticular stitch. Thiersch grafts cut from the patient's thigh are used to cover the gap. Silver foil is placed over the wound, this is covered with gauze, bandages are applied, and the dressing is overlaid by a plaster-of-Paris bandage, which includes the head, neck, chest, and arm. The area from which grafts were taken is dressed with sterile gauze or an ointment containing boric acid.

Formerly I did not open the subclavian triangle. I believed that these

Fig. 894. — The younger Semm's incision for amputation of the breast.

glands were involved only from the axillary lymphatics, that when they were involved the mediastinal glands were sure to be affected (the route to them being more direct) and operation was certain to be useless. When the subclavian glands are involved from the axillary lymphatics this is true, but in some cases they are involved by way of the direct lymph paths from the mammary gland. In such a case the mediastinal glands may be free, and cleaning out the subclavian triangle may save the patient. I always open the subclavian triangle and clear out fat and glands if no glands or only a few small glands were palpable before operation. If there is a large glandular mass in the triangle, operation is useless. I always open the triangle if the tumor of the mammary gland is in the upper hemisphere, or if I discover enlarged glands at the apex of the axilla, whether there are or are not small palpable glands above the clavicle.

The Younger Senn's Incision—A very useful incision is that described by the younger Senn, and shown in Fig. 894. The breast is circumscribed by two curvilinear incisions which meet above, at the border of the great

Fig. 895. Jabez N. Jackson's incision for removal of the mammary gland.

Fig. 896. Method of approximating flaps after breast amputation.

pectoral muscle. The incision is continued a little internal to the outer border of the muscle to about 1 inch above the apex of the axilla, when it is curved outward in the deltoid region, and terminates at the level of the apex of the axilla. The breast is removed from the wall of the chest, and is then suspended by axillary glands and fat, which are removed *en masse*.^{*} This incision gives a free exposure, opens the axilla from in front, enables the surgeon quickly to locate and freely expose the axillary vein, and the resulting scar does not materially limit the motions of the arm.

Jackson's Incision (Jabez N. Jackson, "Jour. Am. Med. Assoc.," March 1, 1906) is shown in Fig. 895. The axilla is entered from above, a quadrilateral flap of skin is raised, and is subsequently pulled down to and inclosing the wound (Fig. 896).

Warren's incision is shown in Fig. 897. It enables the surgeon to close the wound.

^{*} See the younger Senn in Jour. Amer. Med. Assoc., May 27, 1899.

Willy Meyer's Operation ("Jour. Amer. Med. Assoc.," July 29, 1905).—For the last three years I have been performing the operation devised by Willy Meyer. I consider it a most excellent procedure, with distinct points of superiority over other plans. We owe to Gerster the principal of opening the axilla in the beginning of the operation in order to prevent the diffusion of cancer cells and so diminish the chance of rapid recurrence. Gerster's paper was published in the "American Jour. of Med. Sciences" in 1888. The younger Gross, in his later years, used to open the axilla first when there was an axillary mass, but he did it in order to determine in the beginning of the operation if the axillary mass was really removable. Willy Meyer emphasizes the value of his procedure in lessening hemorrhage. In Meyer's operation two flaps are formed by the skin-incision (Fig. 898)—a lower and an upper flap. The incision for the formation of the lower flap begins at the point of insertion of the great pectoral muscle on the humerus, and is carried

Fig. 897.—Warren's incision for removal of the mammary gland.

Fig. 898.—Willy Meyer's operation for carcinoma of the breast. Skin incision as practised since 1893.

downward and inward $\frac{1}{4}$ inch above the border of the muscle and parallel to it. When the incision reaches the base of the mammary gland, it

is carried along the lower margin of the gland, and it ends over the sternum, a little beyond the mid-line (Fig. 898). The lower flap is separated and turned down, a quantity of subcutaneous fat being allowed to remain attached to the breast. This turning down is carried to the border of the latissimus dorsi muscle, to the axillary cavity, and to the chest-wall. Meyer then directs that the border of the latissimus dorsi be followed down to the serratus anticus major, and upward to the mass of fat that enters the bicipital sulcus of the arm. The fat is removed from the anterior border of the muscle by blunt dissection. This anterior lower wound is then packed with gauze.

The surgeon next forms the upper flap by uniting the inner and outer ends of the first incision with another incision carried along the upper margin of the breast (Fig. 898). In this flap, as in the other, the surgeon leaves as

Fig. 899.—Willy Meyer's operation for carcinoma of the breast. Insertion of pectoralis major muscle exposed. Operator's left index-finger exciting its tension.

much subcutaneous fat adhering to the breast as he can spare without inducing the danger of skin-necrosis. This upper flap is raised progressively until the cephalic vein is reached and there is exposure of the lower surface of the clavicle with the sternoclavicular articulation. Meyer directs that the tissues covering this articulation shall not be disturbed.

After the formation of these two flaps the next step in the operation is the division of the tendons of the two pectoral muscles and the exposure of the axillary and subclavian veins. Meyer advises that the cephalic vein be followed up until the insertion of the great pectoral muscle into the humerus is found. The tendon is fully exposed, care being taken to bare it of a distan-

fat. The arm is then carried a little nearer to the side to relax the great pectoral muscle. This tendon is cut off close to the humerus (Fig. 899). The muscle is pulled downward and inward and is loosened from the cephalic vein. It is then cut off near the lower border of the clavicle and the sternoclavicular articulation. It is necessary to divide the nerves that enter the pectoral muscle, and all the vessels that come into view are divided between two clamps and tied.

The next step is to divide the tendon of the lesser pectoral muscle near the coracoid process (Fig. 900). Just beneath this tendon lies the subclavian vein. The surgeon now makes a transverse division of the fascia over the axilla, and thus exposes the axillary and subclavian veins (Fig. 901).

Meyer's third step is to split the axillary fat over the upper portion of the latissimus dorsi up to the axillary vein, "thus dividing it from the mass of fat that enters the sulcus bicipitalis brachii."

Next, the axillary and the subclavian veins are followed up to where the

Fig. 900.—Willy Meyer's operation for carcinoma of the breast. Finger under tendon of pectoralis minor muscle. Above, cut surface of clavicular portion of pectoralis major parallel to clavicle is visible. In the living, the belly of the pectoralis major is not so thoroughly detached from that of the pectoralis minor. It is done here to show the latter's tendon.)

subclavian passes below the clavicle, and every vessel that evidently must be cut is divided between two ligatures and tied. This procedure saves a great amount of hemorrhage. Meyer directs us to be careful to preserve the two superior subscapular nerves, although the third subscapular must be sacrificed.

The next step in the operation is to have the assistant hold up the mass of partly loosened tissues without pulling upon them; for if he does pull upon them, Meyer truly says, he is apt to tear off pieces of periosteum or perichon-

drium; and such bare spots are liable to become necrotic. The surgeon now cuts to the wall of the chest, being careful not to damage the great serratus muscle. Meyer cautions us at this step to hold the blade of the knife horizontal; that is, "perpendicularly toward the thorax." "If he (the surgeon) should not thus turn the blade of his knife, but cut perpendicularly downward toward the subscapular muscle, he would enter the fat covering and enveloping the nerves and blood-vessels of this region, thus running the risk of unnecessarily causing considerable hemorrhage and of injuring the subscapular nerves. In the general run of cases this region need not be explored; only in very advanced cases did I find a few injected glands in this area."

The pectoralis major muscle is now divided close to the wall of the chest, the cuts being parallel to the ribs, and almost level with them, and the mass being gently drawn toward the sternum. By watching carefully, one may

Fig. 901.—Willy Meyer's operation for carcinoma of the breast. Subclavian and axillary veins fully exposed. So far, glands and fat tissue not removed; smaller vessels still in connection with main trunks. Finger under fat toward axilla; nail resting on axillary vein.

see the perforating arteries and veins drawn out by traction before cutting them, and may usually catch each of them with two clamps and divide between the clamps. If this is impossible, they are divided and quickly pressed up. The last tissue that holds the mass to the chest-wall is composed of the muscle fibers from over the sternum. These are divided close to the sternum (Fig. 902). The final steps consist in tying all blood-vessels, draining, and suturing the wound. The draining is done through a perforation in the

posterior flap. It may be tubal or by gauze. Gauze has the advantage of restraining oozing of blood.

This operation has noteworthy merits. It can be performed far more rapidly than can any other method that I have ever employed. The loss of blood is comparatively trivial, because in this operation the chief blood-vessels are divided close to the axillary artery and tied. In removing the mass from the chest-wall there is little bleeding, except what comes from the perforating vessels, hemorrhage from the branches of the axillary being entirely absent; and even many of these perforating vessels are tied before being divided. We are far less apt by this method than by the usual plan to

Fig. 902.—Wally Meyer's operation for carcinoma of the breast. Pedicle of mass over sternum ready to be cut off.

milk lymph-containing cancer cells into the wound, or in aberrant directions through the lymphatics. As Dawbarn says, the squeezing "of the breast by the retractors during its oblation, as also its handling when separated, save for its attachments to the armpit," are real dangers and may be responsible for rapid recurrence of the growth ("Annals of Surgery," March, 1908). The drain is removed in from thirty six to forty-eight hours. The patient is placed in a sitting posture on emerging from ether and is allowed out of bed on the fourth or fifth day.

Dressing and After-treatment.—The dressing must be wide and ample. Fluffed up gauze is pushed into the axilla to obliterate the dead space and the arm is bound to the side for forty-eight hours, when the binding is removed, the extremity is placed on a pillow, and is moved a little more each day. If

the incision was placed well above the axillary border the mobility of the arm will be such that in two weeks the patient can place the hand on the back of the head. Some surgeons place the arm at once after the operation in abduction (upon a pillow or a triangular splint which rests upon the side). This is unnecessary if the incision does not run into the arm and in front and above the anterior axillary margin. If the old incision in the axilla is made early, abduction and all other plans will fail to prevent limitation of movement.

Inoperable Malignant Diseases of the Breast.—This term implies that a radical operation looking to cure is impossible. The conditions in which it is impossible have already been specified (page 1432). Even if the case is judged inoperable from the radical standpoint, it may be wise to remove the mammary gland, in order to free the patient from a hideous, ulcerating area, violent pain, and harassing hemorrhage.

It has been suggested that some cases inoperable by ordinary methods may be subjected to removal of the entire upper extremity or to disarticulation at the shoulder-joint with some prospect of cure. My own view, however, is that when a case has advanced so far that it is not amenable to ordinary operative treatment, neither of the above-mentioned procedures offers any reasonable chance of success. If the pain is extremely violent in an inoperable case, the surgeon may relieve it by dividing the brachial plexus, or perhaps by disarticulating at the shoulder-joint.

An inoperable case may be greatly improved—for a time, at least—by the use of the x-rays; and even when the condition is not benefited in other ways, this new force sometimes mitigates or greatly relieves the pain.

Beatson's Operation, or Double Oöphorectomy.—It has been pointed out by this surgeon that there is a certain similarity between the formation of cancer in the mammary gland and the process of lactation. In each there is an enormous production of embryonal epithelial cells; but in lactation the epithelial cells undergo fatty degeneration, and in cancer formation they do not do so, but penetrate into the tubules and the acini and infiltrate the gland-structure. Beatson further points out that when a lactating cow is spayed, it continues to give milk indefinitely. This seems to indicate that removing the ovaries favors the fatty degeneration of the epithelial cells. This operation has been performed in cases of inoperable carcinoma of the breast, in the hope of bringing about degeneration in the tumor-mass. In the great majority of cases it fails utterly; but now and then it secures a notable improvement, and in a very few cases cure seems to have been obtained. Abbe obtained an apparent cure in two patients. It was at first thought that the operation would be applicable only to persons that have not passed the menopause, but one of Abbe's patients was over seventy years of age. Butlin, however, says that there is no genuine cure secured by this operation on record. My own view is that the procedure offers but little prospect of success, but that, as it does offer some, the exact facts should be placed before the patient, and she should be permitted to choose whether or not she wishes the operation performed. The operation is not to be considered, however, if visceral deposits exist.

XXXIX. SKIAGRAPHY OR RÖNTGENOGRAPHY (THE EMPLOYMENT OF THE X-RAYS). THE FINSEN LIGHT; BECQUEREL'S RAYS; RADIUM RAYS.

The Röntgen or x-Rays.—The cathode rays were discovered by Hittorf, in 1869, while passing an induction current through a vacuum tube. Crookes, of London, greatly improved the vacuum tube, and obtained a rarefaction which left in the tube but one-millionth of an atmosphere. This last-named observer found that when an interrupted current of high potential is passed through a vacuum which is nearly perfect, fluorescence takes place. In a Crookes tube the positive electrode is placed at some indifferent point, and the current from the negative electrode flows not to the positive, but directly to the wall of the tube opposite the cathode, and at this point the phosphorescent glow is detected.

In 1895 Röntgen, of Würzburg, while making a study of cathode rays as developed in Crookes tubes, discovered the energy which he named the *x*-rays. Röntgen showed that at the wall of the Crookes tube opposite the negative electrode a new and hitherto unknown energy is generated. Because of the uncertain character of this energy he gave to its manifestation the name of the *x*-rays or unknown rays.

The *x*-rays are invisible; cannot be deflected, refracted, or concentrated; are not influenced by the magnet, and produce none of the ordinarily recognized effects of heat. The rays cannot be polarized, travel with the velocity of light, and cause fluorescence in certain substances, notably in the tungstate of calcium (Edison), platino-cyanid of barium (Röntgen), and the platino-cyanid of potassium. They have a marvellous power of penetration. Freund says ("Radium Therapy"), "Speaking broadly one may say that the lighter the specific gravity of a body the more transparent is it to *x*-rays. On the other hand, a body's opacity for the rays increases with its density, though not in the same proportion." "V. Novak and O. Sule, also Voller and Walter, proved that the transparency of a body to *x*-rays depends less upon its density than upon its atomic weight."

The *x*-rays in their action on photographic plates or films exhibit actinic effects. If, therefore, an object whose component parts are of unequal density—e. g., the hand—is placed on a photographic plate protected from ordinary light, and exposed to the action of *x*-rays, the plate when developed by photographic methods will exhibit a picture of the shadows cast by the several parts of the object. Such a picture is known as a skiagraph, radiograph, or a Röntgenograph. Similar shadows will be seen on a fluorescent screen if the object is between an excited *x*-ray tube and the screen. The portion of the screen free from shadow glows with fluorescence. Such a screen is known as a fluoroscope or Röntgenoscope.

The real nature of the rays remains unknown. They resemble the ultra-violet and Becquerel rays in their action on a charged electroscope and in producing fluorescence in certain substances, but the latter have not the penetrating power of the former. Many theories have been advanced, but the most acceptable has been on the electromagnetic theory of light. The difference

between the Röntgen rays and a beam of sodium light is said to be that the thickness of the Röntgen ray pulse is very small compared with the wave length of sodium light, and that in the Röntgen rays there is not that regular periodic character which occurs in a train of waves of constant wave length (J. J. Thompson).

Solid bodies which are struck by the *x*-rays emit new rays having similar properties (Sagnac), known as secondary rays, and less powerful than the primary rays.

For practical purposes we may consider that the *x*-rays have penetrating and actinic properties.

For the production of the Röntgen rays the essential is to have an electric current pass through a Crookes tube of rather high vacuum. The state or degree of vacuum controls the nature of the rays. A tube of low vacuum will emit soft rays of low penetrating power, while the rays from a tube of high vacuum will penetrate even pure sheet lead. The vacuum of a given tube does not remain constant with use, the tendency being for the vacuum to become higher. Some get so high that they cannot be used. All modern tubes have some device by means of which the vacuum may be regulated and controlled.

The soft rays are rich in actinic value, but because of their feeble penetrating qualities are of use only in treating superficial conditions, or for the Röntgenography of thin parts, and where much contrast of shadows is desired. On the other hand, in deep and dense parts satisfactory results can only be obtained with hard rays. In the hands of the experienced operator the quality of the rays is adapted to the condition.

To excite the Crookes tube or, as it is more commonly called, the *x*-ray tube it is necessary to have an electric apparatus capable of delivering a current of high tension and as far as possible unidirectional. Röntgen used the induction-coil of Ruhmkorff. The fundamental parts of an induction-coil are a primary winding, which receives and stores up the electricity from its origin or from its source of supply, an interrupter, to make and break the current, and a secondary winding, which receives the current and delivers it to a negative and a positive pole. Wires carried from these poles to their respective terminals on the *x*-ray tube will complete the circuit.

A static machine is frequently used to excite Crookes tubes, but only the most powerful are of practical value in *x*-ray work. The most recent and powerful apparatus is the Röntgen transformer, invented by Snook, of Philadelphia. The first machine of this type was installed in Jefferson Hospital in June, 1907, and this type is now internationally accepted as the best. Many of the German firms are making a more or less exact copy of the Snook apparatus. This apparatus is an epoch-making advance in the construction of the Röntgen transformer.

The induction-coil is the most widely used apparatus, but it possesses many disadvantages, the chief of which is that its output is not constantly unidirectional. The static machine delivers a current of ideal quality, but one lacking in quantity. The Röntgen transformer has none of the disadvantages of the induction-coil, is capable of an enormous output of a current free from inverse discharge, and in quality approaching that of the static current. The most satisfactory source of current is the ordinary electric lighted circuit.

Physiologic Effects of the Röntgen Rays.—Clinical observations have determined that in small or moderate intensity the Röntgen rays act as a stimulant to cell-growth and metabolism, while prolonged radiation produces cell destruction.

Histologic study shows that the cellular elements of the integument are first affected, and that only after repeated or prolonged exposures are the normal connective-tissue elements acted upon noticeably.

Cell degeneration occurs and is followed by inflammatory changes in the surrounding tissues, notably in the blood-vessels.

After sufficient irradiation this process will go on to endarteritis and necrosis.

The cause of these tissue changes under x-ray exposure has been variously conjectured, viz.: liberation of ozone in the tissues (Tesla); interference with cellular nutrition caused by static electric currents "induced by the introduction of the patient's tissues into the high potential induction-field surrounding the tube" (Leonard); the destruction of the nerve supply of the tissue (Hopkins); irritation of the peripheral extremities of the sensory nerves, causing vasomotor paralysis (Rudis-Jicinsky); "no doubt there is some chemic action which causes metabolic disturbances" (Beck); "the effects of x-rays upon tissues and upon substances sensitive to x-rays are due to actinic properties of the same character as those of light" (Pusey).

It is now generally admitted that the rays themselves are responsible for the tissue changes, and not some external agent, such as electric discharges.

The earliest noticeable effect of exposure to x-rays is a tanning of the skin in dark people or reddening of the skin in blondes. Ormsby has noted this analogy between the action of x-rays and the sun rays.

Glandular structures undergo atrophic changes after repeated exposures. Its action on the nervous mechanism is more difficult to understand, but that it has anodyne effects in certain painful conditions is beyond question. There is also testimony, but not certain evidence, that the x-rays have an inhibitory influence on the sympathetic nervous system. It has occurred that a small ureteral calculus, lodged in the lower end of one ureter for a long period, has passed into the bladder within a few days after x-ray examination.

The influence of Röntgen rays is in many cases distinctly inhibitory to the growth of bacteria.

The untoward effects from overexposure to the x-rays may range from falling out of the hair or slight irritation of the skin to the production of sterility, extensive sloughing or even chronic non healing and painful ulcers, cancer, and death. These effects may be acute or chronic. The patient is more apt to develop acute conditions, while the operator or investigator is constantly in danger of the remote or chronic lesions.

The so called x-ray burn is not a burn, but a dermatitis or a gangrenous process. A burn results from heat, begins on the surface and at once, is accompanied by pain from the moment of its origin, and is followed by inflammation starting from the surface burnt. An x-ray burn does not come in evidence for several days or for a longer time after the application of the cause, and the inflammation begins in the skin rather than upon its surface. So called x-ray burns may be classified by stages or degrees. In a burn of the first degree the skin is hyperemic, more or less tender, and may itch or burn,

there is increased pigment formation and the outer layer of the skin will "pull off" as in sunburn. It may develop any time after a few days, but usually does so in from ten to twenty. Such a condition is popularly known as a "reaction." No treatment is required for dermatitis of this degree, unless there is severe itching or burning, when we may use the following preparation advised by Dr. Martin F. Engman ("Interstate Med. Jour.," July, 1903): It consists of 12 drams of boric acid, 1 ounce of zinc oxid, 1 ounce of starch, 1 ounce of subnitrate of bismuth, 1 ounce of olive oil, 3 ounces of lime-water, 3 ounces of lanolin, and 12 drams of rose-water. The powder is rubbed in a mortar, the lanolin is added. The olive oil and lime-water, mixed, are slowly added to the powder and lanolin. The mixture is stirred, the rose-water is added, and the preparation is beaten into a creamy paste. If itching is severe, 1 to 2 per cent. of carbolic acid is added. The paste is spread on several thicknesses of gauze and the gauze is covered with a rubber dam.

In an "x-ray burn" of the second degree the condition becomes more painful, vesicles or even bullæ are formed, there is swelling, and if the blisters are opened the denuded cutis will weep and is sensitive to touch and to direct contact with air.

This condition requires little treatment beyond aseptic attention and protection from further exposure to x-ray or air.

The "x-ray burn" of the third degree involves all the layers of the skin and more or less of the underlying tissue. In an area of sloughing the slough is white, adherent, tough, and stringy. Hopkins calls the process "*white gangrene*" (G. G. Hopkins, "Phila. Med. Jour.," Jan. 6, 1900). The pain is excruciating and constant, seeming as if "red-hot coals were held against the body." Sloughing may continue for weeks or months, and the exudate is profuse and irritating. The process may eventuate in gangrene of a limb or large area. Such ulcers require months to heal, if they heal at all, and are not improved by the treatment which relieves ordinary burns. Excision with subsequent skin-grafting or amputation may be necessary. In the early stages alkaline astringents give the best results, e. g., a mixture composed of 2 drams each of zinc oxid and bismuth subnitrate, $\frac{1}{2}$ fluidram each of liquor potassa and liquor plumbi subacetatis, 2 drams of glycerin, and sufficient lime-water to make 6 fluidounces.

This mixture may be applied twice daily and will relieve much of the itching and burning as well as control the exudate. It should be applied over a considerable area surrounding the seat of inflammation. Ointments should not be used to relieve pain. Leonard considers them conducive to malignant changes.

In extensive ulceration the wound must be kept as clean as possible and free from irritants. When sloughing ceases and granulation tissue forms, mild stimulants may be applied.

The patient's general health should be improved in every possible manner.

Skin-grafting is not usually successful without excision of the floor of the ulcer, but should be tried. In spite of all treatment the condition may remain a chronic ulcer and be subject to malignant change.

Sometimes the results of an x-ray burn may be most serious. In a case reported by J. P. Tuttle it became necessary to amputate the thigh ("Med. Record," May 5, 1898).

The chronic "x-ray burn" or chronic x-ray dermatitis is seen among operators or men working more or less constantly with the rays. The onset is very insidious. Ulcers may not form for a year or more. The earliest signs of trouble are brittleness of the finger-nails and itching about the matrices. Scratches on the fingers heal sluggishly. The skin atrophies, telangiectases form, vesicles appear and disappear, keratoses develop, fall off, and return. Small ulcers start and gradually heal, reappear, become more extensive, painful, and sluggish. The finger-nails drop off, leave sensitive surfaces, and grow again indifferently or in a misshapen condition.

If exposure is continued the ulceration advances, and the tendons and even phalanges may slough away. Usually when ulceration of this kind has started, the damage is irreparable except through amputation or excision, with, of course, absolute protection from further exposure.

These lesions are most common on the hands, but may occur elsewhere.

That malignant changes take place in chronic x-ray lesions has been definitely shown clinically and by the microscope. Porter, of Boston, has made an extensive study of these lesions, and emphasizes the importance either of excision and skin-grafting or amputation as methods of treatment.

His results are excellent. Palliative treatment should be limited to cleanliness and care.

Sterilization of either sex by use of the x-ray is possible and should be guarded against.

Can the x-rays cause death? The x-rays do not cause death directly, but may inaugurate a lesion which eventually causes death. Death may follow a burn without being directly due to it. Carcinomata have developed in chronic x-ray lesions and produced death; 4 fatal cases have been reported in the United States from multiple carcinomata following chronic x-ray dermatitis (C. A. Porter and C. J. White, paper before the American Surg. Assoc. in 1907).

Unnecessary exposure to x-rays is to be avoided. The operator should remain as far away from the excited tube as possible, and have between it and him a lead screen no less than $\frac{1}{4}$ inch in thickness and of dimensions sufficient to protect his entire person. The patient is to be protected from undue irradiation by means of lead-glass or lead-covered tube-holders and lead diaphragms. In the treatment of lesions beneath the skin some form of filter should be used over the exposed area. Sheet aluminium is commonly used. Pfahler has suggested the use of sole leather.

The function of the filter is to absorb the soft rays, which would be otherwise taken up by the skin and would irritate that structure. With proper care patients may be treated safely and frequently over a long period of time.

The Uses of the Röntgen Rays.—In the hands of trained and experienced workers this agent is a most valuable aid in nearly all branches of medicine and surgery; whereas, in the hands of the untaught and inexperienced, it may lead to grave error in diagnosis, and is, even at the present day, fraught with all the dangers of its early use. The general practitioner should not attempt its use without first having had practical training.

For diagnostic purposes studies may be made by means of the *fluoroscope* or by making Röntgenographs (skiagraphs, radiographs).

Edison's fluoroscope consists of four sides of a box, one end being open and

made to fit tightly over the observer's eyes, the other end being closed with cardboard made fluorescent by smearing it with mucilage, and before the mucilage is quite dry sprinkling it with crystals of tungstate of calcium. If it is desired to examine the hand with a fluoroscope, the extremity is held opposite an excited Crookes tube and from 6 to 10 inches away from it, the end of the fluoroscope, which is covered with fluorescent paper, is placed near the surface of the hand which is away from the tube, and the observer looks through the other end of the instrument. The flesh seems but a dim haze, and the shadows of the bones are distinctly outlined. The fluoroscope is of advantage in the examination of the movable organs of the chest and abdomen. This method, except with special forms of apparatus, endangers both the patient and operator. It was used extensively in the pioneer days and caused the vast majority of injuries to the early workers.

Röntgenographic technic has been wonderfully developed in the last few years. This method has the advantage of safety to patient and operator, as well as permanency of record. With the most improved apparatus a Röntgenograph of any portion of an averaged sized person can easily be made with an exposure of five seconds or less, so that the motion of breathing need not interfere as it did in former years. Children are skiagraphed by instantaneous exposure and seldom require an anesthetic. It is the most valuable agent we have for the study of bone conditions. In fractures the rays enable us to determine the nature of the injury, the amount of splintering, the existence of impaction, the question whether or not the fragments are in contact or can be brought in contact, the direction of the line of fracture, the variety of deformity, the existence of more than one fracture, the presence of epiphyseal separation or dislocation alone or with a fracture, the existence of an ununited fracture, the presence of callus, and if the splints are holding the fragments in apposition. By means of stereoscopic Röntgenographs fractures of any part of the skull can be detected; and the actual relations of the parts in fracture or dislocation of the hip, pelvis, or shoulder can be determined.

Fractures of the spine in the lower dorsal region are difficult to demonstrate in stout persons. In bone disease the experienced Röntgenologist can greatly aid the surgeon in making a differential diagnosis. The dissolved appearance of the bone in myeloid sarcoma without evidence of demarcation differs from the tuberculous bone, which presents a picture of impoverishment of mineral matter, but with more or less distinctly outlined foci of destruction. Bone atrophy due to pressure or disuse presents still another picture. Chronic periostitis, osteoperiostitis, necrosis, chronic osteomyelitis, and osteosclerosis cast shadows more or less characteristic. Bone-cysts, giant cell sarcoma, osteoma, and osteophytes show clearly. Conditions about the joints, such as arthritis deformans, ossifying bursitis, and foreign substances within the joints, the character of deformity and whether due to disease or congenital defect can be determined. The bone changes of rickets and scurvy appear in distinguishable manner.

Pathologic processes in the accessory sinuses of the skull and in the mastoid cells are capable of detection, and the condition as well as position of the teeth can be shown with great clearness.

Intrathoracic conditions from very early tuberculous deposit in the lungs to generalized involvement; thickened pleura; extensive effusion; cavity forma-

tion; consolidation, the excursions and relations of the diaphragm (Williams' sign) to fixation of this organ, from the normal heart to all sorts of variations in size, shape, and position; dilated aorta; aneurysm; the presence of enlarged mediastinal or peribronchial glands; and tumors of this region, can be studied to great advantage in connection with physical and clinical findings.

Through the painstaking and untiring efforts largely of Rieder, Holzknecht, and Jonas abroad, and of Hulst, Pfahler, and Leonard in America much has been made practical in the diagnosis of disease of the alimentary canal. By means of the technic they have developed the Röntgenologist can demonstrate constriction, dilatation, diverticulum, and often tumors involving the esophagus; the size, position, shape, motor activity of the stomach; hour-glass contraction, invasion in the walls by irregular indentations of malignant growths, often the probe like opening through a pyloric stenosis, and occasionally the presence of ulcer of the stomach. We can determine the character of peristaltic function in the small intestine or obstruction of the small intestine, and in addition, the presence or absence of ptosis, dilatation, or contraction of the large intestine.

In a study of the urinary organs the Röntgenologist should be able to determine the size and position of the kidneys in a normal subject weighing 160 pounds or less. In larger persons only the best skiagraphs will show the outline of the kidneys. In patients under 160 pounds renal calculi from the size of a No. 2 shot to the largest found, whether single or multiple, in one kidney or both, and relatively their situation in the kidneys (except in stones composed of pure uric acid) can be determined in Röntgenographs of the best quality. One can frequently aid in the diagnosis of movable kidney, tuberculosis of the kidney, advanced pyelitis and pyonephrosis or hydronephrosis, although in these conditions the x-ray evidence is purely corroborative of other clinical findings. Ureteral calculi are subject to the same display as renal calculi. The course of the ureters can be shown clearly if ureteral catheters styleted with fine fuse wire are passed from the bladder to the kidney. This is of value when in the region of the lower end of the ureters there appears a shadow of a foreign body which may be cast by a ureteral calculus, a small deposit of bone in some of the pelvic ligaments, a phlebolith, calcareous gland, an appendolith, or, in the female, calcareous deposits in the mucous membrane of the vagina or in the tubes. The ureteral stone is never round; it is oval or irregularly oblong. In the portion of the ureter overlying the sacroiliac joint it is possible that even a small phosphatic or oxalate stone may escape detection. In doubtful cases the ureters should be catheterized. Stone in the bladder is usually well shown, but here one is more apt to encounter pure uric acid calculi. The Röntgen method is particularly valuable in disclosing the presence of a stone encysted in the mucous membrane of the bladder, or when, because of disease of the prostate, instrumentation is very painful or contraindicated. The Röntgenologist should never say that a stone does not exist, especially in the bladder. An absolutely necessary procedure, prior to study of the urinary organs, is to have the patient thoroughly purged and the stomach empty. The stomach usually lies over the left kidney, the hepatic flexure of the colon overlies the region of the right kidney, and the ureters are throughout their course in a position to be obscured by intestinal contents. Hardened feces in the rectum may be mistaken for vesical calculi.

The liver and spleen offer but little field for useful study. Enlargement may be seen. Biliary calculi are not often seen in the x-ray negative, because they are lacking in density and are surrounded by thick structures. One cannot make a negative diagnosis of biliary calculus by means of the x-ray. Chronic discharging sinuses may be outlined and studied after they have been injected with bismuth paste. This study is best made by means of stereoscopic negatives. In advanced atheroma the outlines of the arteries of the extremities are seen in the Röntgenograph.

Localization of Foreign Bodies.—Metallic bodies, such as bullets, pieces of steel or iron, coins, pins, needles, tin, zinc, brass, etc., can be detected in any portion of the body and accurately localized. Fragments of stone, granite, marble, and lead-glass can be skiagraphed except when very small and deeply situated. Drainage-tubes and iodoform gauze can be found if lost in a sinus or cavity. Anthracite coal, glass other than lead-glass, or splinters of wood are

Fig. 903.—Gunshot wound of the lung. Rib resection for secondary hemorrhage into the pleural sac ten days after the injury. Bullet not removed. Hemorrhage arrested by packing with gauze. Skiagraph taken three months afterward shows the bullet (author's case).

difficult to detect unless they are of considerable thickness, are not superimposed by bone, and are imbedded in thin structures so that the foreign body can be brought close to the sensitive plate. When the fingers are the seat of injury, anteroposterior and lateral views are sufficient. When in the esophagus, trachea, or bronchi the fluoroscope should be used for differentiation, after which a skiagraph will assist.

Foreign bodies elsewhere should be localized, either by stereoscopic Röntgenographs if near a joint or in close relation to some bony surgical guide. (See stereoscopic skiagraph, Fig. 904, of bullet in a shoulder case of mine, where the bullet lay in close relation to the anterior surface of the glenoid process, and on a line perpendicularly below the coracoid process. The bullet was removed with ease.)

Pieces of needle in the palm of the hand or soft parts near the surface are best localized stereoscopically when a definite relation between some known

surface mark and the foreign body can be determined. A thin coating of bismuth on the palm of the hand will cause every line in the skin to show on the skiagraph. When the foreign body is deeply situated and not in close relation to a surgical guide, some method of localization must be used to indicate the depth and direction from a known point on the surface in which the body lies. All localizing methods are based upon displacement of the foreign body shadow by making two or more exposures with the x-ray tube in different and known positions, while the part containing the foreign body and sensitive plate remain in one position. This has been called the triangulation method.

Mackenzie-Davidson first used the cross-threads, from the known positions of the focus point of the x-ray tube to their respective shadows on the negative, the crossing of the threads representing the position of the foreign body in relation to the sensitive plate and focus tube. Measurements were then made

Fig. 904.—Bullet localized by means of stereoscope. Removed.

from some point on the skin of the patient that had registered with a known position on the negative. The Röntgenologist could then say that the foreign body lay perpendicularly beneath a certain point to a definite depth. Nearly all the modern localizing schemes are modifications of this general plan, and differ mainly in the manner of determining the position of the focus point of the x-ray tube.

A foreign body, unless it be large, may easily lie to one side of an imaginary line as drawn by the scalpel to the depth of 2 or more inches; again a change in position of the patient will alter the relation of the foreign body to a perpendicular line from the indicated surface point. A modification of the Mackenzie-Davidson scheme was devised by Snook. Manges improved the apparatus by limiting the possibility of error, and in using it as a guide during the surgical operation. With this apparatus all relations between the patient, foreign body, source of x-rays, and sensitive

plate are obtained, maintained, and regained accuracy.

The localizer is a detachable part of the rographic table, and consists of a metal frame h near their top by a horizontal bar and at the upper bar is deeply notched to a scale of 12. To the curved bar are attached four adjustable are used to establish a relation between the lo to indicate the depth and direction of the fo be moved through a sleeve in the direction of the desired depth by a collar and set-screw. of the tube carriage is graduated on one side

Fig. 905.—Modified Mackenzie—

on the cross-bar of the localizer. The focus (the source of the rays) is accurately determined on one side of the lead-glass tube shield to the shield, and is exactly 6 inches above the level of the localizer. The relation between the focus point and the shield is established by means of a clamp on the edge of the table, the arms projecting over the sensitive plate and a clamp on the upright bar of the carriage rests.

In making the localization the patient is placed in the operation. A sensitive plate, 10×12 or 11×14 inches, is placed over the foreign body, the tube clamp applied, and the tube is adjusted and leveled. Three of

izer are made to touch the surface of the patient at as widely separated points as possible, in which positions they are tightly clamped. These three spots are touched with silver nitrate.

After all adjustments are examined, and the height of the tube from the plate noted, the carriage cross-bar is elevated and the localizer removed. By lowering the tube-carrier to 6 inches below its original position, the focus point of the tube will be at the level formerly occupied by the cross-bar of the localizer, and if the carriage cross-bar is shifted to a definite distance to one side of zero, the focus-point will be in the corresponding position held before by a notch on the cross-bar of the localizer. After carefully adjusting the tube-holder an exposure is made. The carriage is then shifted to the opposite side

Fig. 906.—Bullet localized by method described in the text. Removed.

of zero in the same extent and manner, and a second exposure made. The patient is removed, the plate developed, and tracings of the shadows of the foreign body and arms of the table clamp made on paper. This tracing is taken to the table and put in relation with the table clamp. The localizer is then made to occupy its original position, and threads are carried from the notches on its cross bar to the tracings of the foreign body shadows. At the crossing of these threads is the position of the foreign body in relation to the localizer. The point of the fourth adjustable rod can be made to touch the cross threads from any direction. If the Röntgenologist cannot determine the best direction for incision, he may consult the surgeon, and when this is known, the point of the rod is made to touch the crossing of the threads, and its collar and set-screw fixed.

At the operation for removal of the foreign body the localizer is sterilized and applied to the patient, preferably by the Röntgenologist, if he has had sufficient surgical training to render his assistance of value from the standpoint of surgical technic; or he may thoroughly instruct the surgeon in the manipulation of the apparatus. The following precautions are to be observed. First, the localizer must be handled carefully to prevent displacement of the rods, and second, the patient should be placed on the operating table in about the position he occupied on the Röntgenographic table, so that the three marked spots on the skin receive the three fixed points of the localizer. With the apparatus in position, the indicating rod is placed in its carrier or sleeve and when its point touches the skin the long axis of the rod indicates the direction of *incision*, while the distance between the collar on the rod and the sleeve shows the depth at which the foreign body lies. During the course of the operation the localizer should be repeatedly applied, so that excessive manipulation of the tissues may be avoided.

The determination of the localization of pieces of metal, glass or other substances in the eye or immediately adjacent structures by means of the Röntgen rays requires that the shadow of the foreign body, as shown on the radiograph, be studied in relation to the shadow of one or more opaque objects of known position. Dr. William M. Sweet has designed a localizing apparatus which consists of two ball pointed indicating rods, one opposite the center of the cornea and the other situated at a known distance from the first to the temporal side. The patient is in the recumbent posture, with the photographic plate to the side of the head corresponding with the injured eye. Two negatives are made, one with the tube horizontal or nearly so with the plane of the two indicating rods, and the other at any distance below this plane. A special chart is employed, containing a section of the normal adult eyeball, and lines are drawn indicating the planes of shadow at the two exposures. Where these planes cross is the position of the foreign body in relation to the structures of the eyeball and orbit.

The accuracy of this method of localization has been fully demonstrated by its author and other x-ray workers, but the student found considerable difficulty in understanding the lines to be drawn upon the chart to represent the planes of shadow at the two exposures, so that Dr. Sweet has recently designed an entirely new apparatus, in which a single indicator is employed. As shown in the illustration (Fig. 907) the tube-holder, indicating ball, and plate holder are upon a movable stage, and the tube is in a fixed carrier, so that the angle of the rays with the eyeball and the distance of the tube from the plate are always the same. A telescope and reflecting mirror permit the observer to adjust the instrument until the image of a cross wire in the tube is in direct contact with the lateral image of the summit of the cornea. After this adjustment is made, the indicating-ball is exactly 10 millimeters from the center of the cornea.

The patient fixes with the good eye upon a circular mirror placed 12 inches above the injured eye, so that there is no movement of the eye during exposure, and the visual line of the injured eye is parallel with the plate. The two exposures are made upon one plate, one with the tube in the zero position of the apparatus, so that the rays pass in a direction corresponding with the horizontal plane of the eyeball and the second exposure with the tube at its farthest

point on the graduated rod to the right or left of the first position, depending upon which eye is to be examined. Two metal shutters are used to uncover any desired portion of the photographic plate.

Since the relative position of the tube in reference to the indicating-ball and the photographic plate remains fixed and known, the direction of the rays in passing through the eyeball follows a definite course, which is the same for the two separate exposures. Lines have, therefore, been drawn upon the localizing chart to indicate the direction of the rays at the two exposures, each line with the required amount of divergence to represent rays coming from a point

Fig. 907. Sweet's apparatus for locating foreign bodies in the eyeball and orbit.*

the distance of the tube from the photographic plate. After development the photographic plate is placed in a frame containing cross lines indicating the focal coordinates of the rays. The radiograph is moved until the shadow of the indicating-ball is in apposition with a spot representing the indicating-ball on the key-plate. A reading is then made of both the vertical and horizontal coordinate lines which pass through the shadow of the body on the radiograph, and this is transferred to the corresponding lines on the localization chart. Three readings are taken, and after having been transferred to the chart, the point of crossing of the several lines indicates the location of the foreign body in the eyeball or orbit.

The accuracy of the localization depends only upon the care with which the operator adjusts the indicating-ball opposite the center of the cornea and

*Transactions of the American Ophthalmological Society, 1909.

at a definite and fixed distance from it. After the exposures are made and the plate developed, the determination of the situation of the foreign body is simply a question of reading from a key-plate and transferring these readings to a localization chart.

The x Rays in the Treatment of Diseases.—It may be said that the beneficial results obtained through the use of x-rays is in direct proportion to the skill of the Röntgenologist. No two Crookes tubes are alike in their behavior, they vary widely from day to day, and even during one operation.

Unfortunately there is no accurate method of computing dosage either in quality or quantity. The quality of rays may be fairly well estimated by determining the electric resistance the tube manifests. Tubes of high vacuum offer great resistance, and emit hard or highly penetrating rays, while tubes of lower vacuum offer less resistance to the passage of the electric current and emit softer rays. The quantity of a certain quality of rays may be roughly estimated by the amount of current passing through a tube of known vacuum in a definite period of time. The instrument commonly used in this country for this purpose is known as the milliamperemeter, the standard of measurement of electric units. In Europe the physiochemic properties of the rays are more in vogue as a means of measurement of dosage. In the United States most Röntgenologists give repeated short exposures, while abroad the tendency is to use infrequent but powerful applications of the rays.

In any case, ability gained by experience is essential for the proper selection and control of the Crookes tube in the treatment of a given condition.

The effects of x-rays which offer possibilities of therapeutic application are, according to Pusey, as follows ("The Rontgen rays in Therapeutics and Diagnosis," Pusey-Caldwell): (1) "Their effect in causing atrophy of the appendages of the skin; (2) their destructive action upon organisms in living tissues; (3) their stimulative action upon the metabolism of tissues; (4) their power of destroying certain pathologic tissues; (5) their anodyne effect." A qualitative generalization may be made, *i. e.*, superficial diseases should be treated in most instances with tubes of low vacuum, while deeper-seated lesions should be exposed to the rays from tubes of higher vacuum. Quantitatively, for causing atrophy of the skin appendages, stimulating action upon metabolism, and for the relief of pain in other than malignant conditions, mild applications or short exposures should be given; on the other hand, for destructive action maximum exposures are demanded.

In diseases of the skin the surrounding healthy parts are to be protected from the action of the rays by means of sheet-lead, while the diseased portion is directly exposed. In treating lesions beneath the surface it may be necessary to expose an area beyond the evident limits of the disease, but all overlying healthy skin must be protected from the non-penetrating rays by a filter such as aluminum or leather.

Because of the possible untoward effects of exposure to x-rays, diseased conditions amenable to other forms of treatment should not be treated by the rays except "as a last resort." It is strikingly true, however, that the most signal results of x-ray therapy are obtained in conditions that are frequently incurable by other means. Many of the chronic diseases of the skin that yield but slowly to medication will be found safely and promptly amenable to x-ray

treatment. Among these diseases are acne, eczema, lupus vulgaris, lupus erythematosus, and psoriasis.

The treatment is also beneficial in tinea tonsurans, favus, sycosis, alopecia areata, hypertrichosis, and prurigo.

In the treatment of malignant growths the Rontgen rays find their greatest field of therapeutic usefulness. With improved technic, permitting of massive doses of the rays with safety to overlying and adjacent healthy tissue, the results are far more favorable than in the earlier x-ray days.

In superficial epithelioma, rodent ulcer, and Marjolin's ulcer, without glandular involvement, cure is the rule, recurrence is becoming less frequent and is amenable to cure, and the cosmetic effect is good.

When deeper structures are invaded by carcinoma cure becomes less frequent and recurrence more frequent in direct proportion to the depth of the lesion and the degree of glandular involvement. Even in advanced cases, however, for instance when the entire contents of an orbit are involved, large portions of the nasal structure destroyed, or extensive areas of subcutaneous tissue the seat of foul and painful ulceration, and where operative interference is contraindicated, the x-rays relieve pain and decrease discharge. Some reach a stage of improvement where surgical procedure may be instituted with hope of success, and in a few actual cures result from x-ray treatment alone.

Epitheliomata involving mucous membranes, particularly of the lower lip, anus, or vagina, should not be treated by x-ray until after surgical methods have been exhausted. The rays are used to prevent recurrence after operation. The reason why the rays should be regarded as a last resource in these cases is that mucous membranes are very susceptible to the action of the rays and are as apt to be destroyed as are the cancers. Further, in the lower lip, glandular involvement is almost sure to exist. All forms of carcinoma with glandular involvement, if operable, should be subjected to radical surgical extirpation, and the rays should be used only as a prophylactic measure against recurrence.

It is difficult to determine the value of x-rays in this capacity, but theoretically they should be of use.

All cases of primary inoperable carcinoma, regardless of situation, extent of involvement, or cause for being inoperable, should be exposed to vigorous irradiation. Likewise, all recurrences after operative procedure is prohibited ought to be afforded the possible benefits of x-ray treatment.

In sarcoma the results are becoming more favorable also, but this form of treatment is by no means on a basis of success that it may interfere with or supersede surgical methods. It is a fact, however, that in some cases in which operation was not agreed to by the patient or parents, or in which the condition was deemed by the surgeon to be inoperable, surprising results have been obtained with the Rontgen rays alone or in connection with the use of Coley toxins. I know of a case of rapidly growing periosteal sarcoma of the humerus in a young girl, the onset of which was so rapid that the mass was considered to be a subperiosteal abscess, but which was proved by x-ray examination and later by incision to be sarcoma, that has remained well eighteen months after treatment by x-ray and Coley toxins at first, and later by x-ray alone. The arm is strong and useful, and the girl is robust. At the site of

origin there remains a spur of bone which is about 1 inch long, $\frac{1}{2}$ inch in thickness, and has a density equal to that of the densest portion of the humerus. Isolated cases of inoperable retroperitoneal sarcoma, fibrosarcoma of the uterus, and other deep-seated tumors, clinically or after exploratory operation considered sarcoma, have been reported as greatly benefited, controlled or cured.

Good results in x-ray treatment of inoperable sarcoma are obtained only with the best apparatus. In the deep-seated growths hard, penetrating rays in maximum quantity are demanded. The treatment must extend over a period of months, so that great care and skill is required. There is little reason to believe that x-rays cause metastatic involvement in other parts.

Tuberculous sinuses that are not deep seated are frequently quickly benefited, and old tuberculous glands in which ulceration has recurred after operation should always receive the x-ray treatment, as some remarkable results have been obtained.

Of late years exophthalmic goiter has been treated more or less successfully with Röntgen rays. It is distinctly of value in many cases that are not operable or amenable to other forms of treatment. The Mayos use the rays for a time before operating. Many of the distressing nervous symptoms are relieved, the pulse-rate is materially lowered, and changes favorable to future operation take place in the gland and its capsule. Dr. Manges, the Röntgenologist at Jefferson College Hospital, in an extreme case of exophthalmic goiter, has obtained a remarkably good result from x-ray treatment, so far as relief of the nervous symptoms, tachycardia, and improvement of the general health of the patient are concerned. There is not a marked diminution in the size of the goiter, but the exophthalmus is distinctly less. The patient has been following her occupation as a weaver without inconvenience for nearly a year.

Here again more data is to be desired before other methods of treating this disease, especially surgery, are to be replaced by Röntgenization. These rays are perhaps the most valuable therapeutic agent we have in the treatment of myelogenous or splenomedullary leukemia and lymphatic leukemia. Since Senn's report some years ago this plan of treatment has been widely used in connection with other remedies. A spleen of enormous size will sometimes go back to normal, high leukocyte counts disappear, red cells and hemoglobin increase, and the general health of the patient improves. Stengel and Fancoast have decidedly improved the technic of x-ray treatment in their systematic exposures of the bony skeleton, particularly the long bones, with comparatively little irradiation of the spleen until late in the course of treatment.

Very advanced cases are apt to improve greatly for a time, but even in the early cases recurrence usually appears sooner or later, and becomes less responsive to treatment. Life may be prolonged for many years, but permanent cure is rare.

Chronic suppurating sinuses sometimes heal under the influence of these rays, and varicose ulcers are benefited by moderate exposure. The pain in rheumatic affections and neuralgias is often greatly relieved.

THE FINSEN LIGHT.

It is known that below the spectrum of white light are heat rays and above the spectrum of white light are short violet, actinic, or chemical rays. The short violet, with the indigo rays and blue rays, constitute the Finsen light. Ultraviolet rays cause an electrified body to discharge, excite fluorescence in certain substances, affect a photographic plate, and are bactericidal but have little power of penetrating tissues and, it is said, do not inflame tissues. Ultraviolet rays pass readily through rock salt or ice, which will not transmit heat-rays.

Finsen taught us to use these rays therapeutically. He first obtained the rays from sunlight, intercepting the heat-rays by ice or rock crystals. Later he obtained them from the arc light.

Blood in part prevents the passage of the Finsen light, hence in using the light we must make the area on which the rays are to act nearly bloodless. This is done by pressing firmly upon the part with a rock crystal through which water passes. The rays pass through the crystal and the water absorbs the heat-rays. The rays are especially serviceable in lupus.

BECQUEREL'S RAYS.

Becquerel discovered in 1896 that uranium and some of its compounds give off a radiation similar to but much weaker than the x-rays. Among these radiant substances are pitchblende, radium, and uranium. These rays are luminous, actinic, and skiagraphic (McFarland), and may produce, by prolonged action, dermatitis similar to an x-ray dermatitis.

RADIUM RAYS.

Monsieur and Madame Curie, after prolonged research, found that thorium and certain ores of thorium and uranium (pitchblende) are radio-active, pitchblende being more strongly so than uranium itself. The conclusion was that pitchblende contained a strongly radio-active element and that it was not uranium. In 1903 they discovered the sources of radio-activity to be two hitherto unknown elements, radium and polonium (see Dawson Turner in "Brit. Med. Jour.," Dec. 12, 1903).

Turner tells us (*Ibid.*) that radium gives off a radio-active emanation and three kinds of rays (alpha-rays, beta rays, and gamma rays). It also emits heat, and is itself at a higher temperature than the medium in which it rests. The emanation from radium is a luminous gas, which can be condensed by great cold, and which imparts radio-activity to certain bodies. It is to this gas that most of the curative effects of radium can be attributed.

Alpha-rays consist of a stream of positively charged gaseous particles. Turner points out that these particles are each about twice the size of a hydrogen atom, travel at a velocity of 20,000 miles a second, and have little power of penetration. In fact, the penetrating power of the alpha-rays is so slight that they do not pass through the glass of a tube (Robert Abbe in "Med. Record," Oct. 12, 1907). The beta-rays consist of particles each being $\frac{1}{1800}$ the size of a hydrogen atom and being strongly actinic. These rays are said by Turner to resemble cathode rays and to be far more penetrating than alpha-rays. Gamma-rays resemble x-rays and have great penetrating power (Dawson Turner,

in "Brit. Med. Jour.," Dec. 12, 1903). It is probable that radium also generates or helps to generate a gas called helium, which has no action on tissues.

The actions of radium are extraordinary. A man entirely blind cannot perceive light when radium is brought near him, but one not quite but almost blind can, and one quite blind to form but with retention of some light perception can actually see the shapes of objects near a screen rendered luminous by radium (Turner). Turner tells us that a man retaining vision, who covers his eyes, can detect radium held in a box behind his head. If dry seeds before planting are exposed to radium rays sprouting will be retarded in proportion to the time of exposure. When meal worms are exposed to the rays "they go on living as meal worms, 'veritable Methuselahs,' as it has been said, while their sisters and brothers, unradiumized, progress for generations, completing several cycles of beetles, eggs, meal worms, etc." (Abbe, *Ibid.*). Radium rays are germicidal, but act very slowly and feebly. Skiagraphs can be taken with the rays. Water and other materials may be rendered radio-active by exposure to radium rays. Probably certain natural waters have subtle powers due to radio activity. On the tissues radium may act to produce a retrogressive effect; may increase self-digestion, may cause irritation and inflammation, and so block blood vessels. Severe reaction may result in ulceration. Sometimes a spreading eruption, like that of scarlet fever, follows overaction. Abbe says that when an ulcerated surface is treated or when a tube of radium is inserted in a wound for twenty-four hours, a "specific toxemia" frequently arises. "The symptoms will be headache, chill, general aching, coated tongue, fever up to from 103° to 106° F., and an occasional rash-like scarlatina" (Abbe, in "Med. Record," Oct. 12, 1907). Some hold that radium acts similarly to the x-rays and that the x-rays can do anything radium can do. Most observers believe that the radium rays have a specific action and can accomplish things impossible to the x-rays.

Radium therapy is assuming a high degree of importance. How great its future is to be we can only guess. Sir Frederick Treves bids us be cautious in our estimates, although he thinks there may be a great future for radium therapy in surgery ("Brit. Med. Jour.," Jan. 30, 1909). It has cured many surface carcinomata and sarcomata, keloids, angiomas, moles, pigmented moles, and warts. It is particularly valuable in lesions about the face when it is desirable to avoid scars; in lesions of the nostril, mouth, and other cavities. It has been used most advantageously for epithelioma of the eyelid (see the striking cases reported by Abbe, in "Med. Record," Oct. 12, 1907). When treating a surface lesion the rays are obtained from radium bromid, which material is kept in a hermetically sealed glass tube. In a deep-seated tumor an incision may be made and a tube of radium bromid be inserted in the wound and allowed to remain for some hours or a number of hours. Attempts are being made to treat internal conditions by the inhalation of radium emanations or by the administration of materials which have been rendered radio-active and contain, so to speak, radium emanations in solution. Radio-active water has been tried for cancer of the stomach. It is extraordinary how even very brief applications may be followed by notable changes. In one of Abbe's cases an epithelioma of the forehead disappeared after one exposure of an hour's duration. Another on the side of the nose disappeared in four weeks.

after one exposure of an hour's duration. A cancer involving one-third of the upper eyelid entirely disappeared in two weeks after three five-minute exposures. After an exposure no changes are apparent for several days or a week. The skin at the site of application then begins to burn and itch and becomes reddened. The irritation endures for about two weeks.

Confusion has arisen because of the varying strengths and amounts used by different operators. Bromid of radium is the salt usually employed. Abbe takes as a standard 10 mgr. of bromid of radium and tests other specimens by this (see his method of testing in previously quoted article). He calls the 10 mgr. of strong (German bromid of radium "the working unit." In malignant disease the best results have followed one hour's exhibition of the "working unit" to small growths and three or four hours to large growths, "with an interval of one month for study of the effect" (Abbe, *Ibid.*). Ischemia favors powerful action of radium rays.

XL. INJURIES BY ELECTRICITY.

Effects Produced by Lightning.—Every year in the United States about 224 persons are killed by lightning (McAdie). An individual may be struck directly or he may be shocked by the lightning having struck a nearby object. A person can be struck while in a room, but there is more danger when exposed, especially in the open country. To be under a single tree or under a tree at the margin of a forest during a thunder-storm is dangerous, but to be in a wood or under a hedge is reasonably safe. The oak is struck more often and the beech less often than other trees (Professor McAdie, quoted in 'Draper's Legal Medicine'). It is not safe during a thunder-storm to stand by a chimney or fireplace, in an open doorway, or close to cattle (Professor McAdie, *Ibid.*). One should not use a telephone or ring a bell during a storm. It is unwise to run, as the current of air thus created is a danger. Telegraph posts should be avoided. A pool of water is a dangerous neighbor. Horses and other animals should be given a wide berth. The victim of lightning may be killed instantly. The body may show no mark, but there are usually burns. Burns may be superficial or a large area (as a limb) may be carbonized. Death is the fate of over one-third of those struck. Tidy states that out of 54 cases, 21 died and 33 recovered. Recovery may follow even when there has been severe burning. Post mortem examination may fail to reveal a lesion, but in many cases severe burns are discovered, in some there are laceration of tissue, crushing of bones, and fearful injury. Burns are especially apt to occur at the points where the current entered and emerged. The clothes are usually singed or torn, shoes are especially apt to be torn apart or destroyed. Yet a man may be burned or killed and the clothing be undamaged, or the under-clothing may be destroyed and the outer garments escape uninjured. A person's clothing may be destroyed, he may be left naked, and yet he may not be injured. Clothing may be cast far off, and in some cases is said to have utterly disappeared. The typical lightning-marks are arborescent tracings, representing the course of blood vessels, produced by disorganization and

effusion of blood as the fluid travels through it. Occasionally metal objects, such as buttons, knives, money, keys, etc., are fused, and spread as a metallic film over a considerable portion of the surface of the body. Bichat stated that in death from lightning rigor mortis does not occur. This statement is now known to be an error (see the 3 cases reported by M. Tourdes). As a rule, there are early but perhaps brief rigor mortis, retained fluidity of blood and distention of the brain with venous blood. Putrefaction is early and rapid. A man killed by lightning may remain in the exact attitude in which he was struck dead. He may not be disfigured, his clothing may be intact; and yet, almost at a touch, he may crumble to ashes because the body was practically incinerated (see the apparently authentic cases quoted by Flammarion in "Thunder and Lightning"). In most cases killed the body shows burns. The cause of death by lightning was supposed by Hunter to be destruction of muscular contractility, and by Richardson the resolution of the blood into gases. It is asserted that some deaths are due to actual disorganization of vital structure and that others are due to shock or inhibition. Spitzka believes that death from electric shock is due to asphyxia, to paralysis of the heart with fibrillary contractions of that organ, or to a combination of these conditions. An individual struck by lightning may recover even when he is apparently dead. Sestier collected reports of 77 persons struck by lightning 7 of them were apparently dead for a number of hours, but finally reacted.* Brouardel says in such cases the death-like state may be ascribed to inhibition, caused by a *maximum* degree of stimulus.† When death from lightning is not immediate, the condition may be as above outlined, the individual being apparently dead, without obvious respiration or pulse. He may be insensible, with slow and labored respiration, a weak and irregular pulse, and dilated pupils, and may remain in this condition for a few minutes or for several hours. The above condition is not to be distinguished from severe concussion of the brain. Every individual suffering from the effects of lightning should have his entire body carefully examined to see if physical injuries exist (fractures, wounds, burns, ecchymoses, arborescent tracings). The consequences of lightning stroke are many and various. There may be rapid and complete recovery, gradual recovery, traumatic neurasthenia, sloughing burns, partial paralysis, which is usually recovered from (Nothnagel), but which may be permanent; hysteria, blindness, change of character, and actual insanity.

Treatment.—Do not pronounce a person dead until a thorough attempt at resuscitation has been made. Raise the head a little, draw the tongue forward, make artificial respiration, occasionally tickle the epiglottis, apply external heat, massage over the heart, and, if the means are at hand and the man is apparently dead or all but dead, throw salt solution and adrenalin into a large artery and toward the heart, as advised by Crile and Dolley (page 167). Do not give alcoholic stimulants. If the respiration is feeble, make tongue traction and employ artificial respiration. Apply the stream of a warm douche to the head, rub the limbs with mustard, put a mustard plaster over the heart and another to the back of the neck, wrap the individual in hot blankets, give enemata of hot saline fluid, and strychnin hypodermatically. In some cases

* Sestier, "De la Foudre," Paris, 1866. Quoted by Brouardel in his lectures upon "Death and Sudden Death."

† Benham's translation of Brouardel's lectures upon "Death and Sudden Death."

venesection has seemed to be of benefit. Lumbur puncture may be tried. When the individual reacts, treat any existing condition symptomatically, and treat particular physical injuries according to their character.

Effects of Artificial Currents. Individuals may receive dangerous or fatal shocks by contact with wires carrying a powerful electric current, by contact with a dynamo, or with some metal object which has become accidentally charged by a powerful current. The shock may be from contact with both poles of a circuit (while standing on the ground and touching one pole of a "grounded" circuit), when actual contact has not occurred, but a person has been very close to a high-tension current and the current has jumped an inch or several inches through the air; when a person insulated from the ground grasps the conductor with both hands (Spitzka, *Journal Med. Soc. of New Jersey*, 1909). Workmen for electric companies, pedestrians in the streets of a city which is lighted by electricity or in which trolley cars are employed, roofers, and firemen are liable to be injured by electricity. During many fires in cities live electric wires fall and charge the rails of a street-car track, the iron of a hook-and-ladder truck, water-tower, or a fire-escape. Firemen who come in contact with such charged materials are shocked. I have seen dozens of men thus shocked, but have as yet seen no fatal case. There are enormous differences in individual resistance and susceptibility. Spitzka points out that in one case death followed a shock of 65 volts, and others have survived shocks of many thousand volts. The amount of current the individual gets from the circuit is influenced by the tension of the current; the ground he stands on (metal floors and wet floors are most dangerous); the area of contact (limited area of contact means serious burning and less general shock, broad area means little or no burning and severe shock); the nature of the tissue (the thick palm offers less resistance than the lip and the more callus the palm of the hand the greater the resistance), and the duration of the contact. An alternating current is decidedly more dangerous than a continuous current of equal strength. The constant current causes a shock only as the circuit is opened and closed. While the current is passing continuously there is no shock, although dreadful burns may be caused at this time. The alternating current causes rapidly repeated violent shocks. The arc light is either an alternating or a direct current. "Low-tension currents with 30 to 150 alternations are more dangerous to the heart than if of more than 500 frequency. Greater frequencies, as in Tesla's currents, are practically harmless" (Spitzka, *Ibid*). An artificial current acts like lightning. It may produce instant death, it may produce unconsciousness, delirium, stertorous respiration, Cheyne-Stokes' breathing, or clonic spasms. Its effects can be often recovered from. Not unusually the victim is apparently dead, but subsequently recovers. D'Arsonval reports the case of a man who was apparently killed by the passage of 4500 volts. No attempt at resuscitation was made for one-half hour, and yet he recovered when artificial respiration was employed. Donnellan reports a case of recovery after the passage of 1000 volts. Slight shocks may cause temporary numbness and even motor paralysis. An electric shock frequently causes burns or ecchymoses and, occasionally, wounds. Wounds caused by electricity bleed profusely and are apt to slough. Spitzka, *Ibid.*, sets forth the effects of electric shock as follows:

"I. *Local Signs:*

- (a) Burns of the skin and hair.
- (b) Puncture and rupture of tissues.
- (c) Superficial necroses.
- (d) Metallic impregnation of the surface tissues.
- (e) Hemorrhages.
- (f) Edema, erythemas, 'lightning' figures

"II. *General Effects:*

- (a) Loss of consciousness and of nerve-functions generally.
- (b) Paralysis or spasms of muscles.
- (c) Disturbances of respiration and cardiac action, high temperature

"*Later* Affections of the bowel activity meteorism, constipation, albuminuria, icterus, incontinence or retention of urine, bloody urine, arterial rigor or spasms of arterioles, acute edema of various parts (joints), eye-symptoms of various kinds: blinding, conjunctivitis, keratitis, iritis, cataract, dislocation of lens, etc.; ear-symptoms: rupture of tympanic membranes, deafness, bleeding, epistaxis; thermal symptoms: usually a rise of temperature to 38° to 39° C., amnesia, neuritis, etc."

If death occurs it is due to asphyxia, to cardiac paralysis with fibrillary contractions of the heart, or to both conditions (Spitzka, *Ibid.*). An *electric burn* looks like a blackened crust, it is surrounded by pale skin, and for twenty-four hours remains dry, when inflammatory oozing begins and the skin around it reddens. These burns are seldom as painful as ordinary burns, but sometimes cause severe pain, and recovery requires a long time. When inflammation begins and suppuration occurs, tissue is extensively destroyed, tendons, bones, and joints may suffer, some portions become deeply excavated, and other portions show dry adherent masses of dead and dying tissue, and a burn which was at first small may be followed by a large area of moist gangrene;* lack of tissue-resistance, due to trophic disturbance, is largely responsible for the progress of the sloughing. Even an apparently trivial burn may be followed by extensive sloughing.

Treatment.—If a person is in contact with a live wire, the first thing to do is, if possible, to shut off the current. If it is not possible to shut off the current, catch a portion of the clothing of the victim and pull him away from the wire, but do not touch his body with the bare hand. If a pair of rubber gloves can be obtained, the subject can be moved with impunity and the wires can be safely cut. If it is not possible to drag a person away from electric wires, an individual can wrap his hands in dry woolen material and safely lift the portion of the body in contact with earth or wire, and thus break the circuit and permit of removal of the body.† A dry cloth can be pushed between the body and the ground, and the body can then be removed from the wire. It may be possible to push the wires away by means of a dry piece of wood, or to cut them with shears which have wooden handles and which are perfectly dry, or to push or draw the body away from the wire by the employment of sticks of dry wood. Spitzka warns us to be careful in using shears, as the momentary arc formed between the separated ends may blind the rescuers."

* See the article by N. W. Sharpe on "Peculiarities and Treatment of Electrical Injuries," in *Phil. Med. Jour.*, Jan. 20, 1898.

† See the directions in *Med. Record*, Dec. 28, 1895, from *Med. Press*.

Treat the general condition in the manner set forth in the article on Lightning-stroke (page 1462). Raise the head a little, apply external heat, draw the tongue forward, and at once make artificial respiration. Occasionally tickle the epiglottis with the finger. Massage over the heart region. If facilities are at hand and the victim is apparently dead, inject at once adrenalin and salt solution into a large artery (page 467). While any heart action remains there is a chance of resuscitation. When heart action and respiration are present the prognosis is good. Very severe burns may be caused. The author has dressed a number of electric burns with hot fomentations of salt solution during the first few days. This facilitates the separation of the sloughs and seems to aid the weakened tissues in resisting microbial invasion; after sloughs separate, the part is dressed with dry sterile gauze. Anti-septic dressings can be used from the beginning, but they often fail entirely to arrest the sloughing. Iodoform produces much irritation and should not be employed. Ointments are very unsatisfactory. When the dressings are changed, the part should not be washed with corrosive sublimate, as this agent produces irritation; peroxid of hydrogen should be employed, followed by warm normal salt solution. Sharpe removes sloughs by applying the following mixture: 2 parts of scale pepsin, 1 part of hydrochloric acid, U. S. P., 120 parts of distilled water. This mixture is washed off after two hours with peroxid of hydrogen. The same surgeon treats necrosis of bone by injecting every few hours a 4 per cent solution of hydrochloric acid, using every second day the pepsin solution, and when necrotic areas come away, packing with gauze. When repair begins, the raw surface should be covered with silver foil. Skin grafting by Reverdin's method or Thiersch's method is rarely successful. In some regions it is possible to slide a large flap in place to cover a granulating area which will not heal. In a very severe case amputation or resection may be necessary.

In New York and New Jersey and several other states electricity is employed to execute criminals convicted of capital offenses. The infliction of death by electricity is popularly spoken of as *electrocution*. It is beyond doubt, in the words of my colleague, Dr. Spitzka, "the most humane method of executing criminals." The first electrocution in New York was in Auburn Prison in 1890, and since then over 100 criminals have been executed by electricity in New York state alone. Dr. Spitzka has witnessed 36 electrocutions and made autopsies on 27 of the victims ("Journal Med. Soc. of New Jersey," 1909). The apparatus used is "an alternating dynamo capable of generating 2000 volts, a 'death-chair' with adjustable head-rest, binding straps, and adjustable electrodes. (At Trenton a 2400 volt current is taken from the public service wire and lowered to the desired tension by a rheostat)." The notch bound to control the current is in the death chamber and the dynamo is in another apartment, communication being had by electric signals. The prisoner (usually without fetters) walks in when everything is ready and sits down in the chair, and his arms, legs, head, and chest are strapped to the chair. An electrode moist with salt solution is fastened to the head and another to the calf of the leg. The head need not be shaved.

"The application of the current is usually as follows: The contact is made with a high potential 1800 volts—for five to seven seconds, reduced to 200 to 250 volts until a half minute has elapsed; raised to high voltage for

three to five seconds; again reduced to low voltage, the current elapses, when it is again raised to the high voltage, contact is broken. The ammeter usually shows the amount of current which has passed through the criminal's body.

"A second or even a third brief contact precautionary measure, but more to comply with the body."

"The time consumed by the strapping-in seconds and the first contact is made a few to seventy seconds elapse from the moment he is shocked to death" (Spitzka, Ibid.).

After electrocution the temperature of 129.5° F. Dr. Spitzka finds that after removal of the spinal cord the temperature in the vertebral canal is often over 120° F. There is also a marked cyanosis of the rhages, arterial anemia, and venous congestion of the pons, oblongata, and spinal cord. There is also a marked emphysema, which were perhaps caused by

In electrocution there is no pain, con-
 death is certain, and resuscitation is im-
 criminals being killed by the necropsy and
 nonsense.

Kelly and Myomata of

Myomata of the Uterus. By HOWARD A. KELLY, M.D., Professor of Gynecologic Surgery at Johns Hopkins University, Baltimore, Md. CULLEN, M. B., Associate in Gynecology at Johns Hopkins University. Large octavo of about 700 pages, with 1,000 illustrations. August Horn and Hermann Becker. 1908. \$9.00 net.

**A MASTER WORK
ILLUSTRATED BY AUGUST HORN**

This monumental work, the fruit of over twenty years of experience, will remain for many years the last word upon the subject of myomata. Those who have brought, step by step, the operation of hysterectomy to such perfection that the mortality is now less than 1 per cent., will find in this the record of greatest achievement of recent years.

The illustrations have been made with the aid of August Horn and Mr. Hermann Becker, with whose skill and accuracy that comment is unnecessary. For painstaking detail, and as an example of the practical use of the operating amphitheater with the pathologist, this work is an enduring testimonial.

Surgery, Gynecology, and Obstetrics

"It must be considered as the most comprehensive work on the subject. It will always be a mine of wealth to future students."

New York Medical Journal

"Within the covers of this monograph every variety of uterine fibroids is discussed. It is a splendid example of professional thought."

Bulletin Medical and Chirurgial Faculty of I

"Few medical works in recent years have been so well illustrated, so practical, and so far reaching in their scope as this. Specialist, and student alike."

Cullen's *Adenomyoma of the Uterus*

Adenomyoma of the Uterus. By THOMAS S. CULLEN, M. D., Associate Professor of Gynecology, Johns Hopkins University. Octavo of 275 pages, with original illustrations by Hermann Becker and August Horn. Cloth, \$5.00 net; Half Morocco, \$6.50 net.

SUPERB ILLUSTRATIONS

Dr. Cullen's large clinical experience and his extensive original work along the lines of gynecologic pathology have enabled him to present his subject with originality and precision. The work gives the early literature on adenomyoma, traces the disease through its various stages, and then gives the detailed findings in a large number of cases personally examined by the author. Formerly the physician and surgeon were unable to determine the cause of uterine bleeding, but after following closely the clinical course of the disease, Dr. Cullen has found that the majority of these cases can be diagnosed clinically. The results of these observations he presents in this work. The superb illustrations are the work of Mr. Hermann Becker and Mr. August Horn, of the Johns Hopkins Hospital.

The Lancet, London

"A good example of how such a monograph should be written. It is an excellent work, worthy of the high reputation of the author and of the school from which it emanates."

Cullen's *Cancer of the Uterus*

Cancer of the Uterus. By THOMAS S. CULLEN, M. B., Associate Professor of Gynecology, Johns Hopkins University. Large octavo of 693 pages, with over 300 colored and half-tone text-cuts and eleven lithographs. Cloth, \$7.50 net; Half Morocco, \$8.50 net.

THE RECOGNIZED AUTHORITY

Realizing that it is most frequently the general practitioner upon whom rests the responsibility of first diagnosing cancer of the uterus, and that the prognosis depends very largely upon an early diagnosis, Dr. Cullen has taken special pains to make clear the first signs. Treatment he has detailed with that care and preciseness so characteristic of all his work.

Howard A. Kelly, M. D., Johns Hopkins University.

"Dr. Cullen's book is the standard work on the greatest problem which faces the surgical world to-day. Any one who desires to attack this great problem must have this book."

Ashton Practice of Gynecology

The Practice of Gynecology. By **W. L. Ashton, M.D.**, L.L.D., Professor of Gynecology in the University of Pennsylvania, Philadelphia. Handsome octavo volume with many original line drawings. Cloth, \$6.50 net.

**THE NEW (4th) EDITION
FOUR EDITIONS IN ONE**

Four large editions of Dr. Ashton's *Practice of Gynecology* in many years. The author takes up each point step by step, the student being led from one point to another. On any non-medical subject, the minutest detail cannot fail to be understood even at first reading. On the medical side, granted, the author not only tells his reader what is done, but also *precisely how to do it*. A distinctive feature of the illustrations, numbering 1058 line drawings, is the personal supervision from actual apparatus, living models, and cadaver.

From its first appearance Dr. Ashton's *Practice of Gynecology* has produced a world-wide demand for new editions. The practitioner is shown by the demand for new editions that he has produced a work which is a rich store-house of practical information, precise and complete, cannot fail to be of daily service to the practitioner.

Howard A. Kelly, M.D.

Professor of Gynecologic Surgery, Johns Hopkins

"It is different from anything that has as yet appeared. It is clear and satisfactory. One specially good feature is that it contains many details so often left to the imagination."

Charles B. Penrose, M.D.

Formerly Professor of Gynecology in the University of Pennsylvania

"I know of no book that goes so thoroughly and completely into every thing connected with the subject. In this respect you cannot find a better book."

George M. Edebohl, M.D.

Professor of Diseases of Women, New York Post-Graduate Medical School

"A text-book most admirably adapted to teach gynecology, even to the minutest and most elementary details."

Bandler's Medical Gynecology

Medical Gynecology. By S. WYLLIS BANDLER, M. D., Adjunct Professor of Diseases of Women, New York Post-Graduate Medical School and Hospital. Octavo of 702 pages, with 150 original illustrations. Cloth, \$5.00 net; Half Morocco, \$6.50 net.

THE NEW (2d) EDITION EXCLUSIVELY MEDICAL GYNECOLOGY

This new work by Dr. Bandler is just the book that the physician engaged in general practice has long needed. It is truly *the practitioner's gynecology*—planned for him, written for him, and illustrated for him. There are many gynecologic conditions that do not call for operative treatment; yet, because of lack of that special knowledge required for their diagnosis and treatment, the general practitioner has been unable to treat them intelligently. This work gives just the information the practitioner needs. It not only deals with those conditions amenable to non-operative treatment, but it also tells how to recognize those diseases demanding operative treatment, so that the practitioner will be enabled to advise his patient at a time when operation will be attended with the most favorable results. The chapter on Pessaries is especially full and excellent, the proper manner of introducing the pessary being clearly described and illustrated with original pictures that show plainly the correct technic of this procedure. The chapters on Vaginal and Abdominal Massage, and particularly that on Artificial Hyperemia and Anemia, are extremely valuable to the practitioner. They express the very latest advances in these methods of treatment. Hydrotherapy, especially the Ferguson and Nauheim Baths, are treated *in extenso*, and Electrotherapy receives the full consideration its importance merits.

American Journal of Obstetrics

"He has shown good judgment in the selection of his data. He has placed most emphasis on diagnostic and therapeutic aspects. He has presented his facts in a manner to be readily grasped by the general practitioner."

Surgery, Gynecology, and Obstetrics

"The volume has been prepared especially for the general practitioner. . . . The chapter on Gonorrhea is one deserving of special mention, having never been so well presented aside from elaborate monograph presentation."

Kelly and Noble's Gynecology and Abdominal Surgery

Gynecology and Abdominal Surgery. Edited by HOWARD A. KELLY, M. D., Professor of Gynecology in Johns Hopkins University, and CHARLES P. NOBLE, M. D., Clinical Professor of Gynecology in the Woman's Medical College, Philadelphia. Two imperial octavo volumes of 950 pages each, containing 880 illustrations, some in colors. Per volume: Cloth, \$8.00 net; Half Morocco, \$9.50 net.

BOTH VOLUMES NOW READY

WITH 880 ILLUSTRATIONS BY HERMANN BECKER AND MAX BRÖDEL

In view of the intimate association of gynecology with abdominal surgery the editors have combined these two important subjects in one work. For this reason the work will be doubly valuable, for not only the gynecologist and general practitioner will find it an exhaustive treatise, but the surgeon also will find here the latest technic of the various abdominal operations. It possesses a number of valuable features not to be found in any other publication covering the same fields. It contains a chapter upon the bacteriology and one upon the pathology of gynecology, dealing fully with the scientific basis of gynecology. In no other work can this information, prepared by specialists, be found as separate chapters. There is a large chapter devoted entirely to *medical gynecology* written especially for the physician engaged in general practice. Heretofore the general practitioner was compelled to search through an entire work in order to obtain the information desired. *Abdominal surgery* proper, as distinct from gynecology, is fully treated, embracing operations upon the stomach, upon the intestines, upon the liver and bile-ducts, upon the pancreas and spleen, upon the kidneys, ureter, bladder and the peritoneum. The illustrations are truly magnificent, being the work of *Mr. Hermann Becker and Mr. Max Brodel*.

American Journal of the Medical Sciences

"It is needless to say that the work has been thoroughly done—the names of the authors and editors would guarantee this—but much may be said in praise of the method of presentation, and attention may be called to the inclusion of matter not to be found elsewhere.

Webster's Text-Book of Obstetrics

A Text-Book of Obstetrics. By J. CLARENCE WEBSTER, M. D. (EDIN.), F. R. C. P. E., Professor of Obstetrics and Gynecology in Rush Medical College, in affiliation with the University of Chicago. Octavo volume of 767 pages, illustrated. Cloth, \$5.00 net; Half Morocco, \$6.50 net.

BEAUTIFULLY ILLUSTRATED

In this work the anatomic changes accompanying pregnancy, labor, and the puerperium are described more fully and lucidly than in any other text-book on the subject. The exposition of these sections is based mainly upon studies of frozen specimens. Unusual consideration is given to embryologic and physiologic data of importance in their relation to obstetrics.

Buffalo Medical Journal

As a practical text-book on obstetrics for both student and practitioner, there is left very little to be desired, it being as near perfection as any compact work that has been published.

Webster's Diseases of Women

A Text-Book of Diseases of Women. By J. CLARENCE WEBSTER, M. D. (EDIN.), F. R. C. P. E., Professor of Gynecology and Obstetrics in Rush Medical College. Octavo of 712 pages, with 372 text-illustrations and 10 colored plates. Cloth, \$7.00 net; Half Morocco, \$8.50 net.

Dr. Webster has written this work *especially for the general practitioner*, discussing the clinical features of the subject in their widest relations to general practice rather than from the standpoint of specialism. The magnificent illustrations, three hundred and seventy-two in number, are nearly all original.

Howard A. Kelly, M.D.

Professor of Gynecology, Surgery, Johns Hopkins University.

"It is undoubtedly one of the best works which has been put on the market within recent years, showing from start to finish Dr. Webster's well-known thoroughness. The illustrations are also of the highest order."

The New (6th) I

INCLUDING RELATED GYNCO

OPINIONS OF THE ME

" The popularity of American text-books in this country has increased in recent years. The popularity is probably chiefly due to the fact that they are better than over those of the English text-books. The illustrations are more numerous and far better executed, and therefore more valuable. They are found in the works of writers on obstetrics in our own country.

"The work is an admirable one in every sense of the word written."

"The illustrations are numerous and are works of a time. The author's style, though condensed, is singular to re-read a sentence in order to grasp the meaning. A book on obstetrics should be, we feel justified in affirming."

Hirst's Diseases of Women

A Text-Book of Diseases of Women. By BARTON COOKE HIRST, M. D., Professor of Obstetrics, University of Pennsylvania; Gynecologist to the Howard, the Orthopedic, and the Philadelphia Hospitals. Octavo of 745 pages, with 701 original illustrations, many in colors. Cloth, \$5.00 net; Half Morocco, \$6.50 net.

**THE NEW (2d) EDITION
WITH 701 ORIGINAL ILLUSTRATIONS**

The new edition of this work has just been issued after a careful revision. As diagnosis and treatment are of the greatest importance in considering diseases of women, particular attention has been devoted to these divisions. To this end, also, the work has been magnificently illuminated with 701 illustrations, for the most part original photographs and water-colors of actual clinical cases accumulated during the past fifteen years. The palliative treatment, as well as the radical operative, is fully described, enabling the general practitioner to treat many of his own patients without referring them to a specialist. An entire section is devoted to a full description of all modern gynecologic operations, illuminated and elucidated by numerous photographs. The author's extensive experience renders this work of unusual value.

OPINIONS OF THE MEDICAL PRESS

Medical Record, New York

"Its merits can be appreciated only by a careful perusal. . . . Nearly one hundred pages are devoted to technic, this chapter being in some respects superior to the descriptions in many other text-books."

Boston Medical and Surgical Journal

"The author has given special attention to diagnosis and treatment throughout the book, and has produced a practical treatise which should be of the greatest value to the student, the general practitioner, and the specialist."

Medical News, New York

"Office treatment is given a due amount of consideration, so that the work will be as useful to the non-operator as to the specialist."

GET
THE BEST

American Illustrated Dictionary

The New (5th) Edition

THE NEW
STANDARD

The American Illustrated Medical Dictionary. A new and complete dictionary of the terms used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, and kindred branches; with over 100 new and elaborate tables and many handsome illustrations. By W. A. NEWMAN DORLAND, M. D., Editor of "The American Pocket Medical Dictionary." Large octavo, nearly 876 pages, bound in full flexible leather. Price, \$4.50 net; with thumb index, \$5.00 net.

A KEY TO MEDICAL LITERATURE

Gives a Maximum Amount of Matter in a Minimum Space

WITH 2000 NEW TERMS

We really believe that Dorland's Dictionary is the most useful single book that the medical practitioner can own. We are confident you will get more real use out of it than out of any one book you ever bought.

Nearly every medical paper to-day contains special words which are new to most readers. If you want to get the best out of your journals and text-books, Dorland's Dictionary should be on your desk for ready reference.

This new edition contains 2000 new words. Hundreds of these cannot be found in any other dictionary. Of this edition 5000 have been sold in two months.

PERSONAL OPINIONS

Howard A. Kelly, M. D.,

Professor of Gynecologic Surgery, Johns Hopkins University, Baltimore

"Dr. Dorland's dictionary is admirable. It is so well gotten up and of such convenient size. No errors have been found in my use of it."

J. Collins Warren, M.D., LL.D., F.R.C.S. (Hon.)

Professor of Surgery, Harvard Medical School

"I regard it as a valuable aid to my medical literary work. It is very complete and of convenient size to handle comfortably. I use it in preference to any other."

Penrose's Diseases of Women

Sixth Revised Edition

A Text-Book of Diseases of Women. By CHARLES B. PENROSE, M. D., PH. D., formerly Professor of Gynecology in the University of Pennsylvania; Surgeon to the Gynceean Hospital, Philadelphia. Octavo volume of 550 pages, with 225 fine original illustrations. Cloth, \$3.75 net.

ILLUSTRATED

Regularly every year a new edition of this excellent text-book is called for, and it appears to be in as great favor with physicians as with students. Indeed, this book has taken its place as the ideal work for the general practitioner. The author presents the best teaching of modern gynecology, untrammelled by antiquated ideas and methods. In every case the most modern and progressive technique is adopted, and the main points are made clear by excellent illustrations. The new edition has been carefully revised, much new matter has been added, and a number of new original illustrations have been introduced. In its revised form this volume continues to be an admirable exposition of the present status of gynecologic practice.

PERSONAL AND PRESS OPINIONS

Howard A. Kelly, M. D.,

Professor of Gynecologic Surgery, Johns Hopkins University, Baltimore.

"I shall value very highly the copy of Penrose's 'Diseases of Women' received. I have already recommended it to my class as THE BEST book."

E. E. Montgomery, M. D.,

Professor of Gynecology, Jefferson Medical College, Philadelphia.

"The copy of 'A Text-Book of Diseases of Women' by Penrose, received to-day. I have looked over it and admire it very much. I have no doubt it will have a large sale, as it justly merits."

Bristol Medico-Chirurgical Journal

"This is an excellent work which goes straight to the mark . . . The book may be taken as a trustworthy exposition of modern gynecology."

THE NEW (3d) E

Obstetric nursing demands some knowledg
cologic nursing, really a branch of surgical nu
and training. This volume presents this info
form. This third edition has been very careful
subject down to date.

The Lancet, London

"Not only nurses, but even newly qualified medi
perusal of this book. It is written in a clear and plea
mend."

Garrigues' Diseases of Women

Third Edition, Thoroughly Revised

A Text-Book of Diseases of Women. By HENRY J. GARRIGUES, A. M., M. D., Gynecologist to St. Mark's Hospital and to the German Dispensary, New York City. Handsome octavo, 756 pages, with 367 engravings and colored plates. Cloth, \$4.50 net; Sheep or Half Morocco, \$6.00 net.

The first two editions of this work met with a most appreciative reception by the medical profession both in this country and abroad. In this edition the entire work has been carefully and thoroughly revised, and considerable new matter added, bringing the work precisely down to date. Many new illustrations have been introduced, thus greatly increasing the value of the book both as a text-book and book of reference.

Thad. A. Reamy, M. D., *Professor of Clinical Gynecology, Medical College of Ohio.*

One of the best text books for students and practitioners which has been published in the English language—it is condensed, clear and comprehensive. The profound learning and great clinical experience of the distinguished author find expression in this book."

American Text-Book of Gynecology Second Revised Edition

American Text-Book of Gynecology. Edited by J. M. BALDY, M. D. Imperial octavo of 718 pages, with 341 text-illustrations and 38 plates. Cloth, \$6.00 net.

American Text-Book of Obstetrics Second Revised Edition

The American Text-Book of Obstetrics. In two volumes. Edited by RICHARD C. NORRIS, M. D.; Art Editor, Robert L. Dickinson, M. D. Two octavos of about 600 pages each; nearly 900 illustrations, including 49 colored and half-tone plates. Per volume: Cloth, \$3.50 net.

"As an authority, as a book of reference, as a 'working book' for the student or practitioner, we commend it because we believe there is no better."—AMERICAN JOURNAL OF THE MEDICAL SCIENCES

Schäffer and Edgar's Labor and Operative Obstetrics

Atlas and Epitome of Labor and Operative Obstetrics. By DR. O. SCHÄFFER, of Heidelberg. Edited, with additions, by J. CLIFTON EDGAR, M. D., Professor of Obstetrics and Clinical Midwifery, Cornell University Medical School, New York. With 14 lithographic plates in colors, 139 text-cuts, and 111 pages of text. Cloth, \$2.00 net. *In Saunders' Hand-Atlas.*

American Medicine

"It would be difficult to find one hundred pages in better form or containing more practical points for students or practitioners."

Schäffer and Edgar's Obstetric Diagnosis and Treatment

Atlas and Epitome of Obstetric Diagnosis and Treatment. By DR. O. SCHÄFFER, of Heidelberg. Edited, with additions, by J. CLIFTON EDGAR, M. D., Professor of Obstetrics and Clinical Midwifery, Cornell University Medical School, New York. With 122 colored figures on 56 plates, 38 text-cuts, and 315 pages of text. Cloth, \$3.00 net. *Saunders' Hand-Atlas.*

New York Medical Journal

"The illustrations are admirably executed, as they are in all of these atlases, and the text can safely be commended."

Schäffer and Norris' Gynecology

Atlas and Epitome of Gynecology. By DR. O. SCHÄFFER, of Heidelberg. Edited, with additions, by RICHARD C. NORRIS, A. M., M. D., Gynecologist to Methodist Episcopal and Philadelphia Hospitals. With 207 colored figures on 90 plates, 65 text-cuts, and 308 pages of text. Cloth, \$3.50 net. *In Saunders' Hand-Atlas Series.*

American Journal of the Medical Sciences

"Of the illustrations it is difficult to speak in too high terms of approval. They are so clear and true to nature that the accompanying explanations are almost superfluous."

Galbraith's Four Epochs of Woman's Life

New (2d) Edition

The Four Epochs of Woman's Life: A STUDY IN HYGIENE. By ANNA M. GALBRAITH, M. D., Fellow of the New York Academy of Medicine, etc. With an Introductory Note by JOHN H. MUSSER, M. D., University of Pennsylvania. 12mo of 247 pages. Cloth, \$1.50 net.

Birmingham Medical Review, England

"We do not, as a rule, care for medical books written for the instruction of the public. But we must admit that the advice in Dr. Galbraith's work is, in the main, wise and whoesome."

Schäffer and Webster's Operative Gynecology

Atlas and Epitome of Operative Gynecology. By DR. O. SCHÄFFER, of Heidelberg. Edited, with additions, by J. CLARENCE WEBSTER, M.D. (Edin.), F.R.C.P.E., Professor of Obstetrics and Gynecology in Rush Medical College, in affiliation with the University of Chicago. 42 colored lithographic plates, many text-cuts, a number in colors, and 138 pages of text. *In Saunders' Hand-Atlas Series.* Cloth, \$3.00 net.

Much patient endeavor has been expended by the author, the artist, and the lithographer in the preparation of the plates of this atlas. They are based on hundreds of photographs taken from nature, and illustrate most faithfully the various surgical situations. Dr. Schäffer has made a specialty of demonstrating by illustrations.

Medical Record, New York

"The volume should prove most helpful to students and others in grasping details usually to be acquired only in the amphitheater itself."

De Lee's Obstetrics for Nurses

Obstetrics for Nurses. By JOSEPH B. DE LEE, M.D., Professor of Obstetrics in the Northwestern University Medical School; Lecturer in the Nurses' Training Schools of Mercy, Wesley, Provident, Cook County, and Chicago Lying-In Hospitals. 12mo volume of 512 pages, fully illustrated. Cloth, \$2.50 net.

THE NEW (3d) EDITION

While Dr. De Lee has written his work especially for nurses, yet the practitioner will find it useful and instructive, since the duties of a nurse often devolve upon him in the early years of his practice. The illustrations are nearly all original, and represent photographs taken from actual scenes. The text is the result of the author's many years' experience in lecturing to the nurses of five different training schools.

J. Clifton Edgar, M.D.,

Professor of Obstetrics and Clinical Midwifery, Cornell University, New York

"It is far and away the best that has come to my notice, and I shall take great pleasure in recommending it to my nurses, and students as well."

American Pocket Dictionary

Sixth Revised Edition

THE AMERICAN POCKET MEDICAL DICTIONARY. Edited by W. A. NEWMAN DORLAND, A. M., M. D., Assistant Obstetrician to the Hospital of the University of Pennsylvania, Fellow of the American Academy of Medicine. Over 598 pages. Full leather, limp, with gold edges. \$1.00 net; with patent thumb index, \$1.25 net

James W. Holland, M. D.,

Professor of Medical Chemistry and Toxicology at the Jefferson Medical College, Philadelphia.

"I am struck at once with admiration at the compact size and attractive exterior. I can recommend it to our students without reserve."

Cragin's Gynecology.

New 16th Edition

ESSENTIALS OF GYNECOLOGY. By EDWIN B. CRAGIN, M. D., Professor of Obstetrics, College of Physicians and Surgeons, New York. Crown octavo, 215 pages, 62 illustrations. Cloth, \$1.00 net. *In Saunders' Question-Compend Series.*

The Medical Record, New York

"A handy volume and a distinct improvement of students' compends in general. No author who was not himself a practical gynecologist could have consulted the student's needs so thoroughly as Dr. Cragin has done."

Ashton's Obstetrics.

New 16th Edition

ESSENTIALS OF OBSTETRICS. By W. EASTERLY ASHTON, M. D., Professor of Gynecology in the Medico-Chirurgical College, Philadelphia. Crown octavo, 256 pages, 75 illustrations. Cloth, \$1.00 net. *In Saunders' Question-Compend Series.*

Southern Practitioner

"An excellent little volume containing correct and practical knowledge. An admirable compend and the best condensation we have seen."

Barton and Wells' Medical Thesaurus

A THESAURUS OF MEDICAL WORDS AND PHRASES. By WILFRED M. BARTON, M. D., Assistant to Professor of Materia Medica and Therapeutics, Georgetown University, Washington, D. C.; and WALTER A. WELLS, M.
